Prophylactic and Therapeutic Value of Antidiphtheritic Serum.—Pontano studies the diphtheria problem in its three fundamental aspects: experimental, statistical and clinical. Experiments on the guinea-pig have led to wrong interpretations of human diphtheria. The prophylactic and therapeutic experiments with serums on the guinea-pig show only the prophylactic and noncurative value of the serum. The author took up the experiment by infecting the guinea-pig with bacilli and not merely intoxicating it with a toxin. He confirms the prophylactic value against the bacterial infection, both as to

Function of Stomach Following Removal of Antrum Pylori.—Johnson performed on dogs resection of the antrum pylori and gastro-enterostomy, and, immediately below, a duodenal fistula was made. It was found that the secretion of such a stomach is reduced, especially if porridge and soups are fed; but even if meat, bread and vegetables are given, the gastric secretion is reduced. If soups and porridge are fed, the stomach retains the food only for a short time, but solid foods are retained much longer. As soon as the food enters the duodenum there takes place, even under these unphysiologic conditions, a complete mixture with the duodenal secretions, and thus the hydrochloric acid is largely neutralized.

Aspects of Diabetes with Insulin Resistance.—Serio states that patients with the form of diabetes which is resistant to insulin usually appear well nourished, have only slight acidosis and are influenceable only slightly by dietetic measures. He then describes the clinical history of such a patient. Since dietary measures as well as insulin therapy failed in their effect and since the patient showed slight symptoms of hyperthyroidism, an antithyroidal preparation was administered in increasing quantities. After forty days of this medication the insulin resistance had completely disappeared, so that 14 units of insulin was now sufficient to reduce the glycemia considerably and even to produce hypoglycemic symptoms. The sugar content of the blood during fasting became normal and could be kept in normal limits in spite of a free diet and of tolerance tests, even after the treatment had been discontinued. The renal elimination of sugar continued. This was probably due to a renal factor, which became evident after the hyperglycemia had disappeared.

Intracutaneous Injection and Basal Metabolism.—Crecelius describes experiments which prove that intracutaneous injection, that is, irritation of the sympathetic nervous system, causes changes in the basal metabolism, whereas if the injection is made subcutaneously or intramuscularly there is no such effect. However, not all persons react in the same manner. To what causes it may be ascribed that in some persons there is an increase in the basal metabolism while in others there is a decrease has not been detected as yet. A careful control of the blood pictures gave no explanation, since a certain uniformity was not detectable.

Membranous Colitis a Disappearing Disease.—Boas points out that membranous colitis, which thirty years ago was one of the most discussed intestinal disorders, in recent years has hardly been mentioned, and he is convinced that the reason for this is the decreased frequency of the disease. In the last decades of the last century, when the incidence of membranous colitis was greatest, the various forms of colitis were usually treated by medicated and especially by astringent enemas. Modern medicine has done away with the habitual enema treatment and particularly with the medicated and astringent enemas, and the author thinks that membranous colitis has decreased in the same ratio as the use of enemas. Another reason why he considers enemas and especially medicated ones as the etiologic factor of membranous colitis is that in the rare cases of membranous colitis which came under his observation in recent years the anamnesis always revealed the habitual use of enemas. When the enemas were discontinued and a dietary treatment was introduced instead, the patients no longer complained of the discharge of membranes. On the basis of past experiences, the author concludes that the cause of the membrane formation is a simple colitis, for the treatment of which unreasonable methods, such as enemas, were prescribed. In this manner a simple mucous colitis developed into a membranous colitis. Since colitis is no longer treated in this manner, and since likewise the use of cathartics has diminished, membranous colitis has almost disappeared.

Apple Diet and Intestinal Flora.—Schreiber shows that in acute and catarrhal intestinal diseases, such as Flexner's dysentery, paratyphoid B and the common dyspepsias, an apple diet causes a change in the intestinal flora, which manifests itself in a considerable increase in the coli bacteria and in a decrease in the pathogenic intestinal flora. At the same time, the clinical manifestations disappear. The virulence of the coli strains neither increases nor changes as the result of the treatment, so that a predisposition for the disease may persist in spite of the clinical cure.

Intramuscular Calcium Therapy in Pulmonary Tuberculosis.—Undritz employed intramuscular injections of calcium gluconate in sixty patients with tuberculosis. The injections are given every other day, alternating into the right and left gluteal muscles. In some cases the injections can be interrupted for some time, and later another series may be given. Intravenous injections of calcium gluconate are advisable in cases of hemorrhage, and a prolonged intramuscular administration may be followed by a series of intravenous injections. The author gives a tabular report, showing the results of the treatment in sixty cases, and a detailed report of three cases. He concludes that intramuscular calcium therapy is advisable in all forms of pulmonary tuberculosis, but in patients with high temperature and poor general condition the injections of calcium gluconate should be postponed until the active manifestations have somewhat subsided and the general condition has been improved by camphor therapy. Especially suitable for parenteral calcium therapy are patients with pleural exudation, and also patients who receive pneumothorax treatment, for in these cases the inhibiting action of calcium on the exudation is of especial value. A prophylactic administration of calcium is advisable from one to two weeks before the pneumothorax is induced. In the summary the author stresses that the calcium administration cannot be considered as a causal therapy and that not all patients are benefited by it. However, he considers it a valuable adjuvant. Its efficacy is due to transmineralization of the organism; that is, it does not form calcium deposits, but, in passing through the organism, it displays pharmacodynamic actions, such as increasing the phagocytosis and checking the inflammation and exudation.

Pathogenesis and Therapy of Leukorrhea.—Pulay's observations indicate that leukorrhea is a manifestation of avitaminosis. Clinically considered, leukorrhea belongs to the group of seborrheal eczema, urticaria, chronic rhinitis and hay of intravenous application the action of the extracts sets in half a minute after completion of the injection. First there is a pressure decrease, which in turn is followed by a marked increase. The intensity of the reaction is likewise dependent on the dose. In estimations of the uterine contractions it is also significant to consider other factors that are of influence. There are "spontaneous" contractions caused by the contrast medium. The woman's excitement during the injection also causes strong contractions, and only after these have passed should the influence of the extract be estimated. The discharge of some of the contrast material and whether the tubes are open or closed is also of influence on the contractions. If large doses of the extract are injected there are certain unpleasant general reactions, such as a feeling of anxiety, severe headache, extreme paleness, enlargement of the pupils and retardation of the pulse. If small doses are given, the general reactions are slight.

*Lymphadenoma and Amyloid Degeneration. J. Kostrzewski and Ciechanowski.—p. 834.
Relation Between Pituitary Body and Female Genital Organs. Seidler. —p. 838.

Function of Ovaries After Hysterectomy.—Bochenski divides the clinical symptoms ascribed to hysterectomy into two groups: those resulting from loss of the organ and those attending retrogressive degeneration of the ovaries. The first group embodies all local symptoms due to anatomic changes in the pelvis, plus removal of the internal secretion of the uterus; the occurrence of an internal secretion in the uterus is not, however, a generally accepted theory. Nine rabbits in which the uterus was removed and oophorectomy was performed six to twelve months later, did not show any macroscopic or microscopic changes in the ovaries as compared with control animals. The symptoms frequently encountered in women, and ascribed to hysterectomy, may be due to preexisting pathologic changes in the ovaries.

Lymphadenoma and Amyloid Degeneration (Hodgkin's Disease).—Kostrzewski and Ciechanowski discuss in detail this rare combination, of which only three cases are on record, two reported by Lichtwitz and one by Matthes. The case under discussion is of particular interest because of insignificant pseudoleukemic changes, general advanced amyloid degeneration and rare possibility of premortal diagnosis. The authors state that (1) the complication of lymphadenoma by amyloid degeneration is proved beyond doubt by this case; (2) there is no relation between the location or extent of the two diseases; (3) the presence of amyloid degeneration does not throw any light on the etiology of pseudoleukemia, and (4) the complication of lymphadenoma by amyloid changes proves that Hodgkin's disease is not a local disorder of the glandular system but a systemic disease with glandular symptoms.

Transient Benign Coxitis.—Belmonte calls attention to a transient, benign infection of the hip joint, apparently little known in the Netherlands but frequently described in foreign journals. Coxitis fugax occurs chiefly in children and sometimes presents peculiarities that make early diagnosis possible. This is especially important for differentiation from tuberculous coxitis with a serious prognosis. Special treatment is not necessary. With rest in bed, the subjective and objective symptoms disappear after a few days or, at the most, a few weeks. The course is entirely favorable. A similar disorder occurs in the knee joint and there appears to be a similar spondylitis.

Occurrence of Diastase in Blood and Urine of Patients with Acute Infectious Diseases. Cont'd. K. Germer.—p. 405.

Investigations on Excised Human Thyroids.—Krogh and his associates find that cytologic examinations show exophthalmic goiter, unlike simple goiter, to be characterized by cellular hyperactivity, collapse of storage secretion, and proliferation. In patients treated preoperatively with iodine, the storage secretion is frequently restored but the morphologic signs of cellular hyperfunction, particularly the hypertrophy of the Golgi apparatus, are unchanged. The administration in adult male guinea-pigs of dried glands from simple goiters and from successfully treated exophthalmic goiters, in doses based on their iodine content, led to an increase in metabolism nearly equivalent to that caused by the administration of normal guinea-pig thyroids; glands from nontreated exophthalmic goiters and from unsuccessfully treated ones showed a biologic activity definitely below normal.

*Genuine and Postencephalitic Narcolepsy: Clinical Investigation. S. Wohlfahrt.—p. 342.
*Scorbutic Ménière's Symptom and Otosclerosis. H. Öhnell.—p. 358.

Some Less Common Forms of Torsion of Adnexa.—Marcus describes three cases of torsion of normal uterine appendages. In the first, in the third month of pregnancy, removal of the twisted adnexa did not affect the pregnancy, and normal delivery occurred at term. Excision was also done in the second case, and in the third the twisted adnexa were untwisted. Analogous cases from the literature are cited. The prognosis was good in all cases.

Spasmodic Torticollis and Operative Treatment.—Olivecrona reports six cases in which operative treatment resulted in marked improvement or in complete recovery. He states that recurrences are seldom to be feared and that, in cases of incomplete recovery, further improvement may be expected during the following years, probably because of the tendency of the condition to spontaneous recovery. He emphasizes that surgical division of the intraspinal portion of the accessory nerve should not be considered sufficient but that peripheral exeresis of the accessory nerve should as a rule be done. He advises against waiting for spontaneous recovery, as it usually takes years before the condition becomes somewhat endurable. When internal treatment, psychotherapy and so on are ineffective after six months, operative treatment is advocated. If, however, torticollis is only a partial phenomenon of some extrapyramidal syndrome, operative treatment is considered only in exceptional cases.

Genuine and Postencephalitic Narcolepsy.—Wohlfahrt reports four cases of true narcolepsy, all in younger men, two cases showing definite signs of disturbances of internal secretion closely resembling hypothyreosis. The administration of thyroid resulted in improvement. In three other cases reported, the symptoms are apparently related to a previous epidemic encephalitis.

Scorbutic Ménière's Symptom and Otosclerosis.—In Öhnell's case of Ménière's symptom in a patient with latent scurvy, the abundant administration of vitamin C resulted in marked improvement. The definite improvement in four other patients with Ménière's symptom after vitamin C had been given is believed to support the assumption that Ménière's symptom is in certain cases due to scurvy.

Variations in the acid-base value of diet have been shown by many [6] to influence the absorption and excretion of calcium and phosphorus in rickets and tetany. Acid-forming diets lacking in vitamin D produced rickets in young white rats; base-forming diets under similar conditions produced a very mild degree of rickets; the former shifted the acid-base mechanism of young rats to the acid side, and base-forming diets to the basic side of equilibrium. "Acid-forming diets inhibit and base-forming diets accelerate the rate of growth, metabolism and activity."

In direct opposition to Hermannsdorfer's "acidifying" diet, others have advised, in cases of hypertension, that an alkaline ash diet be stressed and that fruit be increased to replace cereals and meats. With such varying opinions, it is difficult at present to be dogmatic on these points, when proof is so clearly lacking.

DIETARY COMPONENTS

Let us consider the knowledge of the separate constituents of a diet, taking first the question of carbohydrates. Eskimos in their cold climates have been known to thrive on the low total sugar intake of no more than 30 Gm. a day without exhibiting any unusual tendency to arteriosclerosis or kidney disease. The minimum amount of sugar that a person may take and still retain perfect health has not been ascertained, but it is known that, to effect any appreciable metabolic change in the ordinary patient, an increase of at least 20 Gm. over the accustomed amount is necessary.

Proteins.—Definite advice concerning proteins is difficult to give. It would seem that a high protein ration in a great many instances can be carried very well, and for nephrosis, or for convalescents or growing children, 120 Gm. a day or even more may be indicated. In the treatment of disease the exact amounts are hard to fix; perhaps 120 Gm. a day would be an advisable maximum, and 50 a good minimum. In certain cases, such as nephritis, the amount is sometimes cut below this minimum, especially in nitrogen retention cases this may be wise, but ordinarily if such a low amount is supplied in the diet the patient will draw from his bodily resources any additional amount needed.

Fats.—The regulation of fats goes beyond the ordinary diet, for no minor changes in diet-fat will affect metabolism. Dubois relates that he has made sudden changes of 200 Gm. in fat intake without finding any evidence of change in metabolism. It is well known that the human body can hold in reserve large amounts of fat and draw on them at will.

Weigert [7] found that animals overfed on fat showed an increased resistance to tuberculous infection in contrast to the lessened resistance manifested by animals fed chiefly on carbohydrates. Vogt [8] believed that he corroborated this in children. McCann [9] found that for one unit of heat produced from dextrose there is nearly 30 per cent more carbon dioxide than that gotten from the same energy production from fat; so he advises a diet composed largely of fats up to the limits of digestive capacity as one that will produce the least demand on the function of the damaged lungs.

Calcium.—Through the use of parathyroid extract and viosterol, changes in calcium can be effected, but as yet clinical experiments with these have yielded clarifying results only in the treatment of such definite diseases of calcium metabolism as rickets and tetany and osteomalacia. In tuberculosis the calcium metabolism remains yet to be thoroughly investigated; for the proof of a deficiency of serum calcium and tissue calcium in this disease has not yet been established. Experiments on animals have been made to throw light on this point, and in some cases of tuberculosis the serum calcium has been found to be low, but only in the final stages of the disease. We are equally uninformed about the final effects of calcium ionization. But these experiments with animals have yielded certain positive knowledge: it was found that in calcium-normal blood the amount of calcium is not noticeably increased by an addition of calcium to the diet; and in tuberculous organs the amount of calcium in the food did not determine the calcification; furthermore, the calcification did not seem to have any changes which could be brought into ratio with the tuberculous changes.

Sodium Chloride.—In the past, opinions about mineral salts in a patient's diet have been very contradictory. Reduction in the amount of table salt was once strongly advised to reduce edema of the heart and kidney disease, but recently calcium chloride has been advantageously substituted, especially when it has been combined with mersalyl (salyrgan). In cases of hypertension and edema, the sodium and chloride ions of sodium chloride have alternately been considered the chief contributing causes.

Salts can be deposited in the skin, especially in sodium chloride overfeeding. Keining and Hopf [10] found that certain patients, who were first kept for several days on a salt-free diet and then flooded daily with 20 Gm. of sodium chloride in four doses of 5 Gm. each, showed increased urticaria and eczema, almost without exception. This treatment frequently gave the patients severe shock, so that the salt had to be promptly discontinued. The itching became unbearable. Furthermore, in some of the cases, isotonic salt solution produced wheals at the site of injection. An osmotically equilibrated dextrose solution did not cause any wheals in the same cases. A study of the components of sodium chloride responsible for the irritation showed that the anions were not concerned. The sodium was proved to be responsible for the irritation, so that a cation action was involved. Antagonistic cations, potassium, calcium, magnesium and strontium, administered simultaneously overcame the action of producing wheals. It is known chemically that these cations often act favorably on diverse skin disorders. The cations must stand in perfectly definite quantitative relationship to overcome the irritation or to lessen it, and the relative proportion of the constituents of the salt mixture corresponds closely to the cation relationship of the blood plasma.

Functional disturbances have been observed to follow large subcutaneous or intravenous injections of sodium chloride. Instances are those of increased metabolism with simultaneously diminished respiratory quotient, salt glycosuria and so-called salt fever. Some workers report that the addition of suitable amounts of calcium detoxicates the sodium sufficiently to prevent sodium chloride fever. Also surviving organs as nerve and muscle preparations have been injured and have shown considerable changed irritability in pure isotonic sodium chloride which was removable by adding antagonistic cations. Single celled organisms have been severely injured and their development disturbed their recommendations embrace the whole field of body chemistry and involve a change in the soil in which the tubercle bacillus grows.

---

[6] A review of some of the literature may be found in the article by Kugelmass and Samuel (footnote 1).

[7] Weigert, R.: Berl. klin. Wchnschr. **38**, 1907.

[8] Vogt, H.: Therap. Monatsh. **26**: 566, 1912.

[9] McCann, W. S.: Am. Rev. Tuberc. **5**: 870 (Jan.) 1922.

[10] Keining, E., and Hopf, G.: Deutsche med. Wchnschr. **57**: 181 (Jan. 30) 1931.

The essentials of this diet are:

1. The all but complete exclusion of sodium chloride, with a sodium-poor but calcium-rich salt compound being used as a substitute.

2. (*a*) A large percentage of uncooked fresh vegetables in the diet, either in the form of vegetable extracts prepared by pressing uncooked vegetables, such as carrots, beets, spinach and turnips, or in the form of salads with added fruit juices similarly prepared. (*b*) Preparation of cooked vegetables in their own juices in waterless cookers.

3. Marked restriction of meats; Hermannsdorfer and Sauerbruch allow 600 Gm. weekly, Gerson much less. (The table shows the differences.)

Comparison of Suggested Diets for Tuberculous Patients

	Gerson Diet	Hermannsdorfer-Sauerbruch Diet
Proteins..........	About 55 to 67 Gm. daily	About 90 to 120 Gm. daily
80% Animal	Meat....... 100 Gm. weekly	600 Gm. weekly
20% Vegetable	Fish........ 70 Gm. weekly	About the same
	Viscera..... None (sweetbreads, etc.)	Rather freely permitted
	Legumes... None	Permitted
Fats...	About 170 Gm. daily	About 170 Gm. daily
	Cream...... None	About 250 cc.
	Eggs....... Yolks only	Whole egg
Carbohydrates...	Total—250 Gm. carbohydrates given daily	
	Sugar...... 20 Gm. weekly	About the same amount
	Honey...... 50 Gm. weekly	About the same amount
Fluids............	1,400 cc. vegetable juices; fruit juices 600 cc.	Restricted vegetable and fruit juices; about 2½ pints in form of milk, cream, soup, juices, etc.
	Milk........ 250 cc.	About 1,000 cc.
	Soup....... None	
Sodium chloride..	About 1.56 Gm. in food About 1.15 Gm. in juices About 2.7 Gm. of sodium chloride intake daily	
	Ratio of protein to fat to carbohydrate is about 1 to 5.6 to 3.4	Ratio of protein to fat to carbohydrate is about 1.5 to 2.7 to 3.7
Aim..............	Dehydration of tissues and altering body's mineral metabolism. Rich in fat, vitamins and minerals (perhaps protein). Poor in salt and carbohydrate. Vegetables steamed; much raw food given, with cod liver oil with phosphorus, and mineral compound (chiefly calcium). Calories: 21 to 23 calories per pound of body weight; 2,770 or 3,030 if patient weighs 132 pounds (60 Kg.). In Hermannsdorfer diet, calories furnished are 15 per cent by protein, 53 per cent by fat and 32% by carbohydrates.	

4. Restricted water intake, but fairly liberal amounts of freshly expressed juices of fruits and vegetables.

5. Various spices to increase the flavor of the dishes.

6. A mineral compound chiefly of calcium lactate and calcium phosphate, with calcium and magnesium combinations in the form of double salts; strontium, aluminum and silica in colloidal albumin combination, and a cod liver oil, each of these given three times a day.

7. Rich fat and protein, but low carbohydrate elements.

The theories of the mode of action of this diet entail a long and detailed discussion. In this paper I can merely review a few reported conclusions on the value of this diet and add my own impressions resultant from the observation of my own cases and of the cases of others which I was privileged to study in the past two and a half years.

The diet has been both vigorously attacked and enthusiastically supported. Each of the individual dietary factors has been singled out as advantageous by certain workers and just as strongly denounced by others. Some have found that the diet acidifies, others that it alkalizes. Proponents of the diet have aimed at desiccation of tissue through withdrawal of sodium chloride, while others claim a resulting tissue hydration as the cause of extravagant gains in weight.

Dörffel[13] recently found by skin section of treated cutaneous tuberculosis a dehydration of normal and diseased skin as well as a mineral displacement. Potassium was increased, and calcium and magnesium were diminished, while sodium was greatly diminished. These changes were particularly marked in the disease foci.

The withdrawal of table salt has been objected to also on the ground that it is needed for the production of hydrochloric acid of the gastric mucosa, yet actual test has proved the presence of sufficient hydrochloric acid and has shown about 3 Gm. of sodium chloride output in the urine. Its withdrawal has been urged as a measure of healing lupus, by reducing a cutaneous irritant that is stored and excreted by way of the skin. In some cases the diet has been said to increase and in others to decrease the sodium chloride of the blood. Some investigators further report a decrease in the blood calcium level, or an augmented alkali reserve, or high cholesterol values in the blood. The relative percentages of sodium chloride and protein content in the blood have been stressed, and some experimenters have considered sodium chloride as a sort of vitamin, an aid to restriction of protein decomposition. Phosphorus (as given in cod liver oil with phosphorus) has been objected to as dangerous in such dosage to the liver.

Despite the variations in the reported results of separate trials with this diet, many of its most violent opponents have admitted that this therapy is an advance. My own experiences very largely agree with the evaluation of it made by the Hamburg Medical Congress, that the diet is a distinct therapeutic advance as an aid generally effective in the treatment of lupus vulgaris, and occasionally in bone and joint tuberculosis, but that its value in other forms, more particularly pulmonary tuberculosis, is yet to be determined. I have discerned in it an alterative therapy. Symptomatic improvements, even in pulmonary tuberculosis, have been common, but the effective factor, even the psychotherapeutic one, cannot be evaluated here. However, the diet seems directly responsible for many relieved cases of functional disturbances attendant on pulmonary tuberculosis, especially with chronic constipation or gastric hyperacidity. And tuberculosis with the rare toxic nephroses or essential hypertonia or vasoneuroses has been helped by it.

The leading authorities report favorable effects from this diet in the treatment of lupus vulgaris: retrogression of swelling, flattening of the foci, and absorption and disappearance of the individual nodules. Lupus of the mucous membrane reacts even better than lupus of the skin. Foci of the nasal mucosa, the hard palate, the pharynx and the larynx have been benefited; the lupus foci about the gums of the teeth have been the most resistant. Noteworthy influence on exudative processes is clearly shown; the dry squamous forms react less favorably. The best results are seen when light treatment by general exposure in minimal doses is added. My conclusions are arrived at from the bed, new bone may bridge the gap between the cut ends and form a smooth rib that cannot be differentiated from normal rib. Bridges of bone often join two or more ribs.

---

[13] Dörffel, J.: Deutsche med. Wchnschr. **57**: 268 (Feb. 13) 1931.

Linear shadows resembling those seen in the lung at the site of an abscess and similar to some types of tuberculous fibrosis may develop anteriorly along shreds of periosteum left after resection. They are occasionally difficult to differentiate even in stereoscopic films from pulmonary changes. Usually, however, the markings due to periosteal regeneration pass downward almost at right angles to the end of the resected ribs, whereas pulmonary fibrosis due to inflammatory change develops in the direction of the spread of the bronchial branches. In the apical portion of the lungs this is upward and lateral, and in the middle and lower portions downward and lateral, in any case being more nearly parallel to the ribs or at a less acute angle to them than the linear markings of periosteal regeneration.

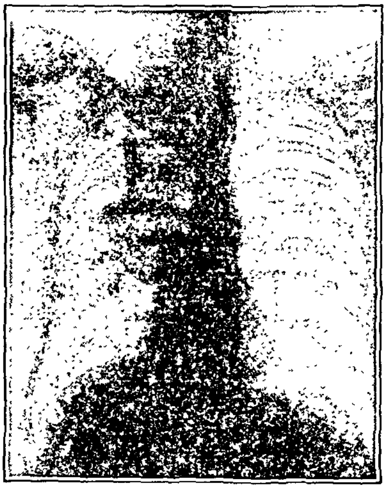

Fig. 1.—Indentation of the lung by gauze packed against the pleura in a man, aged 23, Jan. 30, 1930: Abscess of the right upper lobe, resection anteriorly one week earlier; deformity slight; swelling in the soft tissues.

When the wound is packed with plain gauze at the first stage, the shadows of the lung are not altered unless, as is the case in deep-seated abscesses, a strip of sound lung lies between the abscess and the pleura. The normal lung tissue overlying a deeply seated abscess is compressed by the packing, and a dense crescentic shadow forms at the perimeter of the lung with its concavity peripheral and convexity central (fig. 2). Iodoform gauze used as packing casts a distinct shadow.

It is important for the roentgenologist to know the operative procedure employed, for compression of a lower lobe may simulate an interlobar empyema. Figure 2 illustrates the roentgenographic appearance of a chest in which lobectomy was contemplated for bronchiectasis secondary to pulmonary abscess. A rubber dam placed between the under surface of the lower lobe and the diaphragm and packed with gauze has compressed the lung. The airless compressed lower lobe casts a shadow which might be mistaken for an interlobar empyema.

2. *The character of the pleural changes.* Both preoperative and postoperative changes in the pleura influence the roentgenographic appearance. Edema of the pleura or fluid in the pleural cavity, when present before operation, may obscure the abscess and normal lung and, when occurring postoperatively, hide the rib and pulmonary changes.

Preoperative pleural edema sometimes simulates the density of empyema and may be mistaken for it. It occurs complicating peripherally located abscesses and produces a homogeneous shadow resembling that of fluid. A diagnosis of fluid in the pleural cavity was made in two instances in this series and at operation only a markedly thickened and edematous pleura was found without free fluid (fig. 3).

The commonest roentgenographic finding immediately after operation is an increase in the size of the shadow of the diseased area accompanied by a slight increase in density (fig. 4). It is due to swelling of the pleura secondary to the operation, and is particularly well defined over the axillary border of the chest on the anteroposterior roentgenograms. Return to normal is usually rapid and follows absorption of the edema, though occasionally marked pleural edema may leave a residual thickening persistent for months.

Fluid occasionally develops in the pleura after operation. It is practically always due to extension of the disease to the pleura and is usually independent of the operative procedure. In most instances a pyopneumothorax develops and presents the classic signs of the condition, displacement of the heart and a horizontal fluid level on roentgenograms made with the patient erect. Encapsulated collections of fluid sometimes form, and interlobar collections are occasionally seen. Drainage leads to regression of their shadows.

There is nothing in the appearance of empyema developing postoperatively to set it apart from empyema occurring independently of operation. It usually masks the underlying pulmonary condition. Drainage lessens the density of the shadow, but, even after it has been done, it may be impossible to determine which of the remaining shadows are due to pulmonary disease and which arise from the pleural changes.

3. *The postoperative course of the disease and time after operation that the roentgenogram is made.* Many postoperative alterations are due to the disease and not to the operation. Extension of the lesion may take place, or new abscesses may develop. Their shadows depend on the extent and character of the new changes. Occasionally, small inflammatory foci develop in sound lung tissue and disappear by absorption without actual abscess formation.

In uncomplicated abscess going on to recovery, a gradual diminution in the density of the markings at the site of the abscess takes place. This begins at the periphery and progresses to the center. Usually there is left only an annular scar of fibrous tissue or radiating linear densities taking the direction of the vessels and bronchi. In time these ordinarily disappear and leave a normal pulmonary parenchyma. In the upper lobe fibrous tissue strands course upward and outward, in the lower lobe downward and outward. Scars in the upper lobes may be diagnosed as tuberculous in origin unless one is familiar with the patient's history. Lower lobe scars are similar to the shadows of bronchiectasis; indeed, they are sometimes due to

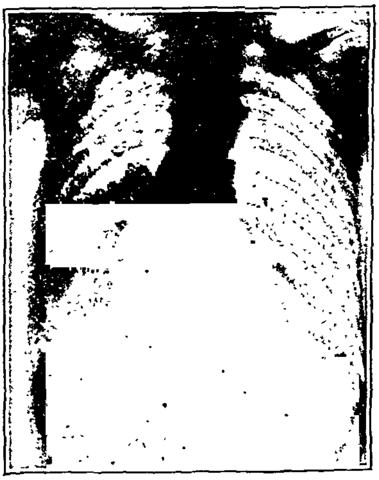

Fig. 2.—Compression of the lower lobe by a pack placed between it and the diaphragm simulating an interlobar collection of fluid, in a man, aged 44.

pleural reaction. Regression of the abnormal shadows in both the lungs and the pleura takes place gradually, and usually the shadows finally disappear entirely.

Bronchopulmonary fistulas sometimes remain after external drainage of a pulmonary abscess. Their presence cannot be detected by direct roentgenography. They may be outlined by injection through the skin opening of an opaque medium such as iodized poppyseed oil. Bronchoscopic pneumonography is frequently helpful in determining the relation of the sinus to the bronchial tree of the lobe involved.

The pulmonary changes depend on the site and size of the abscess, on the condition of the pleura, and on the time elapsed after operation. When peripherally located, a unilocular abscess unaccompanied by pleural complications will lessen in density and extent immediately after evacuation, but if it has a well organized wall an annular shadow will persist unless the wall is excised at operation. An abscess surrounded by a zone of increased density due to indurated lung undergoes peripheral clearing which finally reaches the center of the area. Similar gradual regression follows evacuation of multilocular abscess with an encompassing pneumonitis, but return to normal takes longer and may be followed by a persistent scar of fibrous tissue resembling, when in the upper lobes, tuberculous fibrosis, and, when in the lower, bronchiectasis.

Abscess associated with pleural disease requires a longer time for complete disappearance of the abnormal roentgenographic shadows than uncomplicated abscess.

Change in the position of the thoracic viscera plays but a minor rôle in the postoperative roentgenographic appearance of pulmonary abscess. It is not the prominent feature of abscess that it is of such intrathoracic conditions as bronchial new growth, bronchial foreign body, postoperative pulmonary collapse or pleural effusion. The position of the diaphragm is altered more than that of the heart, trachea or other mediastinal structures; this, too, contrasts with the observations in other conditions. In empyema and obstructive emphysema displacement of the heart, aorta and trachea away from the affected side is pronounced; and in postoperative collapse or atelectasis secondary to bronchial foreign body or new growth, drawing of these structures toward the diseased side is characteristic. The position of the diaphragm in these conditions is often an unimportant diagnostic point; but in roentgenograms made after rib resection for pulmonary abscess the altered position of the diaphragm may be the only evidence of displacement, the heart, trachea and mediastinum maintaining their normal relations (fig. 6).

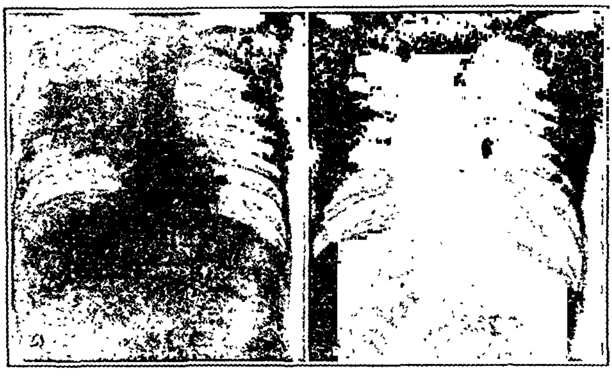

Fig. 5.—Abscess of the right upper lobe complicated by empyema, in a boy, aged 8 years: *A*, before resection for abscess; deformity of the eighth rib posteriorly resected for an earlier empyema is apparent. *B*, thirty-three months after resection. The right half of the chest is less well developed than the left. Dense bridges of bone unite the resected ends, but there is still retraction of the soft tissues. A small scar remains in the lung.

This study has demonstrated that the positional change of the diaphragm after rib resection is directly proportional to the extent of the accompanying pleural changes. In patients without pleural complications, no change takes place. Mild reaction in the pleura causes the half of the diaphragm on the diseased side to rise slightly (fig. 4 *B*) and to remain elevated until the reaction subsides. Extensive pleural thickening or the development of an empyema always leads to marked elevation of the diaphragm on postoperative roentgenograms. After subsidence of the edema or evacuation of the fluid, this persists for a long time; in fact, the affected half of the diaphragm may remain above the normal long after the scar in the lung has disappeared. This persistent elevation is secondary, I believe, to fibrous tissue formed at the site of the abscess. After the empyema is drained or the edema absorbed, the lung is prevented from fully expanding by the scar, and the diaphragm remains elevated. The mechanism of the diaphragmatic elevation differs from that of the elevation seen in extensive fibrotic tuberculous lesions in that the pulmonary fibrosis in tuberculosis is directly responsible for the contraction of the lung, and elevation of the diaphragm follows without intermediary pleural changes. Pulmonary fibrosis is not an outstanding roentgenographic characteristic of pulmonary abscess postoperatively. It is pronounced only in those cases in which there have been marked changes in the pleura. Similarly, and probably for the same reason, bronchiectatic changes occur postoperatively more commonly in abscess complicated by pleural disease than in uncomplicated cases.

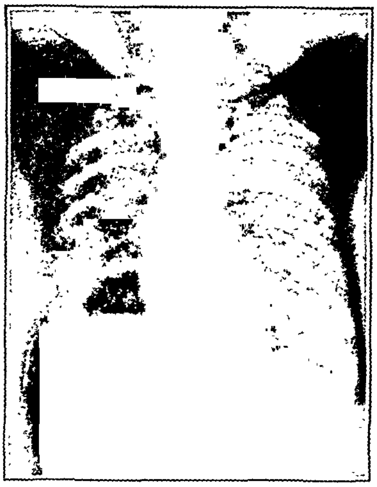

Fig. 6.—Retraction of the subcutaneous tissues five months after resection in the midaxillary line in a man, aged 33; abscess of the middle lobe; regeneration of ribs, residual thickening of the pleura, and scar in the lung at the site of the abscess. Note elevation of the diaphragm. Empyema, probably interlobar, complicated this abscess.

SUMMARY

1. In the study of a series of twenty-three patients, on whom rib resection was done for drainage of pulmonary abscess, it appears that the postoperative roentgenographic appearance of the chest is determined principally by the number and portion of the ribs resected, the character of the pleural changes, and the postoperative course of the disease.

2. Changes in the postoperative roentgenogram are structural and positional.

(*a*) Structural changes involve the skin, subcutaneous tissues, pleura and lungs and are influenced by the type of operation, the size and location of the abscess, the character of pleural complications and the postoperative course.

Since empyemas vary so greatly etiologically, structurally and clinically, it follows that no one method is universally suitable. The treatment to be most effective must be individualized.

Drainage may be accomplished by the so-called closed or open method, with or without irrigation, of which the various drainage devices, operative procedures, and irrigating solutions periodically rediscovered and advocated are simply variations.

After decades of discussion there persist the most divergent and even diametrically opposed views as to the relative merits of the closed and open method, and as to the usefulness of irrigation. Their attempted evaluation has been based chiefly on a comparison of statistics, in which sufficient account has not been taken of the many variable factors that influence the results of any given method. The age and general condition of the patient, the virulence of the infection, and the nature and severity of the underlying disease, as well as treatment, influence mortality. All play a part in the development of complications, which are so frequently the cause of death.

Chronicity may be attributable to the method as such, but also to the failure to carry out the principles involved. If an empyema cavity is kept empty of pus all the time, there will be a minimum of chronicity; while if drainage is not efficient, there will be a relatively large incidence of chronicity, regardless of the method of treatment. Duration of convalescence based on incomparable standards is used as a criterion in comparative studies of methods of treatment. A sinus may persist for months after the patient is discharged and may represent a persistent cavity. The degree of loss of function and of deformity should enter into the evaluation of any method.

Improvement of results and an increasing approachment of opinion regarding methods would seem to lie not so much in the study of inconclusive and incomparable statistics as in the direction of more attention to fundamental principles and more individualization of treatment.

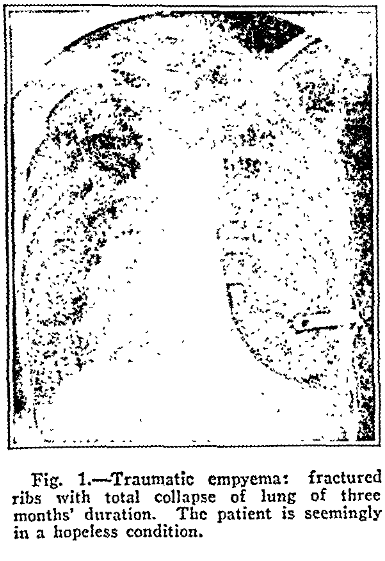

Fig. 1.—Traumatic empyema: fractured ribs with total collapse of lung of three months' duration. The patient is seemingly in a hopeless condition.

The fundamentals of treatment would seem to be drainage without embarrassment of respiration and circulation, reexpansion of the lung and general supportive measures.

The principle of drainage, kept adequate until the cavity was obliterated, established by Hippocrates, and more or less followed up to the time of the Arabian ascendency in medicine, was then, with few exceptions, discarded, up to a half century ago;[1] it is even now not sufficiently appreciated, as evidenced by the discussions as to when a tube should be removed and by the constant succession of chronic cases from insufficient drainage.

Reexpansion of the lung is essential to the normal obliteration of the empyema cavity. The chief mechanism by which it occurs in the presence of an open pneumothorax was explained by Weissgerber,[2] in 1879, as dependent on the paradoxical expansion of the collapsed lung by positive intrabronchial pressure, incident to forced expiratory effort, as in straining or coughing, by which the lung edge may be forced even into the wound. During this oft repeated expiratory expansion the lung gradually becomes adherent to the chest wall, first at the points of firmest and most prolonged contact. Its further expansion is favored by the same mechanism, and by the constantly progressing scar tissue formation and contraction along the angles of contact between visceral and parietal pleura, as pointed out by Roser[3] in 1878. These mechanisms may fail, and the lung then remains collapsed, unless its expansion is assisted by the development of a temporary or continuous, greater or lesser degree of negative tension in the cavity.

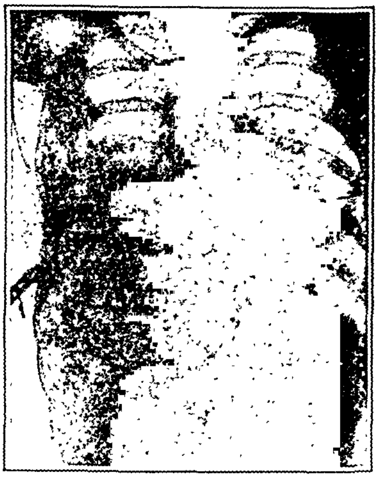

Fig. 2.—Same patient as in figure 1, showing degree of reexpansion of the lungs following irrigation with surgical solution of chlorinated soda through draining sinus.

The possible unfavorable influence of open pneumothorax in the treatment of acute empyema was recognized by the ancients. The simplest unpremeditated device for producing a negative tension in the cavity was the pus soaked dressing, around which air escaped during expiration, but which in part prevented its reentry during inspiration. This principle of the valve, more perfectly applied, is represented in the various skin muscle flaps, which are shaped at drainage operation, and in the numerous mechanical drainage devices that are now in use. Forced respiration by the use of the Wolf blow bottles and by other devices, including carbon dioxide rebreathing,[4] enhance their effectiveness as well as promoting reinflation of collapsed alveoli.

Valve action plus active suction is embodied in the siphon drainage of Buelau,[5] by which suction is kept up to the weight of the column of pus filling the rubber tube, inserted into the cavity through a more or less air tight stab wound. The valve action is provided by keeping the open end of the tube under water. The suction theoretically amounts to the length of the column in terms of water pressure, i. e., from 30 to 40 cm., but it must be recognized that the resistance of thick, more or less sticky, pus against the tube wall greatly reduces this pressure.

One important difference between this method and simple aspiration is that the pus may be practically all removed. What the influences of the air may be seems uncertain. I have used the method in tuberculous empyema but the pus has regularly reaccumulated for many months until thoracoplasty was performed.

Closed drainage can be made to approximate simple aspiration as an operative procedure. It can easily be done in the patient's room. The technic which I have followed with much satisfaction for twelve years is essentially as follows: Under local anesthesia a catheter (number 22 F.) is inserted through an ordinary bladder trocar and cannula, which it just fits, and fastened in place essentially after the method described by Mozingo,[15] and recently by Alexander.[16] Pus is then aspirated by means of a 60 or 120 cc. glass syringe. If the patient is an adult and the cavity is large, from 200 to 300 cc. is drawn off. The tube is then clamped and the piston of the syringe is removed. Saline solution in amount a little less than the amount of pus evacuated is then introduced by gravity, through the barrel of the syringe used as a funnel. The same amount of the mixture of pus and saline solution is now aspirated, a syringeful being first reinjected a few times to bring about a complete mixture. The process is repeated until the solution returns fairly clear. The catheter is now clamped off or attached to a tube after the method of Buelau. The process is repeated every two hours during the day and once or twice at night while the patient is toxic and the cavity is large. The nightly irrigations may then be omitted, but continuing it insures better drainage. Often it can be carried out without awakening the patient from sleep.

If there is no evidence of a bronchial fistula, e. g., no cough and sputum and no irritation during the irrigation with saline solution, surgical solution of chlorinated soda is substituted after the first two or three irrigations. If there is any doubt, the saline solution can be colored with methylene blue (methylthionine chloride U. S. P.). If the patient coughs up colored sputum, the presence of the fistula is proved, in which case only saline or nonirritating, weak, antiseptic solutions are used as long as there is evidence of its persistence.

In infants a smaller catheter is used and only small amounts of pus are withdrawn before saline solution is substituted. In this way there is no appreciable fluctuation in intrathoracic pressure.

Sometimes fibrin plugs the cathether during the first few irrigations. In my experience this has never occurred until some of the pus has been withdrawn. It is then permissible to introduce an equal volume of surgical solution of chlorinated soda for the purpose of softening up the fibrin. After this procedure has been repeated for a few two hour intervals, the fibrin is dissolved. Introduction of acid pepsin for the same purpose is recommended by Hermannsdorfer[17] and

By this simple method the cavity is not only kept emptied of pus but its walls are washed mechanically clean, fibrin and necrotic material are dissolved, and, if surgical solution of chlorinated soda or other bactericidal solutions are used, the surfaces are at least partly sterilized. The lung is kept partly expanded from the others. onset of treatment. The tube remains practically air tight for from one to three weeks or more. If air is excluded from the tube for such a period, which is an easy matter, the degree of expansion of the lung is controlled by the amount of fluid left in the cavity at each irrigation. By filling it to capacity once a day, by a few centimeters of gravity pressure, pocketing of pus is prevented. It is important to observe this precaution, especially during the first week, when dealing with very large primary cavities. Later, the same procedure serves to measure the progressive obliteration of the cavity. After the first few sittings the irrigations can be entrusted to a nurse, with the simple precaution never to inject the solution but always to use gravity in filling the cavity, and to discontinue the irrigation if the patient coughs unusually, or tastes the solution, or if the return becomes blood streaked. By the observance of these simple precautions I have never seen any untoward results from bronchial irritation, "pleural reflex," air embolus or sudden collapse, occasionally mentioned in the literature.

Irrigation is continued until the cavity is obliterated or until there is no further decrease in the size of the cavity. At such a stage the patient is practically always in good condition and the resection of a rib, with or without removal of the parietal pleura for open drainage, is simple and safe. If the cavity is of 50 cc. or more capacity, a complete removal of the roof of the cavity shortens convalescence. It is emphasized that the closed drainage is not done for the purpose of avoiding rib resection but to safeguard the life of critically ill patients, to give the less ill patient the benefit of what may well be termed the "de luxe" treatment, and to prevent the development of a large chronic cavity.

Cellulitis of the chest wall along the catheter sometimes develops, especially in patients who have a virulent infection, such as from mixed anaerobic and pyogenic organisms from the rupture of a lung abscess, and who cough a good deal. Such infection calls for open drainage, and for wide incision of the cellulitis as when occurring elsewhere.

Other varieties of the closed method, based on the procedure of Buelau and of Perthes are on the same principle as that described except that they do not include irrigation. Hart's[18] ingenious method included tidal irrigation, brought about by the respiratory fluctuating intrapleural pressure. Whether or not a rib is resected is of no particular consequence, except that leakage around the tube is perhaps more apt to develop.

In the milder types of acute empyema, in adults in good general condition, the choice between an open or a closed method of treatment depends largely on the size of the empyema cavity. If it is of large capacity, particularly if there is a massive collapse of the lung, the closed method practically assures as much reinflation of the lung as its expansibility will allow, and the antiseptic solution treatment will prevent pocketing and secondary infection, and will hasten recovery.

If the cavity is small and encapsulated, healing will occur by any method that provides and maintains adequate drainage until the cavity is obliterated.

Empyemas with bronchial fistulas are best suited for the closed method. If the fistula is small, irrigation and some degree of negative intrapleural tension can be maintained. If the fistula is large, open drainage

TUBERCULOUS EMPYEMA

An empyema is considered to be tuberculous if it develops primarily without a preceding acute infection. A history of preceding pleurisy with effusion should always suggest the possibility that a later empyema is tuberculous, even if it follows an acute infection.[22] If pyogenic organisms cannot be demonstrated in aspirated pus by smear or culture, it should be treated as of tuberculous origin. Occasionally tubercle bacilli can be demonstrated by smear, and often by culture or guinea-pig inoculation; but the latter procedures require too much time to be of much practical value from the standpoint of immediate treatment.

Differentiation of a sterile tuberculous empyema from one of pyogenic origin is of the first importance to treatment, in that a sterile tuberculous empyema should not be subjected to open drainage. To do so induces a secondary pyogenic infection, which endangers the patient's life and inevitably leads to chronicity. If the pleura is tuberculous it has little resistance to pyogenic infection and little healing power. In such cases only the most radical thoracoplastic procedures will bring about healing.

A sterile tuberculous empyema of idiopathic origin, and without clinical evidence of pulmonary tuberculosis, is treated on diametrically opposite principles to those governing treatment of a sterile tuberculous empyema with active pulmonary tuberculosis on the same side. In the first instance an effort is made to obliterate the cavity by securing reexpansion of the lung. In the latter, treatment is directed to keeping the tuberculous lung collapsed.

The treatment of a sterile tuberculous empyema of the idiopathic type is aspiration of the pus, filtered air being substituted in such an amount that the intrapleural pressure is about atmospheric. The procedure is repeated at intervals as the pus reaccumulates. The pneumothorax usually lessens the purulent secretions. Absorption of the air into the blood stream creates a less than atmospheric intrapleural tension, which tends to reexpand the lung. If pus continues to reaccumulate after from six months to a year of such treatment, and the lung shows no evidence of extensive reexpansion, a graded posterior extrapleural thoracoplasty is indicated. Prolonged absorption of pus usually results sooner or later in irreparable damage of the heart, of the kidneys, or both, and may produce extensive amyloidosis.

Sterile tuberculous empyema with associated active pulmonary tuberculosis is treated similarly to the idiopathic type, except that an attempt is made to prevent expansion of the diseased lung by keeping the pneumothorax pressure atmospheric or positive. If pus reaccumulates indefinitely it constitutes the same indication for thoracoplasty as in the case of the idiopathic type. The age, the condition of the patient, and the presence and the type of the pulmonary or other tuberculous process naturally may constitute contraindications to thoracoplasty.

An undrained tuberculous empyema may be secondarily infected by a bronchial fistula or by the lymph or blood stream. Presumptive evidence of an associated tuberculous pleuritis, in case pyogenic organisms are demonstrated in the smear or on culture, rests on the history of previous idiopathic pleurisy with effusion, or on the presence of an obvious tuberculous process in the lung or elsewhere. If the bacteria are few in number and the clinical symptoms mild, treatment should be the same as for the sterile tuberculous form. If there are large numbers of organisms, particularly streptococci, and if there are marked symptoms of sepsis, drainage must be instituted as in the pyogenic form, except that an erosive solution such as surgical solution of chlorinated soda or that of gentian violet must not be used if there is evidence of a pulmonary tuberculosis. If the pyogenic infection can be cleared up, the case is then treated as the sterile tuberculosis.

A tuberculous empyema secondarily infected by injudicious drainage may present the same presumptive evidence of tuberculosis as the undrained type. Its preliminary treatment is that of the chronic pyogenic type; its final treatment as outlined for the tuberculous. If there is no pulmonary tuberculosis it is desirable to bring about reexpansion of the lung; if there is pulmonary tuberculosis on the same side a thoracoplasty is usually indicated.

SUMMARY

1. Empyema may be of pyogenic or tuberculous origin. Differentiation depends essentially on examination of smear and culture for pyogenic organisms. Treatment differs radically.

2. The mortality rate and the incidence of chronicity in acute empyema depend not only on treatment but also on the type and virulence of infection, on the pathologic anatomy, age and general condition of the patient, and on the nature and gravity of the primary infection, of which it is almost always a complication. Comparative statistics of results of different methods of treatment that do not take these variable factors into account are inconclusive and misleading.

3. The fundamental principle of treatment is drainage, instituted early, by a method that will not embarrass respiration and circulation, and maintained until the cavity is obliterated, plus general supportive measures.

4. In the early stages of an acute empyema, before the lung has become adherent or the mediastinum has stiffened, the two pleural cavities function as one. Open drainage then lowers the respiratory function of the other lung. If the vital respiratory capacity is reduced by a coincident pneumonia and toxemia or other cause, or if the patient is an infant who normally always has a low vital capacity, such open drainage always adds to the respiratory load, often to a degree beyond the patient's compensatory reserve.

5. Closed drainage not only does not interfere with respiratory capacity but improves it. It is therefore the method of choice in all early, acute cases, in severely ill patients and in infants. Irrigation with antiseptic solutions makes possible the removal of all the pus without changing the intrathoracic pressure relationships and is bactericidal.

6. Ordinary rib resection and pus drainage is the alternative method, after the lung has become fixed by adhesions, and is the method of choice in cases with large bronchial fistulas.

7. Closed drainage and irrigation with surgical solution of chlorinated soda in chronic cases usually reduces the size of the cavity to a marked degree, improves the patient's condition and prepares the field for operation.

8. Residual empyema cavities may be obliterated by plastic operations varying according to their size, shape and position. Cavities involving the whole pleural cavity can be obliterated with minimal operative risk [illegible] terior and later extrapleural thora- [illegible] by the removal of the thickened pleura over the residual cavity.

during the night. Properly carried out, it does not tire or irritate the patient. Often he will not be aroused from sleep. If, for any reason, this routine cannot be carried out adequately it will be better for the patient to have wide open gravity drainage as soon as the critical stage of his illness is past. I cannot quite agree with Dr. Alexander that two tubes are necessary. In fact, in my experience a secondary tube has never been necessary. If pus is aspirated first, and if the amount of irrigating solution allowed to flow in is always less than the amount of pus removed, and if air is not admitted, there can be no dilating effect on the cavity. The result, in fact, is to the contrary. In my paper I have referred to Dr. Danna's method. Aspirating the pus and replacement with air is, of course, a recognized method of treatment of sterile tuberculous empyema. Just how effective this method will prove to be in dealing with pyogenic empyema, experience will have to determine. Dr. Danna's results certainly have been good. The method may prove of great value in empyema due to infection of low virulence.

ONYCHOLYSIS

AN INDUSTRIAL DERMATOSIS *

H. J. TEMPLETON, M.D.
OAKLAND, CALIF.

Very little has been written in regard to separation of the fingernails from the nailbeds. Practically nothing has been recorded in regard to such a condition, onycholysis, being related to the industries. Since 1928, I have been called on to determine the industrial status of five cases in which patients claimed that their fingernails had separated in whole or part from the nail beds as a result of their particular occupations. An investigation disclosed that their allegations were correct. The cases all became compensable and, hence, of interest to industrial physicians and insurance companies.

A thorough search of all the available literature failed to disclose any similar cases. Any claim to priority of description of such cases was shattered, however, when in a personal interview Oppenheim told me that he had reported several similar cases in 1910. Although there are some dissimilar features in his cases, there would seem to be no question but that they belong in the same category as mine.

REVIEW OF THE LITERATURE

Oppenheim's cases were all presented before the Vienna Dermatologic Society during November, 1909.[1]

Case 1.—A woman, aged 50, a housewife, with no history of dystrophies of the nails in her family, first noted a separation of her fingernail eight or nine years previously. She believed that her trouble was caused by doing laundry work. All her nails, with the exception of that of the left thumb, showed a separation of the nail from the nailbed in various degrees (fig. 1). This separation was limited by a semilunar line with its convexity proximal. The separation was an extension proximally of the normal separation between the nail and the end of the finger. The nail itself was unchanged in color and luster. The nail lunula and the surrounding skin were normal and the skin of the nailbed was smooth. The separation had never reached the lunula. The toenails were normal.

Case 2.—A woman, aged 35, a housewife, noticed a loosening of her fingernails five years previously, following considerable laundry work. This separation occurred without producing any symptoms. The nails of the second, fourth and fifth right fingers and of the third left finger were involved. The changes were exactly the same as seen in case 1.

Case 3.—A woman, aged 23, a housewife, observed an asymptomatic separation of her fingernails one year previously, which she attributed to laundry work. All the nails of her right hand and those of the third and fourth left fingers were involved. The changes in the nails were the same as in the other two patients.

Oppenheim's patients were all women domestically engaged in laundry work. Their afflictions began gradually without subjective symptoms and lasted for years. Their toenails were all normal.

The author felt that the separation was brought about by laundering with hot water and soda, although the question remained open whether the chemical or the mechanical insults were to be given the greater rôle or whether they work in conjunction. He showed that trauma was applied to the free ends of the nails by their part in rubbing the clothes over the washboard and in wringing the clothes dry. Those fingers were most affected which suffered the most trauma. The chemical factor of the water and soda macerating the tissues under the nails would render them more liable to separation by the mechanical factor.

Case 4.[2]—A woman stated that she used a washing powder called "Persil" for laundering. About one week later small vesicles appeared under the nails, which loosened to the extent shown in figure 2. Four years later the nails had regrown, with the exception of the one on the third finger of the right hand.

AUTHOR'S CASES

Case 1.—Mrs. Anna J., aged 34, began washing paste from labeled catsup bottles, May 14, 1928. She had not been engaged in this type of work previously. It necessitated intermittent submerging of her hands in water throughout the day. On the second day she noticed blue black spots appearing under the nails of several of her fingers (fig. 3). These dark areas spread rapidly and in two days had involved nearly the whole of the nailbeds of all her nails. This process was remarkably free from pain. May 18, four days after beginning bottle washing, she was forced to lie off and consult the plant physician. He found all her nails loosened from the nailbeds. There was a slight serosanguineous discharge from under the nails. There was no evidence of paronychia, nor was there any pus under the nails. The nailbeds were not acutely inflamed. Within three weeks the nails had entirely separated from the

* Read before the Section on Dermatology and Syphilology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

[1] Oppenheim, M.: Ueber eine eigene Art der Nägelablösung bei Wascherinnen, Wien. Arb. d. Geb. d. soz. Med., Vienna & Leipzig, 1910.

[2] An unpublished case, reported by courtesy of Professor Arzt and Docent Fuhs and Matras of Vienna.

trouble occurred in healthy young women who were engaged in washing paste off of catsup bottles which had just been labeled. The catsup bottles were first washed, then filled with catsup and capped. The catsup was then washed off and the bottles were dried. Labels were then pasted on. All the work up to this point was done by groups of girls other than the bottle washers. None of these groups suffered from nail disorders. The bottles, covered with paste, were delivered to the bottle washers on a conveyor and were dumped into wooden wash tubs filled with lukewarm city water to which no chemicals had been added. The bottle washers wore no gloves and used no soap. They were provided with sponges with which they removed the paste. Their hands remained submerged in water a large part of the time.

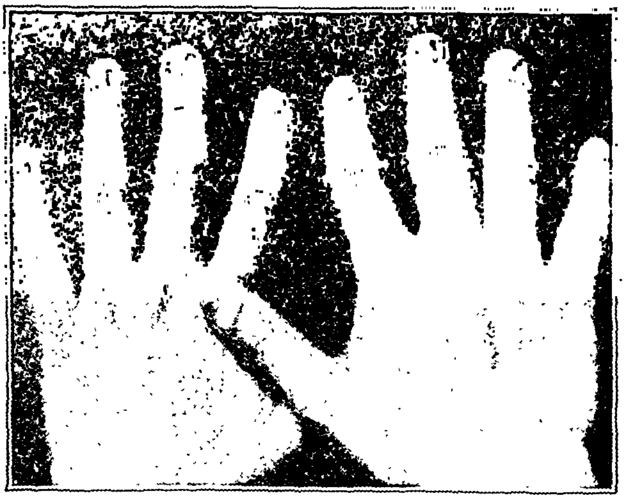

Fig. 4.—Onycholysis in author's second patient.

Possible causative factors which we considered were as follows:

1. Could the catsup have been at fault? This possibility would seem to be eliminated by the freedom of the groups who came in contact with the catsup and by the fact that it was thoroughly washed off the bottles before they were sent to the bottle washers.

2. Could the paste be blamed? The group of girls whose hands were in the paste all day did not suffer from nail disorders.

3. Could the chemicals on the labels be the cause? The label manufacturer informed us that no similar cases had occurred in his plant.

4. Could the chemicals in the water be the cause? No soaps, lyes or chemicals were added to the water. Only 0.06 part per million of chlorine was added to the water supply at its source. As this would have been neutralized in the city mains it could be of no significance.

5. Was there irritation from the sponges? We were unable to secure much information in regard to sponges, but as the ones provided were old and frequently washed we did not believe that they could be at fault.

6. Could maceration of the tissues which bind the nail to the nailbed occur by long continued immersion of the hands in water? This is self explanatory and, I believe, a very important factor.

7. Was mechanical trauma to the free ends of the nail to blame? We observed some of the girls picking at resistant specks of dried paste on the bottles. I think that this factor is one of several, operative in producing the disorder.

8. Is there a personal factor predisposing to ease of separation of the nails? No evidence could be found in our examinations of the afflicted girls to support such an hypothesis. Yet the fact that only a small percentage of new employees were involved speaks in favor of it. If a new employee tolerated the work and did not show loosening of the nails within forty-eight hours, she apparently was capable of washing bottles indefinitely.

SUMMARY

New employees, apparently healthy, developed black spots under their fingernails within forty-eight hours after beginning work washing paste from labeled bottles. Within a few days the nails loosened from the nailbeds at these areas. The process was without symptoms. The nails regrew in from four to six months. Investigations revealed no specific industrial irritants at fault. I believe that the disorder was precipitated by maceration of the tissues by prolonged immersion in water plus, possibly, the mechanical insult to the tips of the fingernails from picking at resistant pieces of paste.

But back of all of this, in my opinion, was some personal factor which made the nails separate from the nailbeds more easily than would those of normal individuals.

COMMENT

Although my cases and those of Oppenheim belong to essentially the same group, it can be seen that there are some differences. My patients presented an acute fulminating separation of the nails, while the process in Oppenheim's patients was essentially a chronic one. This difference might be explained by my patients' immediate removal from the offending work. Oppenheim made no mention of the sudden appearance of blackened areas under the nails, which was so characteristic in my cases.

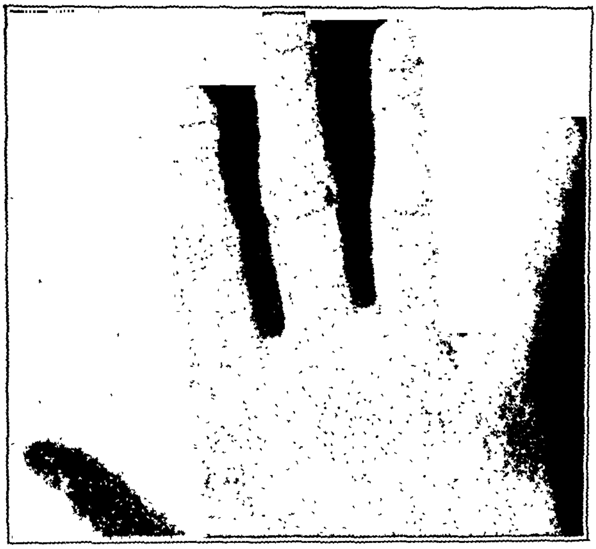

Fig. 5.—Earliest stage of onycholysis, as seen in author's third patient. Only a darkened area can be seen under the fifth nail.

Heller[3] described ten cases of onycholysis in which the etiology was indefinite. He believed that external irritants, such as soda did not play a causative rôle. His cases were unrelated to the industries and differed clinically from mine. He made no mention of sudden onset with darkening of the nailbed.

THE BLOOD PICTURE IN SIX HUNDRED CASES OF GOITER

ESPECIAL REFERENCE TO THE EFFECT OF IODINE AND THYROIDECTOMY *

ARNOLD S. JACKSON, M.D.
MADISON, WIS.

In 1924 I began a study of the blood in toxic goiter to ascertain, if possible, whether or not the data would be of any value in determining the prognosis of the disease. European authorities, notably Kocher,[1] and his American disciple, Crotti,[2] have laid considerable emphasis on the importance of the blood picture in hyperthyroidism. Little study of this subject has been made in our own country, with the exception of an important contribution by W. A. Plummer[3] in 1918, and general observations by Hertzler[4] and a few others. Plummer's report was made before the metabolic rate had come into general use. Hertzler states, in conclusion, that the observations to date are so variable that a further study is much desired. So far as I have been able to ascertain there has been no report of the coordinated blood picture and metabolic studies, nor any of the effect of iodine on the former.

The purpose of this study is to show:

1. Whether or not the blood picture in hyperthyroidism varies from that in the normal person.
2. Whether the differential blood count is or is not of diagnostic and prognostic significance.
3. Whether there is or is not a definite relationship between the blood picture and the metabolic rate.
4. Whether a secondary anemia is typical or atypical of hyperthyroidism.
5. A change or the absence of one in the blood picture through the use of iodine.
6. Whether or not the blood picture in hyperthyroidism is of any practical clinical importance.

Although Miscowicz and Ciuffini in 1904 found a lymphocytosis in the blood of patients with hyperthyroidism, and Caro in 1907 reported similar observations in one case, it was Kocher who in 1908 gave these observations their true significance and considered them as the result of the disease. Since then a number of authors have reported the results of their investigations, upholding these conclusions.

Crile[5] believes that the most characteristic change in the blood picture in hyperthyroidism is the presence of a moderate degree of lymphocytosis.

Crotti states that the chief characteristics of the blood in patients with hyperthyroidism are leukopenia, hyperlymphocytosis and hypopolynucleosis.

Hertzler remarks that the lymphocytes generally are from 25 to 45 per cent but may reach 50 per cent or more. In many of the most severe cases, however, the lymphocytes are actually reduced.

According to Kocher, the differential blood count should be normal in simple goiter, while exophthalmic goiter should be characterized by a more or less marked lymphocytosis together with a general leukopenia in two thirds of the cases. The ingestion of the thyroid products should produce in man and animals a relative, or more often an absolute, increase of lymphocytes and a decrease in the polymorphonuclears.

De Quervain,[6] on the other hand, from a study of 250 cases found practically no change in the lymphocyte count in simple and toxic goiter. He found that the average percentage of polymorphonuclears is 64 in simple goiter, 61 in hyperthyroidism and 65 in hypothyroidism. The lymphocytes range about 28 per cent in simple goiter, 30 per cent in hyperthyroidism and 29 per cent in hypothyroidism. He adds that his results tally with those of Muller, Bielajew, Bauer, Lampe and others with regard to the nonspecificity of the leukocyte formula for the different conditions of the thyroid gland.

Kocher emphasized the presence of a leukopenia and based his conclusion on 106 cases in which there was an average count of about 5,000 leukocytes.

Plummer's series, based on a study of the blood counts in 578 patients with exophthalmic goiter, showed an average leukocyte count of 6,973.5. Plummer found that there is a relative and an absolute mononucleosis and a decrease in the percentage in the polymorphonuclear neutrophils, thereby confirming Kocher's observations. When a leukopenia is present the decrease is in the number of the neutrophils. He found that in the mortality statistics the relative lymphocyte count is a few points under the average but not sufficiently to be of value in prognosis. He believes that the differential count is of limited value in diagnosis. Except for a polymorphonuclear leukocytosis immediately following operation and during tonsillitis and other acute infections, he was unable to determine any factor which influences the characteristic blood picture.

On the contrary, Crotti believes that the differential blood count is of great help in deciding whether one has to deal with a thyrotoxic condition or not, and the same is true of the prognosis. He believes that a marked leukopenia, a high lymphocytosis and a marked hypopolynucleosis will show that the case is a serious one. A high percentage of lymphocytes without or with only a moderate leukopenia is of good prognostic value, whereas a marked leukopenia with a low percentage of lymphocytes must be regarded as a bad prognosis.

Table 1.—*Average Blood Count in Six Hundred Cases of Goiter*

	Colloid Goiter	Nontoxic Adenoma	Toxic Adenoma	Exophthalmic Goiter
Hemoglobin	75	79	78	78
Erythrocytes	4,200,000	4,190,000	4,960,000	4,790,000
Leukocytes	9,543	8,956	8,463	8,412
Polymorphonuclears	64	60	60	59
Lymphocytes	30	33	35	35
Transitionals	4	5	4	4
Eosinophils	2	2	1	2

From these conclusions it is evident that a wide divergence of opinion exists with regard to the differential blood count in goiter and also with regard to its diagnostic and prognostic importance.

In this series of 600 goiter cases, blood studies were made on the following types of goiter: colloid goiter, 100 cases; nontoxic adenoma, 100 cases; toxic adenoma, 200 cases; exophthalmic goiter, 200 cases.

The average blood count for this entire group is shown in table 1.

[6] de Quervain, F.: Goitre, New York, William Wood & Co., 1924, pp. 80-81.

The influence of sex also was considered (table 7).

The influence of age which was also taken into consideration is shown in table 8.

CONCLUSIONS

In a study of 600 cases of goiter, the following conclusions are drawn:

1. The blood picture in hyperthyroidism does not vary essentially from that in the normal person.
2. The differential blood count in hyperthyroidism is not of diagnostic and prognostic significance.
3. There is not a definite relationship between the blood picture and the basal metabolic rate. The lymphocyte count is not varied by an increase or a decrease in metabolism.
4. The blood count is not influenced by the severity of the disease, considering metabolism and weight loss as paramount factors.
5. A secondary anemia is not typical of hyperthyroidism.
6. A leukopenia is not characteristic of hyperthyroidism.
7. Sex and age do not influence the blood picture in toxic goiter.
8. In spite of clinical improvement, no appreciable change was observed in the blood count following the use of iodine in hyperthyroidism.
9. The only appreciable change in the differential blood count in goiter was observed following thyroidectomy for exophthalmic goiter. An increase in the polymorphonuclear count and a decrease in the lymphocyte count occurred.
10. I do not believe that the blood picture in hyperthyroidism is of any practical clinical importance.

MENINGITIS CAUSED BY FRIEDLÄNDER'S BACILLUS

A CASE WITH RECOVERY *

KARL ROTHSCHILD, M.D.
NEW BRUNSWICK, N. J.

Most bacteria that are capable of causing general septicemia have at one time or another been found responsible for a case of meningitis. A most interesting rôle has been played by bacteria of the mucosus type. Reports have been published of meningitis caused by Streptococcus mucosus, and Bacillus mucosus-capsulatus has been several times found to be the cause of fatal meningitis. And yet, it is rather peculiar, in view of the fairly large number of pneumobacillus septicemias, that not more cases of pneumobacillus meningitis have been reported. I was able to find in the American literature only a single case of Friedländer's meningitis. This case was reported by Malis[1] and had a fatal outcome. The scarcity of reported and the rarity of nonfatal cases give me special impetus to report another case of pneumobacillus meningitis, this time with a favorable outcome:

J. M., a Negro, aged 34, a janitor, admitted to the otolaryngologic service of Dr. B. M. Howley, Oct. 30, 1930, and treated by the neurologic department in conjunction with Dr. Howley, complained of high temperature, pain in back of the right ear, stiffness of the neck, and drowsiness.

The patient's father is living. His mother died from heart disease. The other members of the family, two brothers and one sister, are living and well. There has not been any tuberculosis, diabetes or insanity in the family.

As a child the patient had measles, mumps and chickenpox. At the age of 11 years he had a slight attack of malaria. While in the army in France, he had a slight attack of pleurisy. He has had gonorrhea, but stated that he had not had syphilis. He is married. His wife is healthy. They have no children.

Aug. 6, 1930, the patient was out swimming. A few days later he felt as if he had water in the ear. After a few more days he heard noises in the ear but did not have any pain. At that time a physician considered the condition harmless. September 15, he became ill with fever and called a physician, who treated him for nine days. He improved and went back to work. September 24, he saw Dr. Howley, who did a paracentesis. The patient went home and felt better for a few days but became worse again. October 5, Dr. Howley operated on him for mastoiditis. He stayed in the hospital one week and then went home. He felt fine until October 29, when he was seized with a high temperature, delirium, and stiffness of the neck.

At the time of the physical examination the patient was unconscious and was irrational at times. The right pupil was somewhat larger than the left. The pupils reacted well to light. Accommodation could not be tested. The ears and nose were normal. There was a scar behind the right ear, originating from a mastoid operation done three weeks previously. The head was held slightly backward, and it was impossible to bend it forward to any great extent. The skin of the whole face was very sensitive to the touch. The thyroid gland was not enlarged. The apex beat was heard in the fifth interspace, one fingerbreadth within the nipple line. There were no murmurs. The volume was good. The lungs were normal to percussion and auscultation. No râles were heard. Slight general rigidity was noted in the abdomen. Motor power was good in all the extremities. The tendon reflexes of the right arm and leg were slightly exaggerated. Abdominal and cremasteric reflexes could not be elicited. There was no Babinski sign. Clonus was not present. The head was turned toward the right. A temporary diagnosis of brain abscess with meningitis was made.

October 30, a spinal puncture was done, which showed decreased pressure and a very cloudy fluid of a peculiar viscous consistency. Dr. Howley operated immediately and found a subdural abscess, with pus of yellowish color and mucoid appearance.

Urinalysis showed: specific gravity, 1.026; reaction, acid; albumin, a trace; sugar, 1.43 per cent; acetone, negative. Urates and a few epithelial cells were demonstrated microscopically.

Examination of the blood showed: hemoglobin, 55 per cent; erythrocytes, 3,690,000; leukocytes, 21,150; differential count: polymorphonuclears, 88 per cent; large lymphocytes, 4 per cent; small lymphocytes, 8 per cent.

Examination of the spinal fluid gave the following results: cell count, 1,100; globulin, 4 +; Fehling reaction, not reduced. Smears did not show any organisms. Culture was made.

October 31 the patient was in a slightly better condition. The temperature was up to 103 but dropped late in the morning to 99.4. It rose again in the evening to 102. The pulse was between 80 and 100. Respirations were 20 per minute. The patient showed signs of meningitis: slight stiffness of the neck and a medium Kernig sign.

There were no focal signs present. The reflexes were equal on the two sides, and no pathologic reflexes were noted. There was no disturbance of the cerebral nerves.

Mentally, there was a rather marked stupor. After a long interval following an order, the patient opened his mouth. On being given any other order such as show the tongue or open the eyes, he always opened his mouth and did nothing else. Questioning elicited the same answer:

"What is your name?" "John Mason."

"Where do you live?" "John Mason."

"Are you married?" "John Mason."

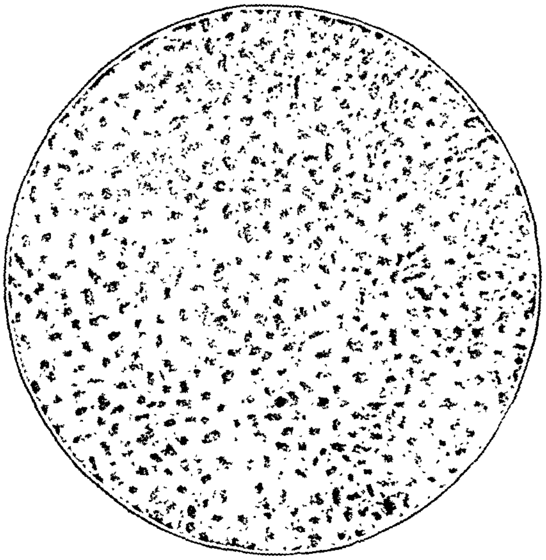
mastoid infection. Comte, Lévy-Bruhl and Dany,[10] in the latest publication on this subject, report a fatal case the bacteriology of which is very similar to that in the case reported here, in that all sugars were fermented with gas formation and later reabsorption, and gelatin was not liquefied. Animal inoculation tests were fatal in mice as well as in rabbits. A case described by Gernez and Razemon[11] has, besides meningitis, signs of osteomyelitis, and they consider this the first case of bone invasion by Friedländer's bacillus. The case of Bocca, Ranque and Sénez[12] was a fatal one in an infant. Rénon and Blamoutier[13] report a case of chronic labyrinthitis with Friedländer's bacillus, which is a rare occurrence and paralleled only by the case of Brain and Valentine.[9] The case of Lion and Minvielle[14] had also a fatal outcome, as had those of Dufourt, Delattre and Bonnet[15] and Lequeux.[16] The fatal case of Ménétrier and Bertrand-Fontaine[17] is mentioned because of the extremely sudden onset with coma (début brutal). The cases of Weichselbaum,[18] Mills[19] and Dmochowski[20] are mentioned here because they were described before the practice of lumbar punctures was known. In their cases the organisms were found in cultures obtained from the meninges on autopsy. Breton and Mahée,[21] in making a survey of Friedländer's pneumobacillus meningitis in 1929, report that of nineteen cases studied twelve were purely meningeal, while in seven the meningitis developed secondarily to other infections. In my case pure cultures of the same organisms were obtained from the spinal fluid and from the brain abscess.



Bacillus mucosus-capsulatus (Friedländer's). Culture from spinal fluid. Note clearness of capsules.

The bacteriology of these peculiar organisms has been described in several articles, by Friedländer,[22] Malis, Brain and Valentine and others, and I will restrict myself to a few general remarks referring to the table for comparison. It has been asserted that the main characteristic of Friedländer's bacillus, besides the formation of mucoid colonies and the capsules (shown in the illustration), is the ability to ferment all the sugars with or without the formation of gas, and its inability to liquefy gelatin.

Two interesting reports have been made lately by Kraus[23] and by Kliewe,[24] who have found a bacterium in two different cases which Kraus calls Bacterium mucosum-mutabile. He found gram-negative mucus-forming rods which in the beginning were hard to differentiate from Friedländer's bacillus, but soon there developed a yellowish color of the colonies which was never found with Friedländer's, and milk was coagulated. Sugars were fermented. Gelatin was liquefied. The patient's serum was agglutinated in a 1:160 solution. The bacillus did not coagulate cultures of other mucoid bacteria. It was pathogenic for mice. In the course of the disease the color changed, and Kraus believes that all capsule bacteria can change their morphology by adaptability of the germs to the environment. Hence he gave this particular one the name of Bacterium mucosum-mutabile. Yet, according to Kliewe, it seems probable that several types are well characterized.

Malis, in his article referred to, shows several photographs of bacilli which are forming long chains and which rather deserve the name of Streptococcus mucosus-capsulatus. Urbantschitsch[25] in 1926 reported a series of eight cases of streptococcus mucosus meningitis in which only one patient recovered. He considers the infection so severe that he recommends, in doubtful cases, an early lumbar puncture and, in case a mucosus germ is present, immediate bilateral operation without consideration of the conditions of the drums.

What makes infection with mucus-forming bacilli so dangerous? As I have mentioned in the description of my case, the pus contained in the brain abscess had the appearance and consistency of a mucoid semiviscous fluid. The spinal fluid, too, was transformed into a gelatinous liquid. It seems to me that these physical properties may be the cause of the grave prognosis. The mucus will tend to fill in spaces and to clot the foramina, and cerebral blocks may well be responsible for the generally fatal outcome.

CONCLUSIONS

1. Cases of meningitis caused by Bacillus mucosus-capsulatus (Friedländer's bacillus) are usually fatal.

etiologic incitant. Scheel and Föien[4] believe that the greater effusions are followed more frequently by tuberculosis than are the less abundant exudates and the dry pleurisies. The acute dry form frequently develops into a pleurisy with effusion, a fact which suggests that a dry pleurisy is but a mild or early expression of the pathologic process which results in the outpouring of fluid. If such is the case, one may justifiably look on an acute dry pleurisy as just as good evidence of tuberculous infection as is pleurisy with effusion. Such is certainly the tendency in the modern textbooks on this subject,[5] yet there are very few figures to support this contention.

The reasons for the paucity of definite data on patients with acute dry pleurisy are apparent. In the first place, because patients with this disease are not often severely ill for any length of time, they are not treated as hospital patients, and therefore hospital statistics are not forthcoming. If they become hospital patients, it is not easy to get adequate follow-up studies on them, for reasons which will be cited later. Secondly, the diagnosis of acute dry pleurisy in the absence of a friction rub or fever is often difficult, however definite the symptoms, and any series of cases must contain some in which the diagnosis will be open to question. Lastly, as stressed by Lord[2] and by Capps,[5] the condition is very rarely if ever primary, being related much more commonly to infection in the lung, lymph glands or other sites not detectable at the time of the acute illness.

The present study was undertaken to secure additional information regarding the subsequent course of patients with acute dry pleurisy. The case histories of all patients seen at the Peter Bent Brigham Hospital from 1913 to 1930 in whom the condition was diagnosed as pleurisy were reviewed. Only those cases were accepted for follow-up study in which the pleurisy was acute, without definite evidence of fluid, and in which no primary disorder could be demonstrated. Thus, all cases of pneumonia, of pulmonary tuberculosis or lung abscess, of pleurisy with effusion, of heart disease in which infarction of the lung was either evident or suspected, of pericarditis or mediastinitis, of definite rheumatic infection, of sepsis and of chronic nephritis were excluded. Four cases with symptoms and signs indicating an acute bronchitis were included in which there was evidence as well of a definite pleurisy. A tabulation of the cases reviewed indicates the incidence with which pleurisy is seen at this hospital. The 930 cases reviewed fall into three groups. One hundred and forty-nine were acceptable as instances of acute dry pleurisy. In the second group there were 142 cases in which this diagnosis might have been made but, because of the absence of a rub or râles, of fever or a clear-cut history, they were not accepted and were classified as "questionable." Our review of these case histories has made us willing to subscribe to the aphorism of Sir Thomas Horder,[6] who wrote, "There are probably few diseases more often diagnosed without adequate reasons than pleurisy; there are probably few diseases that exist more often unsuspected." It is commonly very difficult to make a diagnosis of pleurisy. A patient who complains only of chest pain without cough or fever and who has no friction rub or râles may be suffering from nothing more than myositis or neuralgia, yet the diagnosis of pleurisy nearly always comes first to mind. Hence one finds many instances of "questionable" pleurisy. The third group of 639 contains the cases of pleurisy with effusion or pleurisy secondary to some other condition, such as pneumonia or tuberculosis, which was recognizable at the time the cases were under observation.

Follow-up studies were possible on only 40 of the 149 patients with acute dry pleurisy. Information could be obtained on so few, largely because of the peripatetic habits of ward and dispensary patients, and partly because many of them, having no subsequent illness, did not return to the hospital or were apparently unwilling to do so when asked. The 109 cases in which no follow-up records were obtainable have been discarded because little that is new can be learned from them.

The important facts concerning the forty patients followed are these: There were twenty-one males and nineteen females. The average age was 30 years, with 14 and 54 as extremes. To indicate the extent of the illness, the duration of symptoms before the patients were seen averaged nine days, with one and ninety-six as extremes. The patients admitted to the hospital had an average stay of thirteen days. Concerning the symptoms and signs of pleurisy, all forty had pain, eighteen (45 per cent) of them had cough, twenty-eight (70 per cent) had a pleural friction rub, and twelve (30 per cent) had râles. The average maximum mouth temperature was 99.8 F. Twelve had no temperature higher than 99; eleven had temperature between 99 and 100, and fifteen between 100 and 103. The average white blood cell count was 11,800, with 8,000 and 25,000 as extremes. We are chiefly concerned here with the subsequent course of these patients. Our information about them was obtained in twenty-two instances by correspondence and in eighteen by examination in the outpatient department of this clinic. The patients written to were sent a questionnaire inquiring about their interval history and their health at the present time.

Source of the Material Studied

	Number of Cases		
	Acute Dry Pleurisy	Questionable Acute Dry Pleurisy	Pleurisy with Effusion or Secondary to Other Conditions
House patients (among 36,000 admissions)........	74	23	471
Outpatients (among 139,000 patients)..................	75	119	168
Total..................	149	142	639

Of particular interest is the fact that in only four of these patients did pulmonary tuberculosis develop. The remaining thirty-six who have reported on their health or have been examined after a period of from one to sixteen years have been found to be essentially in good health. The average length of time they have been followed is seven years, one year being the shortest and sixteen years the longest period. Four patients have had one or more recurrences of pleurisy, and two have had lobar pneumonia. A few have reported respiratory infections without any consequential sequelae, and doubtless many of the others had "colds" or bronchitis which they did not report. One patient has

ADVANTAGES OF CECOSTOMY PRELIMINARY TO RESECTIONS OF COLON AND RECTUM *

ALLEN O. WHIPPLE, M.D.
NEW YORK

Cecostomy has been advocated especially in acute obstruction of the colon but has not been sufficiently emphasized as a measure preliminary to interval operations on the large intestine. Wound repair differs markedly according to the tissues injured, the single, repeated or continued factor of injury preceding or associated with repair, the factor of rest, but especially the factors of blood supply and of presence or absence of infection. An uncomplicated, sutured, sterile incised wound of the skin presents the simplest form of repair, for the injury is mechanical and single, and the reparative process goes on without the interference of further injury. Repair in a sutured incised wound of the colon is quite the opposite. It is complicated from the start by factors which not only delay but which may prevent wound healing: infection with bacteria of the most virulent forms, tension on suture points and lines due to peristalsis or distention, and compromised blood supply due to edema of the infected tissue or to vascular compression, the result of a distended intestine.

Unfortunately, the proof of the foregoing premise is the very high percentage of morbidity and mortality associated with the surgery of the large intestine, and unfortunately too many surgeons accept this high risk or evade it by not attempting surgery of the colon. Ought we not rather to analyze the reasons for this risk and seek means of reducing it?

In studying the subject of wound repair in various tissues, one is immediately struck with the similarity in the graphs of the rate and rhythm of healing, as determined by different investigators. Carrel and Lecomte du Noüy,[1] and Spain and Loeb[2] obtained similar curves in cicatrization of skin wounds; and Harvey, Howes and Sooy[3] found remarkably consistent curves in the repair of wounds of the skin, fascia, muscle and stomach. These mathematically measured rates of healing agree consistently with many of everyday clinical observations, but they show definite critical periods. In all these curves there is a "lag" period of from four to six days during which repair is quiescent; then a period of from six to nine days of fibroblast proliferation and organization, when healing rapidly rises to its maximum point of tensile strength. Following this is a long period, varying in different tissues of maturation of the cicatrix.

It is to the "lag" period and the first days of fibroplasia in the colon that I would call attention. During the first two to four days of repair following anastomosis of the colon, the cut ends, or stoma edges, are held together by suture material or by pressure of apposing buttons, if such a mechanical means is used. Leakage is prevented, to a certain extent, by accurate suture, but far more important and effective is the sealing off of the peritoneal lines of contact, which are usually apposed by the seroserous stitch, by the rapidly forming fibrinous exudate. Provided there is no gross leakage and provided the sutured part can be kept at rest for a few hours, the wonderful reparative peritoneal exudate builds up a sufficient barrier to infection until the process of fibroplasia has united the wound edges and the epithelium has bridged the defect.

But it is during this critical first four to six days, when only peritoneal exudate and sutures are holding the barriers, that tension on the suture line either by atonic distention or by overactive peristalsis can accelerate the factor of infection in destroying the peritoneal line of defense and establishing a peritonitis, localized or diffuse, or a fecal fistula.

Distention of the colon both stretches the tenuous line of suture and diminishes the much needed blood supply to the area of wound repair. This in turn favors pressure necrosis of the suture line and leakage.

Whether one uses the suture or button method of anastomosis in a contaminated field, or attempts one of the 200 or more described methods of aseptic anastomosis, the factors of distention and peristalsis will continue to be damaging and even fatal factors during the first two to six days of repair. It is in an effort to reduce these factors and to place the colon at rest during the critical period of healing that I am advocating the use of cecostomy, preferably two to four days before the major procedure on the colon.

The advantages of a cecostomy carried out two to four days before a resection of the colon or rectum are:

1. It makes possible a proper cleansing of the colon before the major procedure.
2. It permits the part anastomosed to be at rest until the period of fibroplasia is complete.
3. It increases the comfort of the patient by reducing distention and pains of ineffectual peristalsis.
4. It obviates the temptation and the necessity in some cases of giving enemas or irrigations in the critical period of repair.
5. In cases of partial or complete obstruction of the colon or rectum it has long been recognized as essential. If it works so well in the patients who are desperately sick, it is even more efficacious in the nonobstructed case.

I advocate cecostomy rather than appendicostomy for the following reasons:

1. The appendix either is missing or is so atrophic in adults as to be of little use as a sheath for a rubber tube.
2. A cecostomy properly done by the Kader or the Witzel method closes more promptly than an appendicostomy.
3. A tube sufficiently large to act as a real safety valve can be placed in the cecum more easily than in the appendix.

There are certain dangers to be avoided in the use of preliminary cecostomy:

1. The overenthusiastic use of the cecostomy tube as a means of administering fluids or enemas or irrigations before and after major procedures on the colon and rectum should be discouraged. This carries risk of leakage around the cecostomy opening and, after resections, of distending the intestine proximal to the suture line.
2. The tube should be kept in one position. If it comes out, it should be left out.

together substances of unequal density and subjects them to any stress or strain, the substance of less density will yield and thereby produce a leak. In the method that I am proposing, one does not pass any sutures through the catheter. If the bowel is not too much damaged, one may make a layer or two of purse-string sutures. The catheter can be brought through the omentum, as described by Dr. Mayo, which adds security to its position, and brought out through the operative incision. When its usefulness has expired, the shank of the catheter is drawn up as closely as possible and cut off, and the remainder is passed out through the alimentary canal by the natural processes of evacuation. It will be found that the method serves many useful purposes and can be rapidly done.

Dr. Allen O. Whipple, New York: I meant to state in the paper that the method of cecostomy was limited to the cases in which the cecum was not involved. Dr. Abell is quite right in stating that it is not a method suitable for cases in which the cecum is to be resected. In regard to the subsequent dealings with the cecostomy, in none of the cases in which this method was carried out was it necessary to close the cecostomy. In some ways, undoubtedly, a cecostomy such as Dr. Horsley mentioned is a more effective method, but it certainly requires a subsequent closure. I am interested in the suggestion of Dr. Hendon in regard to the use of a mushroom catheter. The only objection that I could see, possibly, to that method is that it might be a little more difficult to irrigate in case the openings of the catheter became obstructed, but I should be greatly interested in trying it for that purpose.

Clinical Notes, Suggestions and New Instruments

TRANSITORY HYPERTENSION DURING SPINAL ANESTHESIA: REPORT OF A CASE

Edward P. Heller, M.D., and Carroll P. Hungate, M.D.
Kansas City, Mo.

During the past few years the literature has contained numerous articles intended to encourage the use of spinal anesthesia and pointing out the safety of this procedure. Excluding the conditions in which this type of anesthesia is contraindicated, e. g., intestinal perforation, shock and conditions contraindicating the Trendelenburg position, it has been amply shown that the morbidity and mortality are increased through rapid fall in vascular tension not properly controlled by the use of epinephrine or ephedrine.

The literature stresses the complete relaxation that usually occurs in surgery below the diaphragm following the administration of spinal anesthesia. With this type of anesthesia there is usually an absence of intestinal distention during the operation and during the postoperative period. The latter is usually marked by normal peristalsis, a soft abdomen and the absence of pain associated with distention, which is so common following ether anesthesia. In our work we have found that, in surgery below the diaphragm, spinal anesthesia almost invariably gives complete relaxation and diminishes postoperative discomfort.

In a review of the literature we fail to find any reports of hypertension following the use of spinal anesthesia. McKittrick, McClure and Sweet[1] and practically all others in their reports on this type of anesthesia fail to note any cases in which hypertension developed but rather stress the fall in vascular tension. Twenty-five per cent of the series had a fall of 50 per cent or more in blood pressure. Although the exact physiologic action of ephedrine is not agreed on, Burch and Harrison,[2] in their experiments on dogs anesthetized by spinal anesthesia, found that when ephedrine was given intravenously in no instance did the "mean blood pressure rise above the control value before anesthesia." When ephedrine was given intraspinally the blood pressure was equal to or above normal. They do not record a marked hypertension following the use of ephedrine either intravenously or intraspinally.

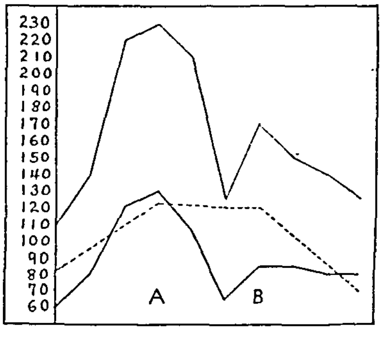
REPORT OF CASE

A man, aged 39, seen by one of us, Jan. 1, 1930, complained of abdominal discomfort with localized tenderness in the right lower quadrant. Periodic attacks of a similar nature had occurred over a period of eight months. He was again seen, July 16, 1931, at which time an operation was advised for chronic appendicitis. On the first date the blood pressure read 125 systolic and 70 diastolic. He was admitted to the Research Hospital, July 17, at which time the blood pressure read 110 systolic and 60 diastolic. He was given a preliminary narcotic consisting of one-sixth grain (11 mg.) of morphine and 1/150 grain (0.4 mg.) of atropine an hour before operation, July 18. He was given 0.025 mg. of ephedrine subcutaneously immediately before the spinal puncture; 3 cc. of a proprietary preparation containing procaine hydrochloride and strychnine sulphate (spinocaine-Metz) was given intraspinally. The blood pressure, pulse and respiration were recorded every five minutes during the operation, as shown in the accompanying chart. The administration and the control of the anesthesia were in the hands of one who is well versed in spinal anesthesia, Dr. Frank Hurwitt.

A right rectus incision was made. Coincidental with the rise in vascular tension there was a marked rigidity of the abdominal musculature. Fifteen minutes elapsed before the patient was moderately relaxed and anesthesia present. During the entire operation, complete relaxation was absent. The appendix was long and tortuous and decidedly bound down by many adhesions. The incision was closed with difficulty. During the closing of the incision, another rise in blood pressure was noted.

The postoperative convalescence was marked by gas pains and distention, insomnia and some febrile reaction. The day following the operation the patient complained of abdominal pain, which was due presumably to distention. This continued for four days. The patient sat up in a chair on the sixth day and was dismissed from the hospital on the ninth day.

During the convalescence the blood pressure was 118 systolic and 80 diastolic. The temperature ranged from 99.6 to 101.2 F., the pulse from 80 to 100. Since returning home he has eaten well, slept well and had normal bowel movements and a good appetite. The wound healed primarily. He began some work at his office, August 1 and has continued at work without difficulty.



Blood pressure (solid lines), and pulse (broken line): *A*, incision; *B*, closure.

After having written to several authorities on spinal anesthesia, we have come to the conclusion that the mechanism of this reaction is perhaps most clearly explained by Dr. L. F. Sise[3] of Lahey's Clinic. He believes that the anesthetic did not get entirely within the dura. A light anesthesia resulted. Therefore, motor paralysis and muscular relaxation were not sufficient. The full dose of ephedrine not being counterbalanced by the full action of the spinal anesthesia would produce the marked rise in blood pressure.

Even though we believe that the spinal anesthesia was given correctly, e. g., the lumbar puncture was done without difficulty and a free flow of spinal fluid obtained at once, Dr. Sise's explanation would seem plausible.

1010 Professional Building.

PHYSICAL CHARACTERISTICS OF THE ULTRAVIOLET RADIATION EMITTED BY COLD QUARTZ LAMPS

Radiation measurements were made on two types of cold quartz ultraviolet generators (mercury glow lamps): (1) a long slender quartz tube type of orificial applicator and (2) a grid type in an aluminum reflector.

The radiometric measurements were made with the vacuum thermopile and a quartz fluorite achromatic spectroradiometer, regularly employed in such work. No attempt was made to obtain spectrum photographs, because they cannot give quantitative measurements, though if intelligently employed they may show something of the spectral quality of the radiation emitted. For example, spectrum photographs of new, clean applicators usually show emission lines of wavelengths shorter than about 190 millimicrons. However, one applicator type of lamp was brought to my attention that, according to the spectrograms submitted, did not emit (transmit) ultraviolet rays shorter than about 226 millimicrons. Assuming that the ultraviolet spectrograph was functioning properly, it appeared that the absence of ultraviolet rays shorter than 226 millimicrons probably resulted from the fact that, since the walls of the quartz tube forming the applicator were no longer perfectly clear, the short wavelengths were absorbed in their passage through the tube; for it requires but little contamination of the surface of the quartz tube to effect great absorption of the very short wavelength ultraviolet rays.

Cold Quartz Orificial Applicator.—The following data were obtained on a cold quartz orificial applicator operated on 0.013 ampere, and 640 volts, or about 8 to 10 watts in the burner. This particular lamp was operable on two voltages. The intensity of the ultraviolet radiation emitted when the lamp was operated on the higher voltage was 1.6 times that obtained on the lower voltage.

By placing the luminous tube of the cold quartz ultraviolet generator lengthwise, close to the slit of the spectroradiometer, it was found that the intrinsic intensity of the 2,537 angstrom unit line is relatively high, being about 215 microwatts per square centimeter at the surface of the applicator. It was observed also that 96 per cent of the total erythemogenic rays (of wavelengths less than and including 313 millimicrons) was emitted by the resonance line at 254 millimicrons. By means of a thermopile and filter method,[6] it was found that 97.8 per cent of the erythemogenic rays was emitted by the line at 254 millimicrons, which is in good agreement with the preceding test.

Cold Quartz Grid Type Ultraviolet Generator.—Measurements of the ultraviolet radiation emitted by this lamp were made with an achromatic spectroradiometer and a vacuum thermopile; also by a balanced thermopile and filter method.[7]

The lamp was operated on 115 volts, alternating current, and 60 cycles on the primary of the transformer, with 30 milliamperes through the lamp as specified.

Under these conditions it was found that the relative intensities (corrected for absorption in the spectroradiometer [7]) of the short wavelength ultraviolet lines that were measurable at 313, 297 and 254 millimicrons were 45, 14 and 865. From this it follows that about 94 per cent of the total radiation of wavelengths less than and including 313 millimicrons is contained in the resonance emission line at 254 millimicrons. This is a trifle lower than the value obtained for the cold quartz applicator. But in the grid lamp examined, the quartz tubes were not quite so clear as in the applicator, which would reduce the intensity at 254 millimicrons relative to the intensity at longer wavelengths.

The total radiation of wavelengths less than and including the line at 313 millimicrons, at a distance of 25 cm. from the center of the lamp, measured by a new balanced thermocouple and filter method [7] was 186 microwatts per square centimeter.

Physiologic tests [7] were made of the erythemogenic efficiency of this lamp, and a close agreement was found between the observed and the calculated time of exposure to produce a minimal perceptible erythema.

Since the publication [8] of experiments on irradiation of cod liver oil, ergosterol and cholesterol, showing that wavelengths shorter than 280 millimicrons are destructive to vitamin D, the feeling is abroad that it is undesirable to use ultraviolet rays of wavelengths shorter than about 280 millimicrons for therapeutic purposes, and hence, in recent years, therapeutic lamps are generally covered with a glass that eliminates these rays.

The radiation from the quartz mercury vapor glow lamp is predominatingly of wavelengths that have a high germicidal action.[9]

In fairness to the purveyor of the particular make of lamp examined, it is relevant to add that the accompanying literature indicated that the device was being promoted as a germicidal agent. Credit is to be given also for the caution sign on the instrument to "protect the eyes at all times by wearing glasses."

Even after this warning is heeded, accidents are possible, as witness the aforementioned case of conjunctivitis in the outer corner of the eye, caused by radiation passing back of the spectacle lens when the subject was standing with the face exposed sidewise to the lamp.

CONCLUSION

It seems relevant to comment on the great difference in the physiologic action of the ultraviolet rays of wavelengths less than 265 millimicrons in artificial sources (absent in sunlight) as compared with the wavelengths from 310 to 315 millimicrons, which are very intense in sunlight. The ultraviolet rays of wavelengths in the region of 254 millimicrons do not penetrate deeply into the skin, the erythema produced is superficial, and an overexposure of several times the dosage required to produce a minimal perceptible erythema does not produce a blister.

In contrast, if the untanned skin is exposed to the more deeply penetrating rays of wavelengths 310 millimicrons and longer, for an interval that is only slightly longer than the dosage time required to produce a minimal perceptible erythema, a painful blister is produced. This phenomenon was noted by Hausser and Vahle,[10] and more recently by us.[11]

During the past summer, further physiologic tests were made,[12] measured amounts of ultraviolet radiation

MALIGNANT CONDITIONS IN RADIOACTIVE PERSONS

Martland,[1] in 1925, reported cases of anemia and of necrosis of the jaw in persons who had been employed in painting watch dials with paint made luminous by the addition of radium, mesothorium and radiothorium. During several years previous to 1924, 800 girls did such work in a New Jersey factory. The girls swallowed small amounts of radioactive paint day after day as a result of pointing the brushes with the lips. Some who had worked for one or more years developed necrosis of the jaw and anemia, from which, up to 1928, thirteen died. Martland, who had followed these carefully, believed toward the end of 1928 that the worst period was over and that, with few exceptions, no more workers would develop radium poisoning. Dial painting was stopped there several years ago. Now, however, another pathologic condition seems to have arisen among the employees who swallowed radioactive paint. Since 1928, rapidly growing osteogenic sarcomas have appeared in at least eight cases. One girl died of sarcoma of the pelvis and of the orbital cavity; another, described as healthy in 1925 although her expired air was radioactive, developed osteogenic sarcoma at the site of a spontaneous fracture of the femur; another dial painter has twice sustained a pathologic fracture of the femur at the same site and sarcoma is suspected, and another former dial painter has recently developed osteogenic sarcoma of the pelvis. Four additional possible cases of sarcoma in former dial painters have come to Martland's[2] attention. These delayed cases of illness passed through the period when necroses of the jaw and anemias were developing in these workers and the present attack on their health is of a different nature. The difference is explained thus: In the early cases, mesothorium, which is physiologically more active than radium, predominated, but enough time has elapsed since their exposure to radioactive substances to allow the mesothorium to diminish in quantity by its own natural decay to below half its former strength. In the late cases which have resulted fatally, only radium, which is less active physiologically than the mesothorium, has been detected, and this has accumulated in the bony skeleton. Gettler, who examined the bones of a dial painter exhumed five years after death, found 0.05 mg. of radium distributed in the skeleton. He estimated that one-fourth ounce of bone from this painter contained $\frac{1}{50,000}$ mg. of radium and that the number of atoms of radium in this amount of bone was fifty billion. One thousand alpha particles per second were ejected from this one-fourth ounce of bone. Alpha particles, which, Martland says, are probably the most destructive agent known to science, consist of nuclei of helium atoms containing two positive charges ejected from the nuclei of the parent radioactive atoms at an initial velocity of from 12,000 to 18,000 miles per second. This destructive bombardment in the bones produces pathologic changes that give rise to anemia and to radiation osteitis and it is these areas of bone in which later sarcomas arise.

Flinn[3] recently suggested a method of treatment that will eliminate radium salts from the organism as well as improve the condition of the bone if continued for sufficient time. His next report of the treatment of radioactive patients is awaited with interest.

The study by Martland and his associates will aid in understanding the effects of other radioactive substances. The high incidence of primary carcinoma of the lungs in the cobalt miners of Schneeberg and in the pitchblende mines of Joachimstahl, and the various lesions produced by external exposure to radium and x-rays, demand investigation. Many of the radioactive substances sold to the public for the cure of various ailments may be dangerous to health. Martland was called to testify against the interstate sale of vials of mesothorium and radium which were to be ingested after being dissolved in water for the cure of disease. If taken as directed, the amount of radioactive substances in them would equal that taken by some of the dial painters. He examined two patients who had taken such water from one to two years; both showed radioactivity when tested by electrometers, and both had extensive necrosis of the upper jaw. Should these waters which are sold to the public contain only emanations in the form of radon or thoron it would be impossible to drink enough to furnish emanation that would be beneficial. Waters containing only emanation, Martland says, are frauds, and he doubts whether they are harmless. In 1926, more than 150,000 emanators were sold on the Pacific Coast. The human body in its normal environment is radioactive, but the makes a physical examination for the specific purpose of helping an individual patient; he is on the watch for definitely pathologic conditions which obviously affect the health of the patient. Doubtless minor degrees of structural or functional impairment are noted and may or may not be mentioned. After the probable major difficulty has been located, the abnormalities on the borderline of significance often receive little attention. However, statistical results are influenced largely by the apparently insignificant deviations from the normal since they constitute the majority. It thus happens that certain types of research of considerable importance in matters of public health depend finally on the uniformity of interpretation by examining physicians. When, for instance, the investigation deals with the influence on health of the temperature and humidity of the air in certain industrial plants, not only the mortality and incidence of sickness but also the physical examination becomes of great significance. Almost no two physicians of equal training, ability and experience will proceed in the same way or attach the same interpretation to their observations. Conditions which one examiner reports within the normal range may be reported as mild or severe by another. Quantitative determinations may be reported in standard denominations, yet the differences in interpretation of what values fall within and what without the normal variation may alter the final conclusions to be drawn from the data. When these cases in point are multiplied many times, as in a nation-wide study of problems of public health, it is obvious that there is a likelihood of differences due largely to the standards of the examiners being incorrectly attributed to factors peculiar to the industry under investigation.

In an effort to obtain greater uniformity of procedure and to enhance the significance of the results of the physical examination, Britten has suggested some principles along which progress might be made. The examiner should, if possible, proceed without knowledge of whether the subject is normal or not; evidence should appear in the report that the condition in question has at least been looked for; some standard scheme for evaluation of degrees of variation from the normal should be established, though it finally devolves on the examiner himself to decide whether or not a condition is pathologic. Since it is necessary that these degrees of abnormality be uniformly understood by all examiners, a definite set of instructions and a short but intensive training in the details of the examination should be given. Not only should a thorough history be obtained but allowance should be made for the presence of an acute condition during the examination and, if possible, the examination repeated after the acute condition has subsided. In an effort to stimulate thoroughness, a minimum time required for the examination should be established.

The foregoing discussion emphasizes one of the problems that have grown out of the expansion in the work of the public health service. It seems reasonable to expect that, in order to obtain results of significance in those investigations depending on the results of physical examinations, this procedure must be standardized to a greater degree than it has been heretofore. This general thesis should, however, be applied with care. While group investigation will doubtless require more or less standardization of procedure on the part of the members of the group, the art and science of medicine will probably be furthered in the future, as it has been in the past, largely by efforts made in the way peculiar to the individual.

Current Comment

OYSTERS—A PLEASANT TYPE OF THERAPY

The announcement by Hart [1] and his collaborators at the University of Wisconsin three years ago that copper is effective in supplementing iron in the cure of anemia produced by an exclusive milk diet in the rat promptly aroused the interest of the medical profession. Despite the importance of this discovery it must be admitted that the inferences hastily drawn by others than the investigators themselves have led to not a little confusion and mistaken advice. The work of Hart referred specifically to a unique type of nutritional anemia in a laboratory animal. There has been no warrant whatever in applying the observations without reservation to some of the unusual conditions of the blood, such as pernicious anemia in man, that have until recently been so baffling to the physician. At the moment there is some debate as to whether copper stands alone in the capacity to promote the function of the indispensable iron in hemoglobin and blood cell formation. Other elements, such as manganese and germanium, are clamoring for equal recognition. Meanwhile all sorts of new products containing both iron and copper are being commercially exploited and foisted not only on an ignorant public but also on an uncertain medical profession, although the Council has reported that the use of copper and iron mixtures lacks sufficient clinical supporting evidence (see page 1967, this issue). The chief objection to such unproved therapy is that a sense of security in the use of some drug leads to the neglect of other modes of therapy that may be far more effective. Many persons assume that copper is a scarce element in our foods, just as iron was formerly assumed to be. The facts are that both elements are more ubiquitous than might be anticipated. Illustrations of this are coming to light in rapid succession. The question Have you had your iron today? no longer conjures up the picture of raisins, which have distressed more than one person through overindulgence. Oysters, for example, have just been shown by Levine, Remington and Culp [2] to be capable of curing the nutritional anemia of milk-fed rats. The presence of copper in the

Chicago

Fellowship in Neurology.—Dr. and Mrs. William H. Wilder, Sr., have established the William H. Wilder, Jr., fellowship in neurology at the University of Chicago, in memory of their son, a student in neurology at the university, who was drowned last summer. The fellowship is to be awarded to a student of neurology nominated by the department of anatomy on recommendation of the professors in charge of neuroanatomy and clinical neurology. Mr. Paul G. Roofe has been appointed the first recipient of this fellowship.

Surgeon General Guest of Honor.—Dr. Robert U. Patterson, surgeon general, U. S. Army, Washington, D. C., will be guest of honor and principal speaker at the annual meeting and dinner of the Medical Department Sub-Chapter, Cook County Chapter, Reserve Officers' Association of the United States in the Drake Hotel, January 6. Other guests of honor will include Major Gen. Frank Parker; Col. Paul C. Hutton, surgeon, sixth corps area; Dr. Arthur D. Black, dean, Northwestern University Dental College; Dr. William H. G. Logan, dean, Chicago College of Dental Surgery, and Dr. Morris Fishbein, editor of The Journal. All medical reserve officers of the sixth corps area, which includes Michigan, Wisconsin and Illinois, are invited to the dinner.

Society News.—At the middle section meeting of the American Laryngological, Rhinological and Otological Society, January 5, the speakers will include Drs. Edward H. Cary, Dallas, Texas, on "The Future of Private Otolaryngological Practice"; Chevalier Jackson, Philadelphia, "Pins at the Periphery of the Lung"; John W. Carmack, Indianapolis, "Maxillary Sinusitis with Blood Stream Infection"; William V. Mullin, Cleveland, "Allergy"; Edmund Prince Fowler, New York, "Prevention of Deafness"; William E. Grove, Milwaukee, "Brain Abscess with Peculiar Bacteriologic Findings"; Edward D. King, Cincinnati, "Nasal Plastic Surgery"; Louis E. Brown, Akron, presentation of new instruments. At a joint meeting of the Chicago Laryngological and Otological Society, Chicago Tuberculosis Society and the Chicago Medical Society, January 4, Dr. Chevalier Jackson will speak on "Suppurative Disease of the Lung Following Operations Involving the Upper Air Passages." Dr. Austin A. Hayden is chairman of arrangements for the meeting.——Dr. Hugh McCulloch, St. Louis, will address the annual meeting of Sunset Camp Service League, January 19, on "Convalescent Homes from the Medical Viewpoint."

INDIANA

Personal.—Dr. Max A. Bahr has been reappointed superintendent of the Central State Hospital, Indianapolis, for the ninth consecutive time, it is reported; Dr. Bahr has been connected with the institution for thirty-two years in various capacities.——Dr. John J. Rife, Boston, recently celebrated his ninetieth birthday; Dr. Rife is still in the active practice of medicine.

Society News.—Dr. Frank C. Walker, Indianapolis, addressed the Hendricks County Medical Society at Danville, November 20, on "Pelvic Cellulitis."——The Montgomery County Medical Society was addressed at Crawfordsville, November 19, by Dr. Mark H. Mothersill, Indianapolis, on "Recent Research in Anemias."——Dr. George Elmo Moses, Worthington, addressed the Greene County Medical Society, Linton, November 12, on constipation.——Dr. Carl A. Hedblom, Chicago, addressed the La Porte County Medical Society at Michigan City, November 19, on "Abscess of the Lung."——The fifteenth annual meeting of the Indiana Academy of Ophthalmology and Otolaryngology was held in Terre Haute, December 9; the guest speaker was Dr. Bernard J. McMahon, St. Louis, on "Progress in Histopathology and Treatment in Otolaryngology."——At a joint meeting of the Fifth District and Vigo County medical societies, November 10, in Terre Haute, Drs. Joseph H. Weinstein and James F. Spigler talked on the "Shoulders resolution," concerning hospitalization of war veterans, and "Abnormal Intestinal Rotation," respectively.——Dr. Herman M. Baker, Evansville, addressed the Gibson County Medical Society, Princeton, November 9, on "Diagnosis and Treatment of Coronary Disease."——The Floyd County Medical Society was addressed in New Albany, November 13, by Dr. Louis Wallace Frank, Louisville, Ky., on cancer.——At the November 12 meeting of the Tippecanoe County Medical Society, in Lafayette, Dr. Charles A. Elliott, Chicago, spoke on "Circulatory Failure in Acute Infectious Disease."——Dr. Cecil L. Rudesill, Indianapolis, addressed the Lawrence County Medical Society, Bedford, November 4, on "Diet in Gastro-Enterology."——At a meeting of the Indianapolis Medical Society, December 15, Dr. Palmer Findley, Omaha, spoke on "Better Obstetrics." Dr. Max A. Bahr addressed the society, December 8, on "Psychiatry in Relation to Crime." The program at the December 1 meeting consisted of case reports.——The St. Joseph County Medical Society was addressed at South Bend, November 18, among others, by Dr. Norman F. Miller, Ann Arbor, on "Bleeding During Third Trimester of Pregnancy."

MARYLAND

Portrait Presented to Faculty.—A portrait of the late Dr. Hiram Woods, Baltimore, was presented to the Medical and Chirurgical Faculty of Maryland, November 17, at a meeting of the Osler Historical Society in the faculty's building. Dr. Lewellys F. Barker made the presentation, and Dr. James M. H. Rowland, president, accepted the portrait on behalf of the medical faculty. Dr. Henry E. Sigerist, professor of the history of medicine, University of Leipzig, gave an address. Dr. Woods died in January. He was a former member of the House of Delegates of the American Medical Association and chairman of the Section on Ophthalmology.

Society News.—Dr. Russell L. Cecil, New York, addressed the annual meeting of the Baltimore City Medical Society, December 4, on "Diagnosis and Treatment of Lobar Pneumonia." Dr. Lay Martin, Baltimore, among others, addressed the society, December 17, on "Early and Late Effects of Nonspecific Protein on Duodenal and Gastric Ulcer."——The Baltimore County Medical Association was addressed at Towson, November 18, by Drs. A. Harry Finkelstein on "Childhood Type of Tuberculosis," and William A. Bridges and John E. Murphy, "Adjuncts to the Routine Treatment of Tuberculosis."——A symposium on the toxemias of pregnancy, the experimental studies in the diagnosis of pregnancy and analgesia in the practice of obstetrics formed the program at the meeting of the West Baltimore Medical Association, November 17; the speakers were Drs. Louis H. Douglass, Alan F. Guttmacher and Francis L. Badagliacca.

The De Lamar Lectures.—Following is the list of the De Lamar lectures given at Johns Hopkins University, together with the names of the speakers:

November 10: Dr. Rolla E. Dyer, acting director, National Institute of Health, Washington, D. C., "Typhus-Rocky Mountain Spotted Fever Group of Diseases."

December 1: Dr. Victor G. Heiser, associate director, International Health Division of the Rockefeller Foundation, "Disease Control and the League of Nations."

December 15: Edgar Sydenstricker, director, division of research, Milbank Memorial Fund, "Statistics of Morbidity."

January 12: Arthur I. Kendall, Dr.P.H., professor of research bacteriology, Northwestern University Medical School, "Filtrability of Bacteria."

February 15: Dr. Charles Armstrong, surgeon, U. S. Public Health Service, "Complications of Smallpox Vaccination."

March 1: William H. Taliaferro, Ph.D., professor of parasitology, University of Chicago, "Experimental Studies on Monkey Malaria."

March 8: Dr. Albert G. Love, medical corps, U. S. Army, "Some Aspects of the Vital Statistics of the United States Army and Their Value in Public Health."

MICHIGAN

Dr. Hickey's Memory Honored.—A bronze plaque in bas-relief of the late Dr. Preston M. Hickey, for many years professor of roentgenology, University of Michigan School of Medicine, Ann Arbor, was presented to the university recently. The plaque, the work of Heinz Peter, was given by the American Roentgen-Ray Society, it is reported, and the presentation was made by Dr. Leopold Jaches, New York, president of the society.

Dr. Bruce Appointed Vice President at Michigan.—The board of regents of the University of Michigan has appointed Dr. James D. Bruce vice president in charge of university relations. This is a newly created position, in which Dr. Bruce's duties will be to centralize all requests made to the university for outside aid and help in meeting them so far as the university's resources allow. Dr. Bruce for the last three years has been director of the department of postgraduate medicine.

Medical Society to Have New Home.—The Wayne County Medical Society recently leased the David Whitney house at Woodward and Canfield avenues, Detroit, and plans to occupy it as new headquarters before January 1, it is reported. The society has been in its present quarters in the Maccabees Building for five years. For the present, only the first two floors and the basement in the new headquarters will be used, but plans for later expansion call for the occupancy of the entire building, it was stated.

Farrell, "Mechanism of Prostatic Obstruction," and Joseph F. McCarthy, "Newer Conceptions in the Management of Prostatic Bars and Hypertrophies."——A symposium on surgery was presented before the International and Spanish-Speaking Association of Physicians, Dentists and Pharmacists, December 18, by Drs. William S. Bainbridge, on surgery of the uterus; Eugene H. Pool, the spleen; Howard Lilienthal, the lungs, and Leo Winter, D.D.S., the jaw.——Dr. Hugh H. Young, Baltimore, addressed the Ocean Medical Society, Brooklyn, December 21, on "Problems in Diagnosis and Treatment of Prostatic Diseases."——Drs. Leo M. Davidoff and Maximilian A. Goldzieher addressed the Bronx County Medical Society, December 16, on "Disease of the Pituitary with Special Reference to Tumors" and "Rôle of the Adrenals in Health and Disease," respectively.

OHIO

Hospital News.—A. O. Fonkalsrud, Ph.D., formerly superintendent of the Sioux Valley Hospital, Sioux Falls, S. D., has assumed the superintendency of the Mansfield General Hospital.

Annual Public Health Lectures.—The Cleveland Academy of Medicine has begun its second annual series of public health lectures under the Health Education Foundation initiated last April (The Journal, April 11, p. 1240). Dr. Elliott C. Cutler, professor of surgery, Western Reserve University School of Medicine, Cleveland, delivered the first lecture, December 6, on "What Science Knows About Cancer." The second will be given, January 17, by Dr. Henry J. Gerstenberger, professor of pediatrics at Western Reserve, on "Why Think About Eating?" and the third, March 20, by Dr. Roy W. Scott, professor of clinical medicine at Western Reserve, on "Fighting Death After ,Forty." In addition to these, a secondary group of lectures will be presented before smaller audiences in outlying sections of the city. Dr. Harry L. Rockwood gave the first of these, December 10, on "Stemming the Tide with Preventive Medicine." A second will be given, January 15, by Dr. Harry V. Paryzek, on "Keeping Well."

Society News.—A symposium on nephritis was presented by Drs. Clinton D. Fife and Michael R. Haley before the Montgomery County Medical Society, Dayton, December 4.——Dr. A. Graeme Mitchell, Cincinnati, addressed the Mahoning County Medical Society, Youngstown, November 17, on "Practical Application of Principles of Nutrition."——Drs. Norris W. Gillette and August H. Schade, Toledo, addressed the Allen County Medical Society, Lima, November 17, on treatment and pathology of goiter, respectively.——Speakers before the Wood County Medical Society, Bowling Green, November 19, were Toledo physicians: Drs. Elmer C. Unckrich on "Infections of the Upper Air Passages"; Alfred P. Hancuff, "Pneumonia Empyema," and Frank B. McNierney, "Infections of the Urinary Tract."——Dr. John Alexander, Ann Arbor, Mich., addressed the Academy of Medicine of Cincinnati, December 7, on "Changing Status of the Surgical Treatment of Pulmonary Tuberculosis." Dr. Austin A. Hayden, Chicago, addressed the academy jointly with the Cincinnati Oto-Laryngological Society and the Cincinnati League for the Hard of Hearing, December 1, as a feature of "Conservation of Hearing Week."——Dr. Charles E. Hauser addressed the Cincinnati Obstetrical Society, December 10, on roentgen-ray diagnosis in gynecology.——Nathan Sinai, Dr.P.H., Ann Arbor, Mich., addressed the annual joint meeting of the Toledo Dental Society and the Toledo Academy of Medicine, December 4, on "The Way of Health Insurance."——Henry F. Vaughan, Dr.P.H., Detroit, addressed the annual meeting of the Academy of Medicine of Cleveland, December 18, on "The Doctor's Practice in the Future."

RHODE ISLAND

Society News.—Speakers at the monthly meeting of the Providence Medical Association, December 7, were Drs. Anthony Corvese, on. "Acute Perforation of Peptic Ulcer"; Howard K. Turner, "Seminal Vesicles as Foci of Infection" and William A. Horan, "Treatment of Fractures at the Hip Joint."

Dr. Chapin Retires.—Dr. Charles Value Chapin, superintendent of health of Providence since 1884, will retire from active service, January 4. Dr. Chapin was born in Providence nearly seventy-six years ago and received his academic degree from Brown University in 1876 and his medical degree from Bellevue Hospital Medical College, New York, in 1879. He has held teaching positions at Brown, Harvard University Medical School and Massachusetts Institute of Technology. He was awarded the Marcellus Hartley Gold Medal by the National Academy of Sciences in 1928 and was the first recipient of the Sedgwick Memorial Medal of the American Public Health Association. In 1927 he was president of the American Public Health Association. Dr. Chapin has served also as president of the Rhode Island Medical Society and the Providence Medical Association, and was the first president of the American Epidemiological Association. He is the author of numerous works on public health and sanitation and has been a frequent contributor to the literature of public health. The Providence Medical Association at its meeting, December 3, adopted a resolution in which tribute was paid to Dr. Chapin's long and distinguished service. The resolution declares that his greatest achievements lie in his own city, "first, in lifting Providence from a condition of well nigh medieval squalor in 1884 to the hygienic and sanitary perfection of today, and, second, in the founding of our city hospital and its later organization, in which he played so important a part." The resolution continues, "In the world his outstanding contribution to mankind is the revolutionary development of medical asepsis with its application to the control of contagious diseases."

WISCONSIN

Society News.—Members of the Green County Medical Society were addressed, November 10, at Monroe, by Drs. Erwin R. Schmidt on "Surgery of the Breasts"; Ira R. Sisk, "Surgical Injuries of the Ureter," and John W. Harris, "Cancer of the Uterus." All speakers are members of the faculty of the University of Wisconsin Medical School, Madison.——The Wisconsin Urological Society met, December 4-5, in Milwaukee. The program included a symposium on injuries of the urinary tract, with the following speakers: Drs. Robert S. Irwin, Wauwatosa; George H. Ewell, Madison; Walter G. Sexton, Marshfield, and Ira R. Sisk, Madison. Other addresses were made by Drs. Russell D. Herrold, Chicago, on "Debatable Questions in the Management of Gonorrhea in the Male"; Maurice J. Reuter, Milwaukee, "Additions to the Treatment of Syphilis in the Last Decade"; Edward L. Miloslavich, Milwaukee, "Pathology of Bladder Tumors," and Herman L. Kretschmer, Chicago, on "Treatment of Bladder Tumors."——Dr. Irving S. Cutter, Chicago, addressed the Medical Society of Milwaukee County, Milwaukee, December 10, on "The Future of the Practice of Medicine."——Dr. Henry K. Pancoast, Philadelphia, addressed the Roentgen Ray Society of Milwaukee, November 20, on pneumoconiosis.

GENERAL

Simmons an Octogenarian.—Dr. George H. Simmons, Editor and General Manager Emeritus of the American Medical Association, who is wintering at his home in Hollywood, Fla., celebrates his eightieth birthday, Saturday, January 2, 1932. The felicitations of organized medicine are tendered him on this occasion.

Bequests and Donations.—The following bequests and donations have recently been announced:

Neurological Institute of the City of New York, $5,000 by the will of the late Mrs. Minnie E. Young.

Brooklyn Hospital, $50,000 under the newly filed will of the late Warren S. M. Mead.

Burlington County Hospital, Mount Holly, N. J., $10,000 by the will of Mrs. Laura Gaskill Crowell, to found the R. Herbert Crowell Memorial Fund; $25,000 more will revert to this fund after the death of heirs who are to receive the interest from it during their lives; 60 per cent of the estate remaining after deduction of numerous bequests is also to be added to the hospital fund.

Temple University Hospital, Philadelphia, $5,000 by the will of the late Mrs. Flora Mae Albright

St. Luke's and Children's Homeopathic and Babies' hospitals, Philadelphia, $50,000 by the will of John Abbot Maguire.

Memorial Hospital, Roxborough, Philadelphia, $2,000 by the will of Mrs. Augusta B. Krook.

Control of Milk Supplies.—During the eight years' existence of the U. S. Public Health Service's milk program, 444 cities, located in 25 states, have adopted it in a coordinated attempt to improve and unify milk control methods in the country. "Before and after" surveys were recently made of the milk sanitation conditions of 152 of the 444 cities. These surveys disclosed that the raw milk supplies of the 152 cities showed a rating of compliance with the grade A raw milk requirements of the public health service milk ordinance of 64 per cent before the adoption of the ordinance, and 91 per cent after periods of enforcement ranging from several months to six years. The pasteurized milk supplies of the same group showed a rating of compliance with the grade A pasteurized milk requirements of 62 per cent before the adoption of the ordinance and 87 per cent after its adoption. The proportion some. Six months later he proved that the tsetse fly was the carrier of the trypanosome. He was the first to show that an insect may carry a protozoan parasite and thus be a source of disease. He studied nagana in a large number of domestic animals and in its latent form in wild animals, leaving little to be added by subsequent observers. In 1903 he was sent by the Royal Society to Uganda to make further investigations into trypanosomiasis, which at the time was being investigated by Castellani. This observer had found a trypanosome in a small number of cases. Bruce at once grasped the situation and stimulated a rapid extension of the observations until evidence was obtained that the organism was the cause of the disease. Later he showed that the tsetse fly, Glossina palpalis, is the carrier of the trypanosome and that the distribution of the former corresponded to that of the disease. During the war he was chairman of the committee on tetanus, which showed the importance of prophylactic injection of antitoxin. He was later chairman of the trench fever committee, when Colonel Byam made the important discovery that the disease is transmitted through the skin by the excreta of the louse. An Australian by birth, Sir David was educated at Edinburgh University and joined the army medical service in 1883. He was assistant professor of pathology at the Army Medical School from 1889 to 1894. He edited the *Journal of the Royal Army Medical Corps* from 1904 to 1908. Many honors were conferred on him, including honorary degrees from the Universities of Glasgow, Dublin, Liverpool and Toronto, and, greatest of all, the fellowship of the Royal Society, which also awarded him a Royal and a Buchanan medal.

Rabies Conveyed by Bats

A mysterious disease which resulted in the deaths of human beings and animals has been reported from southern Trinidad. In his official report to the legislative council, the medical inspector of health, Dr. C. F. Lassale, states that twenty persons died between 1929 and 1931 from an unusual type of ascending transverse myelitis. Dr. Hurst, bacteriologist of the Lister Institute, considers that the disease is due to the virus of rabies of a hitherto unknown type. All the recognized cases were fatal. The report also states that man probably acquired the disease from some biting animal which itself suffers from rabies, but that the animal is not the dog, since the last case of canine rabies occurred in 1914. It was suggested that bats might be concerned in producing the disease in man and in animals. Since this report was issued, Dr. Pawan, the government bacteriologist, has declared that he has found typical rabies lesions in the brain of a Sangre Grande daylight bat.

The Attempt to Alter the Constitution of the Royal College of Surgeons

At the annual meeting of fellows and members of the Royal College of Surgeons the resolution asking for representation of members on the council was brought forward for the forty-third time. The nature of this agitation has been described in a previous letter (The Journal, February 14, p. 541). This year the resolution was moved by Sir Ernest Graham Little, dermatologist and member of parliament for London University. He pointed out that the college contained 2,000 fellows and 18,000 members; that the governing body, the council, was elected entirely by the fellows, and that no fellow in general practice had been elected. The motion was carried by 32 votes to 3. The president, Lord Moynihan, admitted that the resolution had been supported by very fair speaking, but as the council was doing its duty sincerely in the interests of the whole college he could not offer any hope of the representation desired. By permission of the president a member, Dr. T. Wilson Parry, made a long statement which had received the support of the Society of Members. He thought that some members of the council not unnaturally felt that the proposed representation might involve some disaster to the college. To reassure them he suggested that the members should be permitted to elect one fellow who was a general practitioner and one member also in general practice to represent them on the council, thus safeguarding the traditions of the college at the initial step. Dr. Parry referred to Robert Waring Darwin, the father of Charles Darwin and the great-grandfather of more fellows of the Royal Society than exist in any other family; Jenner, the discoverer of vaccination, and James Mackenzie, the founder of modern cardiology, who were all general practitioners. But these interesting facts are as irrelevant as the usual ground of "justice," on which the members' demand is usually based. The college is a scientific and educational body governed by the eminent men of British surgery elected by all its constituents who are surgeons in the full sense of the term. Its government is beyond criticism. The agitation is not inspired by any desire or capacity to improve the functions now so well discharged but rather to drag the college into medical politics.

New Heart Department at the London Hospital

The Heart Department at the London Hospital was originally created for Sir James Mackenzie. It has now been given a new building at a cost of $31,000. There is a tablet recording the fact that it is a memorial to the work of Sir James Mackenzie. At the opening ceremony, Dr. John Parkinson, physician in charge of the department, said that Mackenzie was universally recognized as the founder of modern cardiology. As long ago as 1913 the department had its beds, clinic and laboratory. The London Hospital was the first of the general hospitals in the world to arrange such a special department for the advancement of this great branch of medicine. Other hospitals had followed, and advance in knowledge and practice had been accelerated.

Recurrent Fever Substituted for Malaria in Treatment of Dementia Paralytica

Mr. Auguste Marie, who was one of the first in France to treat dementia paralytica by inoculation with malaria, is endeavoring to substitute for the plasmodium of malaria the spirillum of recurrent fever, which provokes the same manifestations of hyperthermia, and he has recently communicated to the Academy of Medicine the results of his observations. He presents this method rather as supplementary to the malaria method. The results obtained were less sure; but recurrent fever therapy appears to him indicated in some instances when malariotherapy is not applicable; for example, in persons who had malaria in childhood, or in dementia paralytica in which malaria has been employed but which shows a recrudescence. In such cases, attempts to reinoculate malaria often fail. To get around immunity that might be a contraindication to reinoculations of recurrent fever, it is sufficient to alternate the different varieties (induced by various organisms: Spirochaeta duttoni, Spirochaeta berbera, and others), including the Spanish type. Recurrent fever has the advantage over malaria that the incubation is shorter, being only from three to five days in place of about twelve days. Recurrentotherapy should be supplemented by treatment combining arsenic, bismuth or mercury compounds. Of a total of 51 patients treated with recurrent fever, 18 were dismissed with a remission more or less complete and permanent; 16 were physically restored but had to be retained in the hospital. Seventeen patients died, ten of them during the first months that followed the inoculation, and the others after a partial remission. The average age of the patients who were dismissed following more or less complete remissions was 35;

Heart Sounds," and demonstrated sound images of various typical heart sound manifestations and explained their diagnostic importance for bedside practice. Harmonious course of vibrations in a heart tone is characteristic of indurative processes in the vicinity of the site of auscultation, since only tissues with a certain hardness are capable of vibration and can produce a periodic frequency course. For mitral stenosis the wavelike character of the first heart tone is typical. The diastolic murmur in mitral stenosis is registered throughout the whole diastole, although it is usually perceptible in auscultation only during the presystole. All endocardiac murmurs have their chief components in the narrow range between 200 and 400 Hertz units. The Weber theory of the origin of murmurs receives new support from this fact. By reason of the similarity of the sound curves of endocardiac murmurs, one cannot draw from the sound picture any important differential diagnostic conclusions as to their origin. Paracardiac murmurs may, however, be distinctly differentiated from endocardiac murmurs by the greater frequency of interruption of the current as revealed by the course of the curve. The reproduction through loud speakers of heart sounds encounters difficulties, since through marked amplification of sounds subliminal components rise above the auditory threshold and change the nature of the sound. A reproducing apparatus that will overcome this disadvantage will be of inestimable value for clinical instruction.

Finally, the physicist Dr. Sell, who has devoted himself to acoustic problems, explained that a diaphragm which is highly sensitive to body sounds but less sensitive to air sounds, and which possesses a high degree of flexibility, is best adapted to this purpose. If attention is paid to this, no great amplification is necessary. A special loud speaker sensitive to low ranges was constructed. Normal heart tones and heart murmurs become audible, with the new apparatus, for a good-sized audience.

Medical Service on Sunday

For a number of years, the city of Berlin has had not only a special Sunday service as regards the pharmacies but also a special service for urgent medical cases on Sunday. For this purpose, the city is divided into fifty districts, each of which submits, with the opening of each three-month period, a list of physicians who have agreed to perform Sunday duty during the quarter in question. At first, this list lay open for inspection only at the pharmacies, but, later, copies were posted also at the police stations. Now, however, the matter has been further simplified for the public. At the suggestion of the medical league of Greater Berlin, the government telephone service has consented, in response to telephone calls on Sunday, to give the applicant the name of the nearest physician.

Gymnastic Exercise for Women

Gymnastic exercise for women was recently discussed by Professor Sellheim, director of the Leipzig Universitäts-Frauenklinik. In dealing with men, aside from considerations of age, we have to do with only one kind of physical makeup and one mode of functioning of the organism all through life, and can arrange for the strengthening of the physique and for the preservation of robustness by gymnastic exercises by applying what is essentially the same prescription. In dealing with women, one must, in prescribing physical exercises, differentiate precisely between the various types of women with reference to build and the mode of functioning of the organism at the time in question, and only by taking careful account of these differences can one hope to reap the advantages of gymnastic exercise. From the standpoint of gymnastics, eight classes of women must be recognized: (1) the girl approaching puberty and during the years immediately following; (2) the woman during the period of menstruation; (3) the woman during pregnancy; (4) the woman during the puerperium; (5) the woman after cessation of the special functions of the matron and of old age; (6) the woman who is deprived of the privilege of propagation; (7) the woman whose constitution has been undermined by giving birth to too many children, possibly in association with occupational work (these two classes being especially characteristic of the times in which we live), and, finally, (8) the woman with abdominal disease. Specially prescribed gymnastics are more important for women than for men. The more the value of gymnastics comes to be recognized by physicians and the general public, the greater becomes the responsibility of the physician for the sins of omission and commission in this field. There is danger that here the physician may be charged with neglect, and that in case damage results an attempt may be made to hold him responsible.

AUSTRALIA

(From Our Regular Correspondent)

Nov. 4, 1931.

Hospital Finance in New South Wales

The problem of hospital finance in Australia is becoming more acute daily, and in New South Wales the situation is growing serious. The leading hospitals in Sydney, especially the Royal Prince Alfred Hospital, have been on the verge of bankruptcy for the past twelve months. In the Royal Prince Alfred Hospital it has been necessary to close 200 beds and to place many of the paid medical staff on an honorary basis. At best, the hospitals are living a hand to mouth existence in the face of greatly increased demands on their services. Nearly all the New South Wales institutions depend on large annual government subsidies, which in the past have been granted on the basis of £1 for each £1 contributed by the public. Voluntary contributions have fallen away considerably, and the government, moreover, has found it impossible to continue the subsidy, even on a reduced basis. Since the appointment of the Hospitals Commission in New South Wales, the distribution of subsidies has been under its control.

It has always been strange that hospital service should be financed in connection with gambling, but this relationship is apparently the sole remaining exploitable avenue for hospital finance in Australia, and it is being used more and more, as the economic situation becomes more difficult. For many years now in New South Wales, a percentage of the gross proceeds of the totalizers, which are found on all large race courses, has been reserved for hospitals. When funds from this source showed a falling off, the deficiency was made up by heavy taxation on all wagers made with bookmakers. In view of the fact that considerable support was given from New South Wales to a private Tasmanian lottery and to a government lottery in Queensland, the state premier this year passed an act for establishing a New South Wales state lottery in aid of hospitals. This was strenuously opposed by the council of churches, an organization composed of representatives from most of the protestant churches in New South Wales. This council recommended an appeal to church and state. The premier withheld the operation of the state lottery pending the result of this appeal. The appeal was a hopeless failure, and the state lottery has now commenced operations. Today in Sydney will be seen a queue of people a quarter of a mile long, lined up to buy their tickets at 5s. 3d. each, in the hope that they will win the first prize of £5,000. What the actual proceeds from this lottery will be can only be a matter of conjecture. Experience in Queensland, where the "Golden Casket" lottery has been run for some years, is not encouraging. As the result of the holding of twenty-six art unions, the total sum raised for hospital work has amounted to only £190,059. Of every £1 received by the "Casket," 13s. 4d. is absorbed by prizes, taxes, postage and heavy general expenses. It has been the experience in Queens-trachoma. The majority of the trachomatous patients were foreign workmen who had recently settled in the province. The authors have observed among these workmen instances of contagious transmission of the disease. Belgian workmen have likewise been contaminated by trachomatous foreigners. The trachoma cases consisted of two distinct types, depending on which country the laborers had come from. There was the Mediterranean type, which follows a grave course and leaves significant sequels, although it is only slightly contagious, and trachoma of the Orient, of an acute type, with less grave manifestations but contagious. If this recrudescence of trachoma is general throughout Belgium, it would seem to necessitate the adoption of stricter prophylactic measures at the borders. Mr. H. Coppez, who examined the foreign workmen in a coal mine at Limburg, found 25 per cent of them trachomatous. He did not find any instances of contagion among the Belgian workmen. The school children in these localities should be examined; for trachoma is transmitted chiefly during youth.

Proposed Reforms in Ophthalmologic Studies

Mr. Weekers has published a report on the result of the referendum among the members of the Société belge d'ophtalmologie concerning the proposed reforms in ophthalmologic studies. Of the seventy-one replies received, two indicated no preference, seven were opposed and sixty-two were in favor. The Société belge d'ophtalmologie passed a resolution that proper action should be taken to protect patients against grave harm resulting from the practice of ophthalmology by specialists who are insufficiently prepared. In connection with the referendum, Mr. Weekers proposed the following resolutions: (1) that a course of instruction for specialists be officially organized in the universities, and (2) that the various universities come to some understanding in regard to the organization of such a course of instruction. All physicians who desire to do so and who possess the necessary qualifications should have an opportunity to specialize. The physician should be free to choose between the schools that offer such courses as he needs. Eminent specialists who are not members of any university faculty should be afforded an opportunity to collaborate in the training of candidates for specialties, should they have a taste for instruction. In accordance with rules to be agreed on with respect to titles, a specialist should, without an examination, receive a certificate to be issued by a commission composed chiefly of university specialists, and based, as the only precondition, on a short course taken at a university clinic.

In further exemplification of his ideas, the author drew up the following statement: The specialist's certificate should be provided for by law. It will give satisfaction to all. It does not affect in any manner the diploma of the doctor of medicine. There is no constraint about it. It would bring about the elimination of incompetent specialists and would prevent patients from suffering grave injuries at the hands of physicians who are inadequately prepared for the practice of a specialty.

Marriages

Dudley H. Morris to Miss Margaret Donaldson, both of New York, in Greenwich, Conn., October 17.

Vincent W. Koch, Janesville, Wis., to Miss Ardelia R. Olden of Norwood, Pa., October 30.

Eduard Falk Poser, Chicago, to Miss Marcia Louise Bruch of Evanston, Ill., November 7.

Henry Lowey, New York, to Miss Rebecca May of Wilmington, N. C., November 8.

Joseph D. Hayden, Akron, Ohio, to Miss Constance Delaney of Cleveland, September 23.

Dwight L. Jennings to Miss Isabelle Boedeker, both of St. Louis, November 16.

Deaths

Edward Tyler Edgerly ⊕ Ottumwa, Iowa; Chicago Medical College, 1889; formerly instructor of physical diagnosis, Northwestern University Medical School, Chicago; member of the American College of Physicians; served during the World War; medical director of the Sunnyslope Sanatorium; on the staffs of St. Joseph and Ottumwa hospitals; aged 67; died, November 13, in Rochester, Minn., of cholelithiasis.

Edward Milton Pemberton, Little Rock, Ark.; Maryland Medical College, Baltimore, 1902; College of Physicians and Surgeons, Baltimore, 1903; member of the Arkansas Medical Society; formerly professor of physiology and pharmacology, University of Arkansas School of Medicine; aged 50; died suddenly, November 20.

G. Wilfrid Derome, Montreal, Que., Canada; School of Medicine and Surgery of Montreal, 1902; professor of legal medicine, University of Montreal Faculty of Medicine; for many years head of the provincial laboratories of Quebec; aged 54; died, November 24, in L'Hospital Notre-Dame.

Hall Whiteaker ⊕ Anna, Ill.; Barnes Medical College, St. Louis, 1893; served during the World War; formerly member of the state legislature; aged 62; since 1925 on the staff of the Anna State Hospital, where he died, November 24, of acute myocarditis and carcinoma of the prostate.

R. T. Jennings, Columbia, S. C.; University of the South Medical Department, Sewanee, Tenn., 1898; member of the South Carolina Medical Association; formerly city health officer; aged 55; died, November 20, in a local hospital, of injuries received in an automobile accident.

George Graham Hart ⊕ P.A.S., Lieut., U. S. Navy, retired, Beaver Falls, Pa.; Columbia University College of Physicians and Surgeons, New York, 1902; entered the Navy in 1921 and retired in 1928 for incapacity resulting from an incident of service; aged 53; died, September 20.

Ermy Corser Noble, Mayview, Pa.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1907; member of the American Psychiatric Association and the New England Society of Psychiatry; aged 58; died, October 24, in the Randolph (Vt.) Sanatorium.

Edwin Henry Newbold, Oroville, Calif.; State University of Iowa College of Homeopathic Medicine, Iowa City, 1893; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1900; aged 60; died, September 13.

Levi N. Hicks, Burlington, Wis.; Rush Medical College, Chicago, 1878; Medical Department of the University of the City of New York, 1881; member of the State Medical Society of Wisconsin; aged 80; died, November 29, of cerebral hemorrhage.

Austin N. Lakin, State Line, Ind.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1905; Illinois Medical College, Chicago, 1906; aged 64; died, November 22, in the Lakeview Hospital, Danville, Ill., of gunshot wounds.

George S. Watkins, Oxford, N. C.; University College of Medicine, Richmond, Va., 1900; member of the Medical Society of the State of North Carolina; past president of the Granville County Medical Society; aged 53; died, November 18.

George Steely, Danville, Ill.; College of Physicians and Surgeons, Boston, 1905; member of the Illinois State Medical Society and the American College of Surgeons; served during the World War; aged 52; died, November 14, in St. Elizabeth's Hospital, of hypostatic pneumonia and shock following an operation for appendicitis and gallstones.

Edward John Fucik ⊕ Williams Bay, Wis.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903; president of the Walworth County Medical Society; aged 50; died, December 1.

Odeen Luke, Tremonton, Utah; University of Pennsylvania School of Medicine, Philadelphia, 1921; member of the Utah State Medical Society; aged 42; died, October 9, of a skull fracture received in an automobile accident.

John Alphonso Burnett, Hamilton, Ohio; Eclectic Medical Institute, Cincinnati, 1902; member of the Ohio State Medical Association; formerly county coroner and member of the board of education; aged 52; died, November 28.

Jesse Obed Parker ⊕ Owosso, Mich.; University of Michigan Medical School, Ann Arbor, 1899; member of the Radiological Society of North America; aged 55; died, November 30, of a self inflicted bullet wound.

tion of tuberculous allergy. All the interesting reports that have appeared on these questions are scattered in innumerable publications.

I must then believe that my book is not superfluous for American physicians, since many learned foreign and American authorities on tuberculosis, particularly Dr. W. Charles White, chairman of the Committee on Medical Research of the National Tuberculosis Association, have written to me to send a copy of my book. That will be my greatest reward.

Jean Albert-Weil, M.D., Béziers, Hérault, France.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DOSAGE OF HISTAMINE SALTS FOR TESTS OF GASTRIC ACIDITY

To the Editor:—In the *Archives of Internal Medicine* for August, in an article by Moschowitz, the gastric analysis was commented on as including "the neutral red reaction and histamine." Then in the *Archives of Internal Medicine* for September, an article by Bloomfield and Polland states that dimethyl-amino-azobenzene was used as the indicator in their work. In the pamphlet that was written by Victor C. Myers, revised in June, 1930, and sent out by the American Medical Association, the statement is made, "Although the information obtainable with the Topfer method is fairly accurate, it does not give a modern point of view." Is a difference of indicators important, and if so I should like to know the indicator that is most generally used or accepted, and the method that is considered to give the most modern point of view. I should like to know the status of the alcohol test meal at present. Is it preferable to the other test meals as a routine procedure, to be followed by an injection of histamine if at the end of thirty minutes after the alcohol meal there is no free hydrochloric acid? Is the dose of histamine standard for each person or is it still given by weight? Some assert that 0.25 mg. will provoke as much stimulation as 1 mg. Please give the accepted dosage of histamine for this use, and also the most satisfactory preparations. Please omit name.

M.D., Florida.

Answer.—The type of indicator used in gastric analysis is extremely important because the various indicators have very different ranges of acidity in which they can be used. True neutrality in water is expressed by the p_H value 7; any p_H higher than that is more alkaline than water and any p_H lower than 7 is more acid than water. Di-methyl aminobenzene solution (Töpfer's reagent) is red at p_H values of 2.9 or lower and yellow at p_H 4.0 or higher. Obviously this indicator is of value for detecting mainly relatively high acidities in the p_H range of 2.9 to 4.0. Neutral red, however, is of value only in the truly neutral range, that is, at p_H 6.8 to 8.0. In other words, very faint acidity will change the color of the neutral red solution to yellow, and will also increase the acidity. It does not distinguish between the two kinds of acidities. Di-methyl aminobenzene solution is generally applied and is useful when the acidity is measured by titration. The "modern point of view" is to determine the actual hydrogen ion concentration or p_H of the juice rather than the amount of titratable (total and free) acid. For most purposes, however, the titration method is still the more useful. There does not appear to be a distinct advantage in alcohol over the other test meals when it is used as a routine, but it appears to be fairly well established that histamine hydrochloride or phosphate injected subcutaneously frequently stimulates the secretion of hydrochloric acid when the test meal methods resulted in a diagnosis of achlorhydria. However, in true achlorhydria, the histamine does not cause the secretion of hydrochloric acid. It is of no value in cases of hyperacidity. In any case the tests should be repeated a number of times before a diagnosis is made. The greater the dose of histamine, the higher the secretion of juice and acid in normal individuals. A reasonable dosage to employ as a routine is 0.1 mg. of histamine hydrochloride to 10 Kg. of body weight. If histamine phosphate, also called ergamine acid phosphate, is used, the dosage should be increased to 0.17 mg. for each 10 Kg. of body weight. Such dosage in normal subjects produces a maximum secretion in from thirty to sixty minutes, and the secretion may extend over an hour and a half. Histamine salts may be procured from general chemical houses such as Central Scientific Company, 460 E. Ohio St., Chicago; Eimer and Amend, Third Avenue and Eighteenth Street, New York, the Eastman Kodak Company, Rochester, N. Y., or the Special Chemicals Company, Waukegan, Ill.

FLOCCULATION AND WASSERMANN TESTS—GRAM-NEGATIVE INTRACELLULAR DIPLOCOCCI

To the Editor:—What is your opinion as to the reliability of the flocculation test for syphilis as compared to the blood Wassermann test? Are there any diplococci (gram-negative and intracellular) other than gonococci; and if so, please name them. Please omit name and city.

M.D., Mississippi.

Answer.—Although there are reports in the literature of wide variations between results of Wassermann and flocculation tests, careful workers find agreement between the two classes of tests in approximately 90 to 96 per cent of cases.

Both the complement fixation and the flocculation tests are regarded as being of a physicochemical nature and not biologically specific. It is thought that both reactions are effected by the same conditions that control most colloid reactions. At present, serologists are unable to "render the factors exactly the same" in the conduct of complement fixation and flocculation tests, and for this reason serums and spinal fluids containing small amounts of syphilitic antibody may yield differing results.

The flocculation reaction is "greatly influenced by the quantitative relationship existing between the reacting substances present in the serologic system at the time the test is performed. Such relationship varies with each serum tested." Because of this, a given system may not result in a "complete and proper antigen precipitation in every case" (Levine, B. S.: *J. Lab. & Clin. Med.* **15**:985 [July] 1930).

"It would appear that the flocculation tests are more likely to yield falsely positive reactions in the hands of ordinary laboratory technicians than are the complement fixation tests, although in the hands of experts the incidence of falsely positive reactions has been remarkably low with both procedures . . . All flocculation and complement fixation tests are capable of yielding false reactions because of technical errors but the incidence of these is remarkably low in the hands of expert serologists and probably not as frequent as are the clinical errors in the diagnosis of syphilis . . . Under proper technical conditions they possess an extremely high practical specificity for syphilis in this country" (Kolmer, J. A.: *Am. J. Syph.* **15**:383 [July] 1931).

Because some serums will react at one time to a flocculation test and not to a Wassermann test, and vice versa, the two classes of tests supplement each other, and when carefully performed should show a high degree of relative agreement. It is thought that a weakly positive flocculation test is more difficult to read and to interpret than a weakly positive Wassermann reaction. A serum showing a strong positive flocculation test and a negative Wassermann reaction in a patient for diagnosis indicates the advisability of repeated tests and study of the patient.

The foregoing remarks refer more particularly to the routine test of Kahn, which is the most widely used flocculation test in this country; also to the routine Kline microscopic test and to the Hinton test. The remarks do not apply to the Kahn "presumptive test" or to the Kline "exclusion test." These two tests are too sensitive for routine use and may give false positive reactions. "There is a limit to which the delicacy of serologic procedures may be advanced without introducing the possibility of false positive reactions" (Kilduffe, R. A.: *Am. J. Clin. Path.* **1**:69 [Jan.] 1931).

The common gram-negative intracellular diplococci are the gonococcus and the meningococcus (Neisseria intracellularis or meningitidis).

According to Ford, Micrococcus catarrhalis is "occasionally intracellular in exudates" (Ford, W. W.: Textbook of Bacteriology, Philadelphia, W. B. Saunders Company, 1927, p. 380).

Ford also cites Diplococcus intracellularis-equi Johne "found by Johne in Borna's disease of horses (acute encephalitis)."

INFESTATION WITH STRONGYLOIDES INTESTINALIS

To the Editor:—I have a boy, aged 12 years, with a heavy infestation of Strongyloides stercoralis or intestinalis. I cannot find any definite reference to treatment. What would be a proper course to pursue? Please omit name.

M.D., West Virginia.

Answer.—In suggesting treatment, it is assumed that the infesting parasite is the one mentioned; i. e., Strongyloides intestinalis (stercoralis).

The following treatment should prove helpful: The patient should be given a soft, liquid, fat-free diet for three days, and each night 4 cc. (1 fluidrachm) of fluid extract of cascara sagrada in hot water. On the morning of the fourth day, the patient should remain in bed and have no breakfast. At 9 and 11 a. m. 1 Gm. (15 grains) of powdered thymol U. S. P. in 0.3 Gm. (5 grain) enteric capsules should be administered. Each hour, for five hours, the patient should take a cup of hot, weak, black, sweet coffee. At the end of that period, 0.8 Gm. (2 drachms)

Book Notices

Selected Writings of John Hughlings Jackson. Volume I: On Epilepsy and Epileptiform Convulsions. Edited for the Guarantors of "Brain," by James Taylor, M.D., F.R.C.P., with the advice and assistance of Gordon Holmes, M.D., F.R.C.P., and F. M. R. Walshe, M.D., F.R.C.P. Cloth. Price, 25/-. Pp. 500. London: Hodder & Stoughton, Ltd., 1931.

Probably the number of neurologists who think and of those who care to know of the evolution of neurologic knowledge will be fairly indicated by the extent of the sale of this volume and of the one to follow; for no thinking neurologist can afford to be without this work and no one interested in the history of his chosen specialty will want to miss it. The papers composing the present volume concern epilepsy and epileptiform convulsions. The book contains such a mass of information that detailed review is out of the question, but no physician can read it without learning a multitude of things, besides enjoying a scientific banquet of neurologic knowledge. Any one of several chapters (on study of convulsions, on the scientific and empiric investigation of epilepsy, on convulsive seizures, on temporary paralysis after seizures) will richly repay the purchaser. In truth, one cannot be fully informed on epilepsy without study of Dr. Jackson's principal papers. For instance, the three (Harveian) lectures on the diagnosis of epilepsy are more, much more, than directions on how to detect epilepsies and to distinguish them from other conditions. They embrace a fascinating and illuminating discussion of the nature of the symptoms, a graphic description of different types, a philosophical consideration of the physiology and pathology of fits, and illustrative examples, with sage remarks based on the wide experience of an acute observer. Dr. Jackson, we fear, is known to most physicians only for the one type of epilepsy named for him, but the wide range of his meticulous observations, the clarity of his reasoning and the broad scope of his conclusions may well serve as a model and an inspiration alike to practitioner and to savant. With infinite patience and tact he constantly strove at the impossible task of teaching others to observe and to think as he did. His exposition of the logical approach and further procedure in the study of any case is not to be improved on; it is valuable equally to clinician and to research worker.

Medicolegal

Power of Workmen's Compensation Commissioner to Punish for Contempt

(In re Hayes (N. C.), 156 S. E. 791)

On March 3, 1930, Dr. R. B. Hayes was present as a witness before the chairman of the North Carolina industrial commission. He had professionally attended the claimant, who was seeking compensation. Dr. Hayes had been sworn and had testified on both direct and cross examination. The chairman of the commission then asked Dr. Hayes whether he had an opinion as to whether or not a blow received by the claimant on October 19 would have produced a paralytic stroke on January 12. Dr. Hayes admitted that he had an opinion, but he refused to express it unless he received compensation as an expert. Section 3893 of the Consolidated Statutes provides that experts, when compelled to attend and testify as witnesses, shall be allowed such compensation and mileage as the court in its discretion may allow. The chairman of the commission, however, maintained that it was not up to him to qualify Dr. Hayes as an expert and committed him to jail for contempt of what the chairman described as "the Court." Dr. Hayes sought to obtain his release through a writ of habeas corpus, but failed. Thereupon he obtained a writ of certiorari for a review of the case by the Supreme Court of North Carolina.

Power is expressly conferred by the statute creating the North Carolina industrial commission, said the Supreme Court, for that commission or any member of it to subpena witnesses to attend and testify at a hearing before the full commission or before any member, and the statute provides that "the superior court shall, on application of the commission or any member or deputy thereof, enforce by proper proceedings the attendance and testimony of witnesses and the production and examination of books, papers and records." This provision that the legislature had made for enforcement by the superior court of the attendance and testimony of witnesses and the production and examination of books, papers and records, however, the Supreme Court thought was not adequate for a situation such as that presented in the present case. If a witness in attendance at a hearing, after having been duly sworn, can with impunity refuse to answer a question propounded to him which is pertinent to the matters in dispute between the parties, then, the Supreme Court thought, the industrial commission would be without adequate power to perform its duties. Since the legislature in providing the commission with the aid of the superior court in enforcing the attendance and testimony of witnesses did not in express terms—nor, in the opinion of the Supreme Court, by implication—deny to the commission or any member thereof the power to compel a witness in attendance at a hearing, after having been duly sworn, to testify, the court, without deciding whether the North Carolina industrial commission was or was not a court, and without citing any statutory authority or judicial precedent in support of its opinion, concluded that the commission or any of its members has the power to adjudge a witness in contempt who has deliberately and persistently refused to answer a question propounded to him and to punish such witness by fine or imprisonment. The judgment of the industrial commissioner was therefore affirmed.

The question raised by Dr. Hayes at the hearing before the chairman of the industrial commission, said the Supreme Court, when he refused to answer the question addressed to him because it was addressed to him as an expert and he had not been paid as an expert nor assured that he would be so paid, was not presented to the Supreme Court for decision and had not been decided by that court. It has been held in a few courts that a witness who has been summoned as an expert in a judicial investigation cannot be adjudged in contempt for refusing to give such testimony unless he has been compensated for his professional opinion. The better opinion, however, said the Supreme Court of North Carolina, is that an expert summoned to testify, who refuses to answer questions "without compensation other than his witness fees," is in contempt, and when an expert voluntarily submits himself to an examination as such, he can in no case refuse to answer one particular question after having without objection answered others.

Evidence: Admissibility of Physician's Office Records.—The appellee, Dennis Bisimanis, based his suit on double hernias, which he claimed were caused by his having been negligently struck by the defendants, with an automobile, Oct. 30, 1929. The case was tried, Jan. 30, 1930, and judgment given in favor of Bisimanis. Thereafter the defendants learned that some time before the date of the alleged accident a physician had found that Bisimanis was then suffering from double hernias. They then moved for a new trial, on the ground of newly discovered evidence. In connection with that motion, it was stipulated between counsel for Bisimanis and counsel for the defendants that a certain physician, if he were present and testifying on the motion, would testify that the records in his office showed that he examined one Dennis Bisimanis in his office, March 25, 1929, and found that he was suffering from double hernia, and that he advised an operation, but that the physician had no recollection of the matter independent of his office records. A rehearing was denied, and the defendants appealed to the Supreme Court of Alabama. On behalf of Bisimanis it was argued that neither the hospital [sic] records nor their contents were evidence of the facts. But, said the Supreme Court, these records, under the well settled rules of the court, were admissible on proof that the witness knew the facts when the records were made, knows that the records show the true facts, and now has no independent recollection. The cause was remanded for a new trial.—*Ohme v. Bisimanis (Ala.), 132 So. 161.*

Lymphatic Leukemia Attributed to Trauma.—The cause of lymphatic leukemia is not known to medical science. It cannot be inferred, however, from the facts that the plaintiff was well and able to work up to the time of an injury and after the injury was found to be suffering from lymphatic leukemia, that the injury caused the disease. If the disease was caused or aggravated by the injury, the plaintiff must establish that fact by a fair preponderance of evidence.—*Boyer v. Department of Labor and Industries (Wash.), 295 P. 737.*

Workmen's Compensation Acts: Compensability of Carbon Monoxide Poisoning.—The death of a workman in a mine from the inhalation of carbon monoxide in the course of his employment was, in the opinion of the court of appeals of Ohio, Carroll County, due to an "accidental injury" within the meaning of the Ohio compensation act, and not to an occupational disease.—*Industrial Commission of Ohio v. Tolson (Ohio), 174 N. E. 622.*

Privileged Communications: Waiver by Offering Testimony of Physician.—Where a party to an action puts his physician on the stand to prove that the party was incompetent to make a certain contract, he thereby waives his statutory privilege of maintaining the secrecy of communications between him and his physician. The adverse party may thereafter cross-examine the physician.—*Travelers' Building and Loan Ass'n. v. Hawkins (Ark.), 34 S. W. (2d) 474.*

Compensation of Physicians: Liability of Member of Family Who Summons Physician.—It is a general proposition supported by many authorities that he who orders a physician to come to his home to treat a member of his family becomes responsible for payment for the physician's services unless he makes it known to the physician that he disavows responsibility.—*Benton v. Stadler (Wis.), 234 N. W. 739.*

Society Proceedings

COMING MEETINGS

Annual Congress on Medical Education, Medical Licensure and Hospitals, Chicago, February 15-16. Dr. William D. Cutter, Secretary, Council on Medical Education and Hospitals, 535 North Dearborn St., Chicago.

Mid-South Post-Graduate Medical Association, Memphis, Tenn., February 9-12. Dr. A. F. Cooper, Bank of Commerce Building, Memphis, Secretary.

Society of American Bacteriologists, Baltimore, December 28-31. Dr. James M. Sherman, Cornell University, Ithaca, N. Y., Secretary.

teristics: persistence, fixity in the constitution of the person, disadvantageousness, incorrigibility, short-sightedness, basally defective affect, and a tendency to slip into psychosis or psychoneurosis. Psychopaths are abnormal and usually require institutional control. If no psychotic or psychoneurotic process is present, they should be disciplined for law breaking. If wise discipline has proved ineffectual after two or three applications, the offending psychopath should be permanently restrained in a proper state institution.

Torsion of Normal Ovary and Tube with Rupture of Ovary.—Northcutt and Baron report a case of torsion of the normal ovary and tube with rupture of the ovary. They believe that this is the fourteenth case on record in which the ovary was involved and that it is the first case on record in which rupture followed the torsion. In the differential diagnosis of abdominal pain in young girls, torsion of the ovary must be considered, particularly when associated with pain on straining at stool. Anatomic anomalies must be considered a strong factor in the predisposing causes to torsion of the normal ovary and fallopian tube.

Roentgen Diagnosis in Intravenous Pyelography.—According to Peters, intravenous pyelography offers a simple, painless method of examining the kidney pelvis, ureters and bladder, roentgenographically producing urograms of diagnostic quality. While this method is reasonably innocuous, its indiscriminate use is not to be encouraged. With more experience in its use and skill in the interpretation of the observations, the diagnostic criteria will be as definite as those of cystoscop pyelography. Intravenous pyelography does not replace t older method. Its use in demonstrating function in surgic conditions of the kidney is of great value, both alone and wi ureteral catheterization. The uses of this method alone and combination with retrograde catheterization will increase wi more experience. Iopax serves a dual purpose. The time appearance of the opaque medium on the film, together wi physical and chemical tests of the urine, gives a fair estima of kidney function. This method broadens the field of pyelo raphy to the following, heretofore denied this important dia nostic aid: (*a*) infants and children, (*b*) debilitated adults, (urethral stricture cases, (*d*) cases with deformities, and (malignant cases and others unsuited for retrograde catheteriz tion. It is the method of choice in the absence of a compete urologist.

Tuberculous Meningitis.—Hearn emphasizes the fact th severe headache in a person with tuberculosis which is n relieved by ordinary methods, and especially if accompani by high temperature and elevation of the pulse, should regarded as suggestive of tuberculous meningitis. No improv ment can be hoped for, and death usually occurs within fo to six weeks from tuberculous meningitis, but spinal punctu done every forty-eight hours will help make the patient mo comfortable.

Free Choice of Physicians. A. H. Peacock, Seattle.—p. 467.

Chronic Pyuria in Children.—Campbell points out tha when chronic pyuria exists in a child, the diagnosis of chroni pyelitis is usually made and the child is inadequately treate for months or years. Because the renal lesion is primarily suppurative interstitial nephritis and the pelvic changes are o lesser importance, he believes the pathologically correct desig nation pyelonephritis should supplant the clinically convenien though inadequate term pyelitis. These patients should be give the benefit of an intensive course of medical therapy, but i after one month, they remain pyuric, a complete urologic exami nation should be carried out. From a large clinical experienc in this field it is found that infants and children may suffe with almost every one of the various types of diseases of th urinary tract which in the past one has been accustomed t consider as adult lesions. The treatment of these diseases i juveniles differs in no wise from that in adults. It cannot to urgently be stressed that these young patients are entitled t the same advantages of modern urologic methods that adul demand, especially since in juveniles the morbidity risk entail by examination is less than half that in adults. Only by thi method can the correct diagnosis be made and only by radica surgical treatment will many of these children be permitted t enjoy adult life.

*Pellagra-Preventive Value of Canned Spinach, Canned Turnip Greens, Mature Onions, and Canned Green Beans. G. A. Wheeler.—p. 2663.
Technic for Adjustment of *p*H of Tissue Cultures Planted in Carrel Flasks. W. R. Earle.—p. 2668.

Pellagra-Preventive. — Wheeler tested canned spinach canned turnip greens, mature onions and canned green beans for their relative pellagra-preventive potency. He found that canned spinach supplies the pellagra-preventive vitamin but cannot be regarded as especially rich in it. It is, however, considered an important contributory source of this factor. Canned turnip greens supply the pellagra-preventive vitamin and, at least in liberal quantity, adequately supplement an otherwise pellagra-producing diet. This substance meets many of the requirements of a practical and effective dietary supplement in of antigens, which are tested for sterility and innocuousness; that is, for nontoxicity with the lowest irritating power. The diphtheria toxins, freed from toxicity by the addition of solution of formaldehyde, so-called formol toxoids or anatoxin are the most recommendable for active immunization of children. For testing of these vaccines and others, it is necessary to determine a standard vaccine to be used for comparison, by testing each batch. Exact definite regulations are needed for the methods of testing. In order to obtain immunity of sufficient strength and duration, one must make three injections of the vaccine, increasing the doses. Intramuscular injections of the formol toxoids must be made. Investigation must be made to determine whether the methods of testing the immunizing power of the vaccines in large series of animals by testing them within a certain time after immunization with definite quantities of toxin can be replaced by other direct or indirect methods (flocculation, determination of the binding power, and so on). The immunization can be carried out during an epidemic. Animal experiments show that a negative phase after the injection of immunizing vaccine does not exist. Immediately after injection, one can find a resistance against infection with living bacilli or its toxins.

Intractable Incontinence of Urine.—Gibson reports a case of intractable incontinence ensuing on traumatic stricture of the urethra and complicated by grave renal sepsis. Mechanical relief of the incontinence was effected by transplantation of the ureters into the pelvic colon. The pathologic condition of pyonephrosis in the right kidney, however, precluded any hope of a successful cure. A marked feature was the progressive anorexia of the most incorrigible type. Emaciation thus became extreme. Doubt is cast on the value of nephrostomy as a surgical procedure, the resulting urinary fistula tending to prove intractable. The suggested cure of such a fistula by nephrectomy was out of the question in the author's case. The procedure of transplanting the ureters into the intestine is of great value in such cases as the one described, more especially if carried out before renal sepsis has supervened. It is a sound surgical procedure not fraught with any serious risk, provided due attention is paid to details of technic.

*Volhard's Tests of Renal Function. Pasteur Vallery-Radot and A. Lafitte. —p. 1557.

Volhard's Tests of Renal Function. — Pasteur Vallery-Radot and Lafitte stress the value of specific gravity in the study of urinary function. Volhard's tests are (1) the dilution test and (2) the concentration test. The dilution test is performed as follows: The subject in a fasting condition, having urinated, drinks 1,500 cc. of water or very weak tea between 7:30 and 8:30 a. m. He remains in bed and urinates every half hour from 8 to 12. It is important to consider, on the one hand, the quantity of urine eliminated and the manner of elimination and, on the other hand, the specific gravity of the specimens of urine. A subject with normal kidney function will eliminate in the four hours a quantity of urine equal to and sometimes larger than the quantity of water ingested; during the first two hours, more than half of the total is voided; the different fractions of urine are not eq quantity; and finally the specific gravity should be low 1.000 to 1.003) but not higher than 1.003, and the total evacuated should be at least 1,300 cc. The concentratio is performed as follows: The subject two days before th gets an ordinary diet and drinks from 1,500 to 2,000 liquid. The day of the test he remains in bed and in during a period of twenty-four hours, bread, meat, eggs, p rice or potatoes, normally salted. Green vegetables and are excluded because of the water which they contain. drinks altogether from 400 to 500 cc. of water in small tionated quantities. He should urinate every two to four Normally the total volume of urine varies the day of th from 300 to 750 cc. The specific gravity of the urine is i tant—a portion should have a specific gravity of at least (a smaller figure denotes that the kidneys concentrate po The two tests demonstrate by dilution the function o glomeruli, and by concentration the function of the tu The tests of Volhard are compared with other tests in c usage, such as blood urea, Ambard's constant, and the p sulphonphthalein test. The authors conclude that there parallelism between Volhard's tests and other tests. In test the renal functions examined are distinctly different. number of described instances the other tests would not nate the difficulty that was clearly demonstrated by Voll tests. The tests cannot be interchanged.

*Diagnostic Value and Pathogenesis of a New Dorsal Pain Point. Campanacci.—p. 485.
Researches on Bacterial Flora of Cystitis Following Nephrecton Renal Tuberculosis. C. A. Velo.—p. 490.
Allergic Diseases. A. Cionini.—p. 493.

Diagnostic Value and Pathogenesis of a New Do Pain Point.—Campanacci recalls the subjective and the o tive pain symptoms that are encountered in appendicitis, re ing particularly, on the one hand, the abnormal localiza of subjective pain, and, on the other hand, the painful p (direct and indirect) that are objectively observable. He describes a new (dorsal) painful spot, to which he first c attention in 1927, occurring in cases of appendicitis. He how to locate it, how frequently it is manifested, its cli diagnostic value and its probable pathogenesis.

was traced to the eating of cheese; a portion of the suspected food was obtained for me by the kindness of Dr. Costa Mandry, and yellow staphylococci were found in it; filtrates of broth cultures of these organisms, prepared as before described, reproduced the symptoms of food poisoning in three human volunteers. To these may now be added a fourth,[7] caused by chicken gravy eaten by two persons in the Panama Canal Zone. In this instance also, staphylococcus filtrates were obtained which reproduced the typical symptoms in several human volunteers.

Still another instance of staphylococcus food poisoning has been studied in the laboratories of the University of Chicago:

> In November, 1930, a portion of a layer cake ("devil's food"), purchased at a store in Milwaukee, was served at the evening meal to four adults. One person did not eat any of the cake and was not ill; the other three partook of the cake and became violently ill with vomiting, diarrhea and abdominal pain. On the following day the mother of one of the patients ate some of the cake and became ill in a few hours with similar symptoms. We were informed that four other persons had become ill after eating cake from the same batch, but we were not able to secure any definite histories. Complaints were received about four cakes. Other cakes belonging to this batch of cakes (twenty-nine in all) were eaten without producing any noticeable ill effects. Portions of two cakes that had presumably caused illness were received at the laboratory and subjected to careful bacteriologic examination by Dr. G. M. Dack. Yellow hemolytic staphylococci were isolated and were present in large numbers (540,000 per gram) in the cake substance; they were also present in the filler, but in smaller numbers. Through the cooperation of Major John R. Hall, M. C., U. S. Army, I was able to test the toxicity of the sterile broth filtrates of this strain on human volunteers. Three adult male volunteers were each given 2 cc. of the unheated filtrate in pasteurized milk; two of the three became ill with typical symptoms. Two others, given 5 cc. in the same manner, were both affected. An experimental cake was inoculated by Dr. Dack with this strain of staphylococcus and portions of the cake and filler (containing living staphylococci as well as their products) were eaten by two volunteers; both became ill.

There are thus four instances in which we have found that food epidemiologically implicated in food poisoning contained staphylococci in large numbers; the staphylococci when isolated in pure cultures have yielded a broth filtrate (two days) which, when swallowed in small amounts (from 2 to 10 cc.) by human volunteers, has reproduced with fidelity the typical symptoms observed in the original patients.

There are also two reported instances in which the drinking of milk inoculated with pure cultures of staphylococci has caused illness. In one of these, the report by Barber in 1914, already cited, the staphylococci were of the albus variety; in the other, recently reported by Ramsey and Tracy,[8] an orange colored staphylococcus, believed to be of the aureus type, was apparently incriminated.

In addition to these six instances of quite well established staphylococcus food poisoning, our files of food poisoning outbreaks have been found to contain several reports in which staphylococci may be regarded with more or less definiteness as the probable inciting agents:

> (*a*) In June, 1929, twenty guests at a wedding party in Chicago were seized with violent gastro-intestinal illness soon after partaking of a wedding cake. It was reported to the city health authorities that other cakes distributed by the same baker about this time caused similar illnesses in four or five families. A large piece of the wedding cake, brought to our laboratory, was subjected to bacterial examination (by Miss Dorothy Reiter). No organisms of the paratyphoid group were found (Endo medium), but large numbers of yellow gram-positive staphylococci were present. Monkeys fed with portions of the cake, of the filler and of the staphylococcus culture did not show any signs of illness. No experiments were made with human volunteers.
>
> (*b*) In July, 1929, five firemen in one squad in Chicago became ill with nausea, vomiting, diarrhea and cramps about two to four hours after an evening meal in which canned beef and layer cake were the chief articles of diet. Beef from the same can had been eaten by others who were not ill, but the eating of cakes from the same bakery batch was found to have been followed by twelve cases of illness in one family (two others who did not eat the cake remaining well) and three in another. In the latter instance, cream puffs and not the layer cake had been eaten and, since the same custard filler was used in the two, it seemed probable that the filler contained the active toxic agent. Examination of other samples of cake from the implicated bakery did not bring to light any bacteria of the paratyphoid group (Endo medium), but microscopic examination made in our laboratory showed the presence of gram-positive staphylococci. At the time, the staphylococci were not suspected of connection with the outbreak.[9]
>
> (*c*) In July, 1928, approximately 150 persons in Boston and vicinity became ill with acute gastro-intestinal disturbance in a few hours (mostly from one to three and one-half hours) after a midday lunch in which chocolate cream pie seemed to be the common factor. A report of the outbreak was published later[10] and the epidemiologic evidence there presented seemed to warrant the conclusion that the cream filling of the pie was the cause of the outbreak. A volunteer experimenter in Boston became ill after eating a piece of the pie. Through the courtesy of Dr. George H. Bigelow, commissioner of public health of Massachusetts, specimens of the incriminated food were sent to me. Bacterial examination of the pie and filler did not result in the isolation of any member of the paratyphoid group but showed the presence in the filler of streptococci and staphylococci.[11] At the time, the streptococci were considered of greater interest than the staphylococci, and cultures were made in milk and broth and fed to monkeys in large amounts (150 cc.) without, however, causing any illness in these animals. The staphylococci were not experimented with further. In the light of our later knowledge, they may perhaps have been responsible for this outbreak.
>
> (*d*) In April, 1931, sixteen persons in five families in Jersey City became seriously ill with acute gastro-intestinal symptoms from three to four hours after partaking of layer cake. While individual cakes were served in each family, the cake all came from one bakery and had been baked at the same time and filled from the same batch of filling. A portion of the implicated cake was sent to us through the courtesy of Dr. D. J. Sullivan, deputy health officer. No members of the group of paratyphoid bacilli were found, but large numbers of staphylococci were present in the filler and cake (from 25 million to 30 million per gram).[12] In this instance the epidemiologic observations, the symptoms, the period of incubation and the large numbers of staphylococci found in the incriminated food strongly suggest that this outbreak was due to staphylococci.

Other records in our laboratory reports show that staphylococci were present in food suspected of causing food poisoning, but these instances do not seem worthy of specific mention, since either the epidemiologic evidence implicating the food was inadequate or the staphylococci in the sample examined were too few to establish any significant relation.

Occasionally in the literature one comes across descriptions of outbreaks of food poisoning in which staphylococci have been reported present in large numbers in the incriminated food, whereas no paratyphoid bacilli could be found. The following statement, for example, appears in the 1927-1928 report of C. W. Arthur, the bacteriologist of the Pasadena Health Department Laboratory:

---

[9] Dr. W. E. Cary supplied the data in this case.

[10] Nelson, N. A.: New England J. Med. **199**: 1145 (Dec. 6) 1928.

[11] The laboratory work was done by Mrs. I. J. Kirkman.

[12] Laboratory data by Dr. S. A. Koser.

> Two outbreaks of food poisoning occurred, one originating from French vanilla ice cream and one from custard-filled cream puffs. The symptoms in the outbreaks were practically the same: acute nausea and vomiting and diarrhea with spastic abdominal pains, beginning in from three to five hours. When the intestinal tract was cleared, recovery occurred quickly in most instances. In neither food was it possible to demonstrate organisms of the Salmonella group. However, a gram-positive coccus with the same characteristics was present in enormous numbers in and isolated from each food.

Since the publication of our first papers,[13] two outbreaks of food poisoning in New York State have been described,[14] both of which may have been due to staphylococci. In one of these, a cake purchased at a church fair caused violent illness in four members of a family of six, the two persons unaffected having eaten the other articles of food served but not the cake. The incubation period was less than an hour, and the symptoms were similar to those observed with staphylococcus filtrate. Staphylococci were found to be the predominating organisms in the cake and "no organisms of the enteric disease group were isolated." In the other instance an outbreak of gastro-enteritis, estimated at not less than 125 cases, occurred among persons eating cream puffs or chocolate eclairs manufactured and distributed by a wholesale bakery. The onset of symptoms occurred within a few hours after eating. Staphylococci were isolated from the filling, but "none of the organisms generally associated with enteric diseases was isolated from the filling of the pastry or from the feces of patients."

COMMENT

The staphylococcus type of food poisoning differs in several respects from the more familiar type due to members of the Salmonella or paratyphoid group. It could, of course, never be confused with botulism.

There is a distinct difference in the incubation period. Staphylococcus food poisoning usually develops within a few hours after the toxic substance is swallowed. In the outbreaks thus far traced to this source, nearly all the persons affected have manifested symptoms within four hours, although rarely symptoms have appeared later. Human volunteers, of whom we now have a record of approximately 100, almost invariably show the first objective symptoms in from two to four hours after swallowing toxic staphylococcus filtrates. Vomiting appears with considerable regularity about three hours after the feeding.

Salmonella food poisoning, on the other hand, has as a rule a considerably longer incubation period. Although marked individual differences are observed, the onset of symptoms is on the average at least from six to twelve hours after eating the food and is probably somewhat longer. In many authentic instances the Salmonella incubation period is more than twenty hours.[15]

No deaths have yet been observed from food poisoning of the staphylococcus type. In the four outbreaks definitely traced, twenty persons are known to have been acutely ill, without any fatalities. The same is true of the instances reported by Barber and by Ramsey and Tracy, living staphylococci as well as their products being swallowed in these cases. In the four additional outbreaks previously summarized (*a*, *b*, *c* and *d*), in which there is strong evidence that staphylococci were the inciting agents, 206 persons were affected, without a death. Approximately 100 human volunteers who have become ill after swallowing sterile toxic filtrates have all recovered completely. The symptoms are, however, in some cases alarmingly violent and accompanied by great prostration. I do not believe that it can yet be said that this form of food poisoning is without danger to life. The mortality in the Salmonella form of food poisoning is usually estimated at about 1 to 2 per cent.

Perhaps the most important difference yet found between the Staphylococcus and the Salmonella types of food poisoning is that the staphylococci isolated in these cases yield a sterile broth filtrate which reproduces the characteristic symptoms when swallowed in as small amounts as 2 cc., whereas Salmonella filtrates have been fed to human volunteers in as large amounts as 145 cc. without producing any symptoms.[16]

The staphylococci concerned in food poisoning, as far as they have been studied, do not seem to differ in their main cultural characteristics from the common and widely distributed members of this group. Both albus and aureus varieties are found among the strains yielding toxic filtrates. There is evidence that strains that at one time produce the toxic substance do not produce it at another time, and vice versa. The majority of the toxic strains that we have isolated have lost (temporarily?) after some months of cultivation the power of yielding toxic filtrates. In two instances,[6] strains that produced a toxic filtrate early in 1930 soon after isolation (strains 1 and 5 in this paper) still produced, a year later (February-March, 1931), filtrates that caused illness in human volunteers. The potency of the filtrates from these year-old strains was not as great, however, as that of two more recently isolated strains, one from the Milwaukee cake (March, 1930) and one from chicken gravy (March, 1931).

The source of the staphylococcus contamination of food has not yet been determined. In connection with the Milwaukee cake outbreak, we were able to obtain samples of the materials used in preparing the cake: frozen eggs, flour, sugar, cocoa, soda, flavoring compound and "crisco." While abundant bacterial growth occurred from several of these ingredients, staphylococci were not found in large numbers in any. Samples of batter mixed by hand by six different workers in the bakery were also examined without in any instance disclosing staphylococci in noteworthy numbers. There is evidence that staphylococci with food poisoning qualities are sometimes present in cow's milk,[5] but since it has been shown[6] that staphylococci from the apparently normal human throat and other sources are also able to produce a substance that is toxic when swallowed, the derivation of the staphylococci causing any particular outbreak may not be easy to determine. The thorough study of a larger number of outbreaks than yet available will be necessary before the question of origin can be satisfactorily settled.

The properties of the toxic substance are still under investigation. Progress in this field has been necessarily slow because of the difficulties entailed by having to use human volunteers. Some degree of tolerance appears to develop in man fed with toxic staphylococcus filtrates, but there is no evidence of the generation of any true immune body.[17] Repeated attacks of gastro-intestinal disturbance may be produced in the same individual by successive feedings. The toxic substance is not completely destroyed by boiling for thirty minutes but is perhaps somewhat weakened.[18] Sterile toxic filtrates stored at low temperatures retain their original strength for at least three or four weeks; in one instance, 5 cc. of a 67-day old filtrate produced violent symptoms in a volunteer.[18] The toxic quality of a filtrate is not destroyed by contact with a rather strong chlorine solution (0.1 cc. of 0.0915 per cent chlorine (Cl_2) solution added to 5 cc. of a toxic filtrate three minutes before swallowing).

Clinical Notes, Suggestions, and New Instruments

SUCCESSFUL REMOVAL IN AN ELDERLY PATIENT OF AN ENDOTHELIOMA OF THE SPINAL CORD

Mark Gerstle, Jr., M.D., and Edmund J. Morrissey, M.D.
San Francisco

The features of the case that we are about to describe which in our opinion render it worth while to report are, first of all, the cervical location of the tumor; second, the advanced age of the patient; third, the long duration of the symptoms which were repeatedly misinterpreted, and, finally, the excellent result of the surgical extirpation.

Miss J. E., aged 67, when first seen by one of us (M. G., Jr.), in July, 1929, was confined to bed at her home. Her chief complaints were spastic paralysis of both legs, incontinence of urination and defecation, and spastic weakness and beginning contractures of both hands.

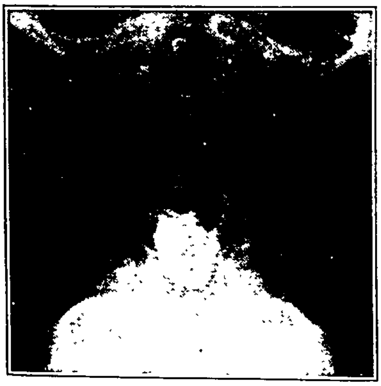

Fig. 1.—Anteroposterior view of iodized oil arrested opposite the fifth cervical vertebra; distinct filling defect.

The family history is inconsequential. The patient's health before the onset of the present illness had always been excellent. She had lived in California most of her life, where she used to be a school teacher.

June 9, 1923, the patient presented herself at a well known clinic complaining of weakness and occasional loss of control of her right ankle and leg. Following several examinations at the clinic she was advised to enter the hospital for observation, which she did, June 23, 1923. She remained there four days and remembers that among other procedures a lumbar puncture was performed. She then returned to the clinic, where some medicine was prescribed for her. A few days later she had "eruptions in the form of water blisters" across the back. Shortly afterward she discontinued her visits to the clinic and employed a chiropractor, who treated her with ultraviolet rays and massage without benefit. In 1924 she paid monthly visits to a physician, who stated that her symptoms were due to "high blood pressure." In 1925, the weakness of her right leg had grown much worse and she then began to notice a similar loss of power in the left lower extremity. She also began to be troubled with paresthesias in both limbs which she describes as "hot, creeping sensations" and "ice-like feelings" chiefly in the soles of both feet. Then followed a long period of attempted treatment by a second physician and also by a member of the orthopedic staff of the San Francisco clinic, which she had previously attended. On the advice of the orthopedist, September 13, she again entered the hospital, where she remained six days. At this time roentgenograms of her spine were taken, following which she was discharged unimproved.

In 1926 she entered the hospital, where her legs, teeth and spine were once more roentgenographed and where she was given massage and electrotherapy. She returned home greatly discouraged, but in the same year she returned for a tonsillectomy, which she had been strongly recommended to have performed. The second night after her return home she noticed for the first time she had completely lost control of her left leg. Thereafter she was confined to her bed except for brief periods spent in a wheel chair. A diagnosis of arthritis was made with a poor prognosis.

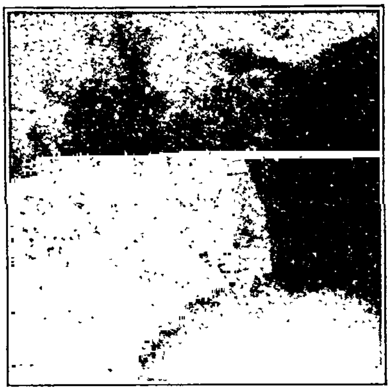

Fig. 2.—Lateral view of the phenomenon illustrated in figure 1.

In 1927 she noticed that the little finger of the right hand became "separated from the other fingers." She soon became unable to grasp anything with this hand, and a few weeks later the left hand suddenly became "useless." Both hands became "ice cold" and remained so. She began to have involuntary micturition and defecation. During the latter part of 1927 and the early months of 1928 the symptoms in her hands gradually increased and she became absolutely confined to her bed and was unable to sit up unless heavily supported. She also began to notice a feeling of "painful pressure" between her shoulder blades.

In July, 1929, the patient was visited by one of us (M. G., Jr.). At this time she presented the picture of a spastic paraplegia. An atrophy of the small muscles of both hands was noticed. Her general nutrition was excellent, however, although the patient was completely incapacitated and bedridden. On this occasion a tentative diagnosis of spinal cord tumor was made and the patient was hospitalized for further investigation. August 12, the patient was transported to the French Hospital in San Francisco by an ambulance, where the first systematic examination was made. The essential observations were:

1. Atrophy and spastic weakness of the thenar and hypothenar muscles, more noticeable in the right hand than in the left.

2. Complete spastic paralysis below the waist. The tonus of both legs was greatly increased. The patient was unable to move her lower limbs or feet in any way. The abdominal reflexes were absent. The knee and ankle jerks were very hyperactive. There was a well sustained bilateral ankle clonus and a positive Babinski response in both feet. During the examination the patient passed feces and urine involuntarily. There was a moderate amount of generalized atrophy of the muscles of both thighs and legs, but no more than would inevitably occur from almost three years of disuse. The sensory examination disclosed a hypesthesia and hypalgesia extending to a level approximating the first dorsal segment. This was somewhat patchy and difficult to demarcate. Deep joint and vibratory sensibilities were completely absent in the lower extremities.

Despite the patient's excellent nutrition the possibility of a metastatic cord tumor was considered, but flat plates of the femurs, pelvis and rib-cage revealed no evidence of a malignant growth. However, these roentgenograms showed a rather advanced hypertrophic arthritis of the knees and lumbodorsal spine.

[17] Dack, G. M.; Jordan, E. O., and Woolpert, Oram: J. Prev. Med. 5: 151 (March) 1931.

[18] Jordan, E. O., and Dack, G. M.: J. Prev. Med. 5: 383 (Sept.) 1931.

A spinal puncture was then performed. The fluid was clear and colorless, the pressure 6 mm. of mercury (normal). The Queckenstedt test was definitely positive, there being absolutely no rise in pressure on bilateral compression of the jugular veins. The cell count was 6 lymphocytes, the Pandy test was positive, and the total protein was 160 mg. per hundred cubic centimeters. These observations strongly pointed to a subarachnoid block, probably the result of tumor. Accordingly, the clinical observations were confirmed and the level was estimated to be about the first dorsal segment.

Two days later a cisternal puncture was done, 1 cc. of fluid removed and 1 cc. of warm iodized poppy-seed oil slowly injected. The patient was held in the sitting position and fluoroscopy was performed by Dr. L. B. Crow, the iodized oil descending to a level opposite the upper border of the fifth cervical vertebra, where it stopped, showing a distinct filling defect. Plates taken one hour and twenty-four hours later revealed the same evidences of block.

The diagnosis of a cord tumor was accordingly concurred in by the neurologist, neurosurgeon and roentgenologist. The lack of painful symptoms was in favor of an intramedullary growth and this point leading, of course, to a bad prognosis was carefully explained to the patient. She, however, decided to be operated on, despite the fact that no great hope of alleviation or cure could be offered her.

August 19, one of us (E. M.) under local infiltration with procaine hydrochloride performed a laminectomy on the patient. After removal of the laminae of the fifth, sixth and seventh cervical vertebrae and opening of the dura, an endothelioma which lay between the meninges was removed. This tumor weighed 2.5 Gm. and had compressed the right side of the cord, thereby reducing its caliber to about one-third its normal size. The dissection of the tumor was complicated toward the end by the necessary pulling on the posterior roots, which caused the patient considerable pain. It was, however, completely removed and the patient returned to her room in excellent condition.

Within half an hour after the operation had been completed, the patient noticed that she was able to flex her left ankle slightly and move the toes of her left foot. Within twenty-four hours she began to regain the use of her left hand. Within a week, flexion, extension, adduction and abduction of the left leg and thigh were performed and about this time she began to recover the ability to bend and extend the toes of her right foot. The patient remained in the hospital for three weeks, owing to a small sinus in the wound. On her discharge she was able to control her hands perfectly, bend and extend her left leg and flex her right leg.

From that time to the present her improvement has gradually increased. In November, 1929, a letter was received from the patient in which she stated that she was able to use her hands as well as ever in her life, she was able to sit up unsupported, and she could swing her legs from one side of the bed to the other so that she could get in and out of a wheel chair unsupported. The control of her sphincters had almost completely returned and she expected to attempt the use of crutches in the near future. The atrophic muscles of her hands had noticeably filled out and their power was excellent.

In March, 1931, the patient was last seen and examined. Her improvement had been very marked. She was able to walk around her house and garden without the use of crutches or any other support. Her general health was excellent. She had regained control of her sphincters, and her only complaints were occasional burning, prickling sensations in the right foot and in the region of the right knee.

The physical examination at this time showed that the right ankle and knee jerks were still very hyperactive and that the Babinski reflex on the same side was positive. The ankle clonus, however, had disappeared. The power in both lower extremities was excellent and there were no noticeable sensory changes.

COMMENT

This case illustrates the advantages of cooperation between clinician, surgeon and roentgenologist. All three individuals contributed in an essential way to the favorable outcome. It also illustrates the lack of careful examinations and useless therapy to which such patients are often subjected. It appears to us that the favorable result is remarkable owing to the rather advanced age of the patient, the cervical location of the tumor and the long duration of the symptoms.

HYPERINSULINISM: REPORT OF A CASE

Henry J. John, M.D., Cleveland

Jan. 24, 1929, a physician, aged 61, came to the Cleveland Clinic with a history of diabetes. His weight had decreased from 230 pounds to 137 pounds (104 to 62 Kg.), a loss of 41 per cent. He was 5 feet 8½ inches (174 cm.) in height. He gave the following history:

After an attack of influenza a month previous to entering the clinic, he lost weight rapidly and became very weak. He was exceedingly nervous and a tremor was present. Nocturia and glycosuria developed. He took some medicine by mouth but kept on losing weight and strength, and jaundice developed. The previous history contained nothing of importance.

On physical examination the patient was found to be extremely weak and emaciated. The teeth and tonsils were infected. The chest was clear, but a pulmonic systolic murmur was present. The liver was enlarged. The blood pressure was 136 systolic and 70 diastolic, the pulse 108 and the temperature 99.2 F. The basal metabolic rate was plus 83 per cent. Roentgen examination of the gallbladder revealed shadows suggestive of stones. Roentgen examination of the gastro-intestinal tract gave negative results.

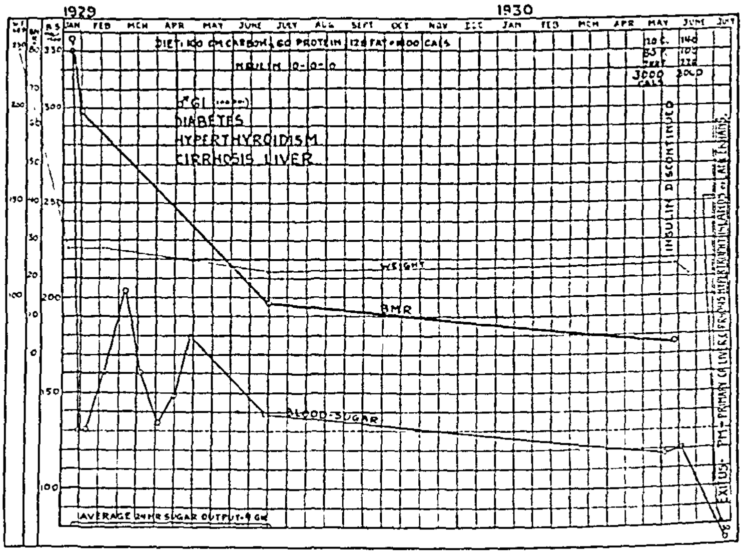

Fig. 1.—Clinical conditions in a patient presenting hyperthyroidism and diabetes, with hyperinsulinism.

The diagnosis included hyperthyroidism, diabetes mellitus, septic teeth and tonsils, and hypertrophic cirrhosis of the liver.

The patient entered the hospital and was put on routine diabetic treatment and compound solution of iodine (Lugol's solution) 15 minims (0.9 cc.) three times a day. The infected teeth were extracted. Marked improvement was noted; the blood sugar dropped to a normal level, where it remained. The patient was putting out about 4 Gm. of sugar in twenty-four hours during his stay in the hospital. The nervousness and tremor decreased and in less than five months the basal metabolic rate dropped to plus 13 per cent. The patient's weight, however, did not increase, and he suffered from diarrhea. He went to Florida for a few months and on his return in May, 1930, he was free from sugar. The basal metabolic rate at that time was plus 3 per cent (fig. 1).

Insulin was discontinued, and the patient's diet was increased from 1,800 to 3,000 calories. Examination at this time showed a normal blood sugar and sugar free urine. The carbohydrate content of the diet was now increased to 140 Gm. and the protein content to 100 Gm., the total number of calories remaining the same. The patient did not gain in weight and the diarrhea persisted. He reentered the hospital, July 19, 1930, in coma. The temperature was 100.4 F., the pulse rate 156, and the respiratory rate 24. The blood sugar content was 30 mg. per hundred cubic centimeters. Dextrose was administered intravenously, but the patient died in a few hours.

The observations from the postmortem examination were as follows: hyperplastic lymphoid tissue (lymph nodes, spleen); chronic fibrotic myocarditis; atrophic cirrhosis of liver (hyperplastic bile ducts); thrombosis of splenic and portal veins; primary carcinoma of the liver and secondary carcinoma of the gallbladder; infarcts of lungs; chronic interstitial pancreatitis, with atrophy and hypertrophy of the islands; acute bronchitis and bronchopneumonia; gastro-intestinal hemorrhages; Bacillus coli abscesses in the spleen; arteriosclerosis, and jaundice.

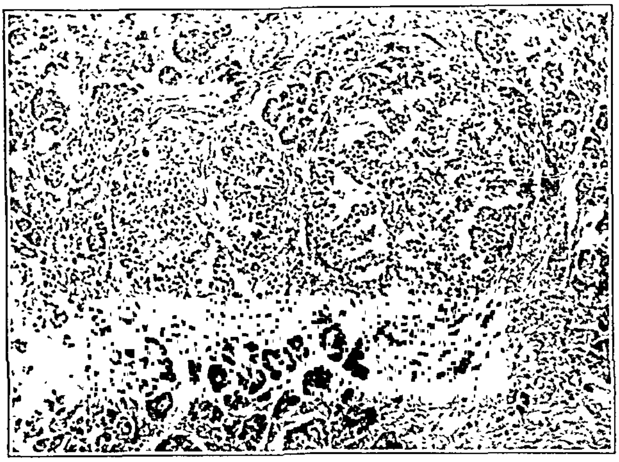

Fig. 2.—Hypertrophic condition of the islands of Langerhans.

Figure 1 shows several interesting points in connection with this case. The severe hyperthyroidism and diabetes responded to treatment with compound solution of iodine and insulin so that, after sixteen months, insulin was discontinued and a normal blood sugar level was maintained even on a markedly increased diet. The emaciation and diarrhea, however, persisted in spite of treatment. The low blood sugar level at the time the patient was readmitted to the hospital in coma would have been difficult to explain but for the postmortem examination.

Figure 2 shows the markedly hypertrophied islands of Langerhans. Such islands produce more insulin than normal islands in spite of the tremendous reserve in normal islands. The question arises, Is it the hypertrophy of the islands per se which causes hyperinsulinism or is it the regulating mechanism of the insulogenic output which brings it about, either in the presence of hypertrophy of the islands or when the islands are normal? Hyperinsulinism is seen in both instances.

Purpura Hemorrhagica Associated with Tuberculosis.—Purpura hemorrhagica is a condition associated with marked diminution in the blood platelets, spontaneous bleeding from the mucous membranes and purpuric lesions of the skin. It may occur in a primary or idiopathic form (called essential thrombopenia), or as a secondary manifestation in pernicious anemia, lymphatic leukemia, diphtheria and tuberculosis.—Litvak, A. M., and Holzsager, T. G.: Purpura Hemorrhagica, *Am. J. Dis. Child.* **42**:1160 (Nov.) 1931.

Committee on Foods

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public. They will be included in the Book of Accepted Foods to be published by the American Medical Association.

Raymond Hertwig, Secretary.

AMERICAN BAKERS ASSOCIATION ADVERTISING CAMPAIGN

Sponsors.—American Institute of Baking, Chicago.

The following statements in promotion of "white bread" have been accepted and may be used in advertising in conjunction with the seal of the committee in accordance with the Rules and Regulations:

White bread is a wholesome, nutritious food. As such, it has its rightful place in the normal diet of the normal individual. Its avoidance for fear of any untoward nutritional consequences or the fear that it is the cause of any disease condition when properly used in the normal diet is without scientific foundation.

PABST PASTEURIZED PROCESS CHEESE (PIMENTO)

Manufacturer.—Pabst Corporation, Milwaukee.

Description.—A pasteurized process American cheese containing disodium and trisodium phosphates as emulsifiers, with pimentos and salt.

Manufacture.—The manufacture is essentially the same as that described for Pabst-ett (A Pleasing Combination of "Process" Cheese, Milk Proteins, Milk Sugar, Milk Minerals) (The Journal, Oct. 24, 1931, p. 1227) excepting that canned pimentos are added but no whole milk or concentrated milk whey.

Chemical Composition (submitted by manufacturer).—

	(sample as is) per cent	(moisture free basis) per cent
Moisture	39.9	...
Ash	5.0	8.3
Salt in ash	1.6	2.7
Fat (ether extract)	30.4	50.6
Protein (N × 6.38)	22.6	37.6
Lactose (by difference)	2.1	3.5
Phosphorus (P)	0.35	0.58

Calories.—3.72 per gram; 105.6 per ounce.

Vitamins.—The vitamin content is essentially that of Pabst-ett (A Pleasing Combination of "Process" Cheese, Milk Proteins, Milk Sugar, Milk Minerals).

Claims of Manufacturer.—See this section for "Pabst-ett."

PIXIE STRAINED TOMATOES

(Mildly seasoned with salt)

Manufacturer.—Fruit Belt Preserving Company, East Williamson, N. Y.

Description.—Canned, sieved tomatoes containing in large measure the mineral and vitamin content of the raw tomatoes used; contains a small amount of added salt.

Manufacture.—Mature tomatoes are sorted and washed, and green sections, cores and defective spots are trimmed out by hand and again washed. The prepared tomatoes are broken down by steam in a closed kettle and then sieved, canned and processed by essentially the same method as those described for Strained Carrots (The Journal, Nov. 14, 1931, p. 1467). The final processing involves twenty minutes' heating in boiling water. A small amount of salt is added to each can.

Chemical Composition (submitted by manufacturer).—

Specific gravity 20 C./20 C.	1.06
	per cent
Moisture	88.8
Total solids	11.2
Ash	1.2
Fat (ether extract)	0.1
Protein (N × 6.25)	1.9
Carbohydrates other than crude fiber (by difference)	7.4

Calories.—0.38 per gram; 10.8 per ounce.

Vitamins; Micro-Organisms; Claims of Manufacturer.—See these sections for Pixie Strained Carrots.

FEE SPLITTING—AN OLD ETHICAL PROBLEM

A basic principle in medical practice demands that the physician call as a consultant the best available man for the purpose. That principle is determined, of course, by a fundamental consideration: the one impelling motive in every action taken by a physician must be the good of his patient. For these primary reasons, ethical physicians oppose fee splitting in any way, shape, manner or form. Every one now realizes that the general practitioner who makes the diagnosis and who is primarily responsible for the care of the patient deserves a much greater percentage of what the patient is able to pay than he actually gets when the patient is referred to a surgical, otolaryngologic, ophthalmologic or other consultant. Nevertheless, if this is accomplished by the secret division of fees it is an abomination full of evils. If patients could come to understand that the general practitioner's fee, when a specialistic procedure is necessary, should be greater than on ordinary occasions, the difficulty would be largely overcome.

Still more hazardous to the patient and to the honesty of the medical profession are the inroads on the traditional ideals of medicine brought about by the entrance into the medical field of innumerable technical procedures. The changing nature of medical practice means that medicine is now conducted not only by the 150,000 physicians who practice in our country but also by several hundred thousand nurses, laboratory technicians, nonmedical roentgenologists, anesthetists, dietitians, physical therapy aides and similar groups. These workers do not have the background conferred by scientific medicine. To them in many instances "ethics" is merely a word. Moreover, technical services are being purveyed by corporations sometimes controlled by business men who are not physicians, sometimes by physicians who are primarily business men. In various parts of the country, physicians are being urged to arrange for laboratory service, for x-ray service, for physical therapy help, for colonic flushing, and for dietetic service with corporations, institutions, laboratories or technicians who are willing, provided the physician sends his patients to them, to give to the physician a portion of the income derived from such clientele. If it is essentially unethical for a physician to choose, as a surgeon for his patient, the operator who will give him the largest percentage of the fee rather than the one who would seem to be the best available surgeon for the purpose, it is equally wrong for him to select any other service to be given to the patient on the same basis. With this point of view there cannot be any argument. The essential dishonesty cannot be evaded by any form of charter, contract, mutual agreement or similar arrangement.

The nature of the times is such that men driven by economic necessity seek to find plausible apology for evasions of ideals and principles that in more liberal times they would support without the slightest hesitation. Manufacturers whose competitors give them little concern in times of prosperity burn with indignation at the slightest hint of unfair competition during times of economic depression. The traditions and ideals of scientific medicine have weathered many an economic storm during the two thousand years that they have guided the noblest of professions. It is reasonable to believe that the tottering of a few during this time of stress will not become the example that will lead the rest of the profession to follow the black sheep blindly over the precipice.

MORE ABOUT THE MENACE OF METHYL ALCOHOL

The comparative toxicity of methyl alcohol, or methanol as it is now frequently designated, has been known for many years. Soon after the middle of the nineteenth century it was clearly established that "methylated spirits," or wood alcohol, represented a serious hazard in certain industrial processes. For some time the exceptionally poisonous properties were attributed to impurities in the commonly used methanol, wood alcohol. Improvements in the processes of its production led to removal of offensive odors and other purification resulting in increased sale for a variety of purposes. The dangers were not lessened. Then several factors came to the fore in bringing about greater danger from methyl alcohol. The prohibition of the sale of alcoholic beverages led to the substitution of methyl alcohol for the forbidden grain spirit, ethyl alcohol, frequently on the unwitting assumption that these chemical compounds so similar in many properties were practically interchangeable from a physiologic standpoint. Impure methyl alcohol began to be used as a denaturant of ethyl alcohol, to permit the latter to be employed for technical purposes and yet make it unfit for human consumption. This led to numerous fatalities through the drinking of "industrial alcohol" containing methyl alcohol or products distilled from it. Furthermore, the growing number of automobiles has led to widespread use of methyl alcohol as an antifreezing agent in radiators of motor cars. Fumes of the heated alcohol rarely might be inhaled to an extent that brings disaster. Finally, the employment of methyl alcohol as a solvent has introduced additional hazards when the products are applied in enclosed spaces.

In their monograph on noxious gases, Henderson and Haggard[1] have pointed out that the solubility of the alcohols causes them to be eliminated only slowly through the lungs. The slow elimination is, however, in part counterbalanced by the oxidation of some of the alcohols within the body. This destruction of alcohol in the body is particularly marked for ethyl alcohol but does not occur to more than a small extent with methyl alcohol. Ethyl alcohol is more toxic than methyl for equal concentrations maintained in the body, but the rapid oxidation of ethyl alcohol to water and carbon dioxide prevents its acting as a serious toxic agent when it is absorbed through the lungs from any ordinary concentration of its vapor in air. On the other hand the vapor of pure methyl alcohol is an anesthetic, a nonreactive gas of high solubility, which therefore accumulates in the body and exerts a direct poisonous action on the nervous system, particularly the retina. According to Henderson and Haggard, more than a week is required to eliminate the methyl alcohol acquired by a single large absorption. If the exposure is repeated before the elimination is completed, a cumulative effect results; the amount absorbed at each exposure is added to that which remains uneliminated. A toxic concentration is thus gradually built up in the blood as a result of exposure to concentrations that do not cause an appreciable effect on a single exposure.

The salient facts just reviewed have been presented repeatedly in THE JOURNAL. In addition to the deliberate or the unsuspected imbibition of the harmful methyl alcohol there are the dangers not only of inhalation of its vapors but also of its possible absorption through the skin. Various industries and "filling stations" are particularly involved. It is reported that more than two hundred deaths occurred during the winter of 1930-1931 as a result of unintelligence and free access to methyl alcohol in filling stations and other little controlled sources. These circumstances raise questions of public safety beyond the peculiar present-day incentives to the menacing use of methyl alcohol for beverage purposes.

A recent investigator[2] has pointed out that the participants in the discussion of the toxicity of methyl alcohol are divided into two major groups. One group maintains that the reasonable and intelligent use of methyl alcohol in industry and commerce is safe and practical and may be expected to be attended by no harm to those persons handling it. The other group maintains that reason and intelligence may not be expected from those who are exposed to or have free access to methyl alcohol. In studies on animals at the Industrial Health Conservancy Laboratories in Cincinnati, McCord[2] has found that methyl alcohol applied to the skin has invariably led to damage consistently like that arising from the oral intake of this substance. This evidence of absorbability of methyl alcohol has been noted in optic atrophy observed clinically by ophthalmologists, and after death as observed in lipoidal degeneration. The regular recovery of methyl alcohol on the distillation of all organs derived from skin-treated animals, and the absence of similar conditions in control animals, constitute inescapable proof of absorbability.

How great may the actual danger become? According to McCord, if the results obtained from monkeys may be applied to man, approximately 1 ounce (30 cc.) of methyl alcohol repeatedly in contact with the human body, under conditions favorable to retention and evaporation, constitutes a threat to well being. The threshold of danger by inhalation is well below 1,000 parts per million of methyl alcohol vapor. If this degree of toxicity obtained from monkeys applies to man, the vapors from one ounce of methyl alcohol entering the human body constitute a threat to life even when the exposure is distributed over two or three days. Perhaps the time has come to reappraise the situation that confronts us in the United States and decide whether it calls for further protective measures for the safety of the public. This is particularly true when elaborate studies have led the investigator to regard it as reasonable to assume that "practical hazards for human beings may be produced under conditions of apparently trivial exposures."

EXPERIMENTAL POLIOMYELITIS

Years ago, Lee[1] pointed out that bacteriologists have shown great ingenuity in devising methods by which micro-organisms may be cultivated and studied. He recalled how their laboratories have become veritable bacteriologic gardens, where living germs are kept under the best possible conditions. The species are separated from one another; the proper foods are given to each; the most advantageous surroundings as to light, air, temperature and moisture are provided; the bacteria are nursed when ill, and every effort is made that they may lead healthy lives. Opportunities are thus given for the exact study of their activities. These are, of course, important features in the warfare on disease, and they represent an almost indispensable part of the attack in the field of infectious disorders. In response to microbiotic invasion, the body develops unique methods of defense. In part they are cellular, in part chemical. Antibodies of surprising potency may

result. Specific serums have thus become of life-saving value both as curative and as preventive agents. Problems of immunity are being opened for solution.

In the course of the study of contagion and infectious diseases, investigators have come to appreciate the importance of discovering susceptible experimental animals. It is not enough to isolate the harmful microorganisms or to separate the more elusive filtrable viruses. The response of the body to their presence—the results of their invasion into the fluids and tissues—forms a significant part of the picture of the resultant disease. All the features should be reproducible in their entirety in order to facilitate the study of etiology and treatment. Different species of animals show quite unlike susceptibilities to some of the human ailments. The initiation of progress in combating them is in no small measure made possible, therefore, by finding susceptible animals for the study of the manifestations on the one hand, and for the production of immune serums on the other. Medical history affords illustrations alike of the help afforded by the discovery of suitable animals, such as the horse, in the development of antidiphtheritic substances, and of the retardation of scientific advancement in other instances owing to the inability to imitate specific disorders with certainty outside man.

This has to some extent been true of the dreaded poliomyelitis. The monkey was early found to show some susceptibility. Heretofore it has appeared that only a portion of the human strains of the virus can be implanted in the experimental animals. Flexner[2] has pointed out that, not infrequently after the first successful inoculation of monkeys with human spinal cord or medulla obtained in fatal cases of poliomyelitis, the succeeding inoculation of the spinal cord of the affected monkey has failed to induce disease. The reason for this disparity is not known. Newly announced investigations[2] at the Rockefeller Institute for Medical Research, New York, indicate a way to increase the proportion of successful inoculations of affected human and monkey spinal cords and brain stems. It consists of repetition of the injections of the virus-bearing tissues. According to Flexner, the abortive can be converted into the progressive paralytic disease by means of reinoculation. Whether the acceleration is due to virus alone or to alien tissue elements remains uncertain. It may be merely a summation of virus effects. The immediate feature of moment is the improvement in research technic, for the numerous experimental failures can now presumably be turned into a liberal quota of successes. The 1931 epidemic of poliomyelitis has sufficed to impress the public as well as the physician with the need of persistent investigation. For such studies in poliomyelitis an improved tool of research now seems to have been devised.

THE PROBLEM OF VITAMIN ASSAY

Any one who has had occasion to deal in any thorough way with the modern problems presented by the discovery of the vitamins must realize the difficulties that attend the quantitative aspects of the subject. It has become obviously important to secure estimates of the varying content of vitamins in the numerous foods that carry these indispensable nutritional substances. The need of suitable methods of assay has been further accentuated along with the growing efforts to separate the different vitamins from their natural carriers and to prepare concentrates that shall be far richer in the food factors than are the natural products. The questions of comparative potency arise in relation to the influence of the varied processing and culinary procedures that foods may be subjected to in the home as well as in the factory. Wherever food conservation is involved, the possibility of deterioration is presented; and this applies to the essential vitamins as well as to the energy-yielding nutrients. A good illustration is afforded by cod liver oil. The value of this widely used medicinal food lies above all in its richness in vitamins A and D. On this account the Council on Pharmacy and Chemistry of the American Medical Association requires that the specific vitamin potency of brands of cod liver oil and cod liver oil concentrates accepted for inclusion in New and Nonofficial Remedies shall be declared on the label and in the advertising of such products.

Unfortunately, assay procedures have been attended with great difficulties. So long as the chemical identity of a vitamin remains undetermined, a statement of potency depends on reference to some reasonably stable and readily obtainable product that shows little variability with respect to the factor in question. Such well defined products have been difficult to secure. On this account the determination of potency has tended in recent years to be based on the physiologic response of a test animal to a given intake or dose of the product to be assayed. This is illustrated in the first standard procedure, for cod liver oil, to be introduced into the U. S. Pharmacopeia X—a method for measuring the content of vitamin A. It consists in ascertaining how much of the oil is required to induce growth at a selected rate of gain in body weight when the substance to be tested is added to a vitamin A free ration of defined character. Experience has shown many pitfalls and opportunities for error. The species of animal, the preliminary depletion of the test animal with respect to vitamin A, and other factors are liable to modify what is in essence a "curative" test. The details of the difficulties need not be rehearsed here. Some workers have preferred to deal with "preventive" tests whereby the quantities required to avert symptoms of avitaminosis are ascertained.

The establishment of units has been confronted with even greater difficulties. The intricacy of the subject is apparent in consideration of assays of vitamin D. Shall the criterion be growth, the mineral content of the bones, or some other symptom? And when the antiscorbutic vitamin C is brought into the fold it is found that the rat—the conventional test animal for vitamins A, B, D and G—cannot be used because it is not susceptible to lack of the factor under consideration.

---

[2] Flexner, Simon: Accelerated Infection in Experimental Poliomyelitis, Science **74**: 520 (Nov. 20) 1931.

The difficulties have multiplied, and the opinions as to procedure have varied to such an extent that some concerted action seems imperative if chaos is to be averted. In the case of immune serums and likewise in the assay of insulin, tenable understandings have been reached, so that a statement of the number of "units" employed is understood the world over. Recognizing the need of a cooperative spirit and undertaking, the American Drug Manufacturers' Association established a vitamin assay committee. Its report has been presented by A. D. Holmes.[1] A conference has also been called in connection with the revision of the U. S. Pharmacopeia and a representative committee has been appointed to deal with the technical problems and terms of vitamin assay, for inclusion of revised standards in the new volume XI. The official character of this book and its semilegal status lend great importance to the deliberations of the group.

Meanwhile the Permanent Standards Commission of the Health Organization of the League of Nations has been concerned with the problem of vitamin standards and units. In the deliberations in London during June, 1931, the United States was represented by Harry Steenbock of the University of Wisconsin and E. V. McCollum of Johns Hopkins University. The London conference[2] has agreed unanimously in favor of defining vitamin units in terms of standard substances rather than in terms of a biologic test. This means that the methods of assay were not considered in detail. It was decided that "when the value in units of a test substance is to be estimated, the test substance and the standard preparation are investigated simultaneously by the same method, and the test substance should therefore show the same value in terms of the standard, whatever biologic technic is employed." The standards thus far selected are as follows: for vitamin A, one international unit is the potency of $1\ \gamma$ ($=0.001$ mg.) of pure carotene, which is converted into vitamin A in the body; for the antineuritic vitamin B, 10 mg. of a special adsorption product prepared by Seidell's method from rice polishings; for the antiscorbutic vitamin C, the activity of 0.1 cc. of fresh juice of the lemon, Citrus limonum; for the antirachitic vitamin D, the activity of 1 mg. of the international standard solution of irradiated ergosterol (viosterol), issued from the National Institute of Medical Research in Hampstead.

Some of the advantages of the plan outlined are obvious. All "units" will represent international standards referable to chemical substances that are to be made available to laboratories throughout the world. The establishment of products of fairly well defined character for vitamin assays will be welcomed. It will not do away with the necessity of biologic testing; the behavior or response of the test animal will continue to be a dominant factor in the assay process. There still remains that variability inherent in all such methods of research. Other objections will also doubtless be raised. It remains to be seen whether the American committees will agree to adopt the proposed schemes in their entirety. Of course, the ideal procedure would be a chemical analysis comparable to that by which many drugs can be examined. This eventuality may not be far away. The isolation of vitamin D or its equivalent in a state of crystalline purity has only recently been announced.[3] In any event there are signs of progress ahead.

Current Comment

THE SUGAR IN NEPHRITIC URINE

There are numerous phenomena in physiology and pathology that are observed so frequently and intimately that their nature is taken for granted. On careful consideration, however, many such manifestations raise more questions than can be answered with any real assurance of accuracy. For example, it might properly be assumed that our knowledge of the functions of the gallbladder would be fairly complete after the many years during which this organ has obtruded itself to the attention of clinicians and physiologists. Some of the shortcomings of current information on this topic were recently referred to in The Journal.[1] Much the same sort of criticism might be applied to our knowledge of vomiting[2]—a phenomenon of daily occurrence in the bedside experience of the physician. Sometimes a critical student is led to amazement at the paucity of fundamental facts that enter into medical problems. It was known for a long time that there was some kind of "sugar" in the blood. Its actual identification as dextrose is barely older than the century. The familiar sugar of the urine was early recognized as dextrose, but presently came the demonstration that lactose may at times find its way through the kidneys. Subsequently it was learned that "normal" urine carries traces of "reducing substances" and that these are only in part fermentable as dextrose is. What they actually are remains to be learned. The story of urine carbohydrates is not yet a closed book. A significant chapter has recently been added by Hiller[3] from the Hospital of the Rockefeller Institute for Medical Research, New York. It had been known for some time that fermentable reducing substances were frequently increased in all types of nephritis and that in some of the degenerative cases the excretion amounted to gross melituria.[4] Hiller has now clearly identified the presence of dextrose (by distinction from levulose, mannose, lactose or maltose) in the renal excretion of such patients.

AMERICAN FOUNDATIONS

The general impression prevails that vast sums of money are distributed by various foundations for the public welfare, but thus far little accurate information has been available as to just how much money is distributed and the uses to which it is put. In order to answer this question, the board of trustees of the Twentieth Century Foundation has canvassed the situation and made available a report on American foundations and their fields, covering distributions up to the end of 1930. The definition used indicates that a foundation must be a separate organization with its own board of trustees or directors set up to disburse money not only in operating its own activities but in particular by making direct grants to outside beneficiaries. Religious foundations are not included in the present survey. Apparently the foundations make grants to almost every phase of human activity. One hundred and twenty-two are included in the compilation. The capital funds involved amount to $853,450,114. Since seventeen foundations did not make available the facts, an estimate of approximately $1,000,000,000 seems reasonable. The largest foundations include the Carnegie Corporation with $160,000,000, the Rockefeller Foundation with almost $150,000,000, and the General Education Board with almost $94,000,000. Out of the total of $950,000,000 for all the foundations, 20 of the 122 comprise $725,559,829, or 85 per cent of the total. Grants paid during the year amounted to $52,476,137. The field of medicine and public health was most popular, receiving $18,627,222, or more than one third of all of the funds given away. General education came next. An analysis of the manner of distribution of funds for medicine and health reveals the entrance of the foundations into almost every aspect of medical care.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts at 11:15 a. m. on Saturday over Station WBBM (770 kilocycles, or 389.4 meters).

The program for the week is as follows:

December 12. Cold Facts About Colds.

Five Minute Health Talks may be heard over Station WBBM of the Columbia Broadcasting System at 2:25 p. m. on Monday, Wednesday and Friday.

The program for the week is as follows:

December 7. Dandruff, Dandruff Everywhere.
December 9. New Hazards for Old.
December 11. The Healthy Mind.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

GEORGIA

Dr. Hoke Appointed Surgeon at Warm Springs.—Dr. Michael Hoke of Atlanta has been appointed surgeon-in-chief of the Georgia Warm Springs Foundation, effective December 1. He succeeds Dr. Leroy W. Hubbard, chief surgeon since 1926, who, according to the report, will do extension work for the foundation. Dr. Hubbard will make trips to areas of epidemics, consult with state, county and city commissioners of health, and advise with hospitals in regard to medical treatment.

Health at Atlanta.—Telegraphic reports to the U. S. Department of Commerce from eighty-two cities with a total population of 36 million, for the week ended November 21, indicate that the highest mortality rate (19) appears for Atlanta, and the rate for the group of cities as a whole, 11.1. The mortality rate for Atlanta for the corresponding period last year was 15.9, and for the group of cities, 11.8. The annual rate for eighty-two cities for the forty-seven weeks of 1931 was 11.8, as against a rate of 11.9 for the corresponding weeks of 1930. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

ILLINOIS

Conference of Health Officers.—A conference of Illinois health officers and public health nurses will be held in Springfield, December 17-18. The principal theme of the convention will be ways and means of minimizing the effects of the economic depression on health and of extending more rapidly the newer methods of controlling epidemics. Among the subjects to be presented are poliomyelitis, whooping cough, state diagnostic laboratory in relation to health officers and practicing physicians, recent advances in immunology, convalescent serum in control of communicable diseases, toxoid as a diphtheria preventive, current statistics on diphtheria in the United States, health problems caused by the depression, White House Conference on Child Health and Protection and its medical aspects, new phases of pediatric medicine, public health nursing, economic problems of dental public health, and child hygiene work in the county health unit. Guest speakers will include Harry E. Barnard, Ph.D., director, White House Conference on Child Health and Protection, and Drs. Walter T. Harrison and Estella Ford Warner of the U. S. Public Health Service, all of Washington, D. C.; Mr. C. C. Young, director, state laboratory, Lansing, Mich., and Dr. John E. Gordon of the Detroit health department.

Chicago

Dr. Sigerist to Lecture.—Dr. Henry E. Sigerist, professor of the history of medicine and director of the Institute of the History of Medicine of the University of Leipzig, will deliver four lectures under the auspices of the University of Chicago and Rush Medical College, Institute of Medicine of Chicago, Society of Medical History of Chicago, and Northwestern University. The first lecture will be held, December 7, at the University of Chicago on "Medical Literature of the Early Middle Ages"; the second, December 8, at Rush Medical College, "Medicine of the Renaissance: Fracastor, Paracelsus, Vesalius, Ambroise Paré." The latter will be the John Dodson lecture. The third lecture will be given, December 8, on "Problems and Methods of Historical Pathology," before the Institute of Medicine at the City Club. This meeting will be preceded by an informal dinner in honor of Dr. Sigerist. The last lecture will be given, December 9, at Northwestern University, on "The Sanctuary of Asklepios in Epidauros."

Society News.—At the meeting of the Chicago Urological Society, November 25, Drs. Herman L. Kretschmer and Lawrence E. Pierson, Sioux City, Iowa, spoke on "Fibrolipomatosis of the Kidney"; Harry C. Rolnick and Clement P. O'Neill, "Skin Metastases in Carcinoma of the Bladder," and Benjamin Earl Fillis, "A Spontaneously Expanding Bougie for Ureteral Dilatation."——Dr. Charles L. Scudder, Boston, addressed a joint meeting of the Central States Society of Industrial Medicine and Surgery and the Chicago Society of Industrial Medicine and Surgery, December 2, on "Present Status of the

---

[4] Hawkins, J. A.; Mackay, E. M., and Van Slyke, D. D.: J. Clin. Investigation 8: 107 (Dec.) 1929.

Treatment of Fractures."——The Chicago Laryngological and Otological Society will be addressed, December 7, by Drs. Samuel Salinger on "Nasal Deformities—Surgical Correction"; Harry L. Pollock, "Implants—History and Use," and Alice K. Hall, "Pharyngo-Mediastinal Abscess Recovery."——The Chicago Council of Medical Women, at its meeting, December 4, was addressed by Drs. Irma Aleshire and Louise O. Kappes on "Urticaria" and "Food Allergy in Children," respectively.

Health Service for University Employees.—A health service program for the staff and employees of the clinics group, University of Chicago, was approved by the board of trustees and became effective, December 1. The program will be administered by the University Health Service under the direction of Dr. Dudley B. Reed. The contribution of one dollar a month to be deducted from their salaries will be required of all employees. This money will form a fund to be used only for meeting the costs of medical and hospital service to the individual participants in the plan. The plan will be obligatory for all new appointees and reappointments with no exceptions; participation in the public health aspects of the plan will be obligatory for all present employees and full participation, including monthly payments, will be required of all present staff and employees, unless specifically exempted. The benefits to be derived include:

1. All services performed in the outpatient department of the health service: that is, ambulatory medical care.
2. House calls in the district bounded by Fifty-Third Street, Cottage Grove Avenue, Sixty-Third Street and Lake Michigan.
3. X-rays and consultations with other clinics as directed by the health service staff.
4. Refractions (not including glasses).
5. Elective correction of remediable defects after the beneficiary has been a participant in the plan for not less than one year.
6. All necessary hospital expenses up to two months of hospital care, for conditions commonly cared for in the University of Chicago Clinic. This covers accommodations at minimum rates. More expensive accommodations may be occupied, the difference in cost to be met by the individual.

The plan does not include:

1. Hospitalization for tuberculosis, mental and chronic diseases not ordinarily admitted to the clinics except that such cases may be received for purposes of diagnosis.
2. Prenatal and obstetric care.
3. Elective operations for remediable defects discovered at time of employment, it being understood that persons having such defects which might interfere with the proper performance of their duties would, as a condition of their employment, be required to have these defects remedied within three months at their own expense or on their own responsibility.
4. Glasses, appliances and medicines except so far as any of these are included as part of the ordinary hospital care.
5. Dental service, except consultation for diagnosis on request of the health service.

A committee of participants will be formed to advise with the University Health Service. According to Dr. Franklin C. McLean, director, University Clinics, the plan has been under consideration for more than a year.

INDIANA

Personal.—Dr. John W. Morr, Albion, has been appointed health officer of Noble County to succeed the late Dr. John H. Ravenscroft.——Dr. George W. Washburn, Star City, has resigned as health officer of Pulaski County on account of ill health; Dr. Thomas E. Carneal, Winamac, was appointed to fill the unexpired term.

Society News.—The Elkhart County Medical Association was addressed, November 5, by Dr. Ralph M. Waters, Madison, Wis., on "Oxygen Deficiency."——A feature of the Wayne-Union County Medical Society's meeting, November 6, was the presentation of motion pictures on "Anatomy of Female Pelvis and Perineum," "Abdominal Subtotal Hysterectomy for Fibroids," and "Repair of Urethrocele, Cystocele and Laceration of Cervix."——Dr. Donald C. McClelland, LaFayette, addressed the Jasper-Newton County Medical Society, October 30, on "Irradiation Treatment of Benign Uterine Hemorrhage."——A plan for care of the indigent sick was discussed by Dr. Edwin L. Libbert at the October 29 meeting of the Dearborn-Ohio County Medical Society at Lawrenceburg.——Dr. Robert S. McCaughey, Danville, Ill., addressed the Fountain-Warren County Medical Society at Hillsboro, November 5, on "Disease of the Colon."——Dr. Edgar F. Kiser, Indianapolis, addressed the Hancock County Medical Society at Greenfield, November 6, on "History of Medicine," and J. T. Waldo, D.D.S., "History of Dentistry."——The Thirteenth District Medical Society was addressed, November 4, among others, by Drs. Harold A. Quint, Evanston, Ill., on "Injection Treatment of Varicose Veins"; Francis V. Martin, Michigan City, "Bacterial Endocarditis"; Mark M. Piper, Rochester, "Prenatal Care, with Special Reference to the Offspring"; James L. Wilson, South Bend, "Toxic Thyroid"; Henry J. Graham, Mishawaka, "Appendicitis in Children," and William H. Holmes, Chicago, "Nephritis."——Dr. Lowell G. Hunter, Versailles, addressed the Ripley County Medical Society at Osgood, November 4, on surgery of the sympathetic nervous system.——The Rush County Medical Society was addressed, November 2, by Dr. Frank C. Walker, Indianapolis, on "Pelvic Infections."——Dr. Raymond W. McNealy, Chicago, addressed the Academy of Medicine, Terre Haute, November 6, on "Blood Vessel Surgery, Past and Present."

KANSAS

Society News.—The Wyandotte County Medical Society was addressed, November 3, by Judge William H. McCamish on "Expert Medical Testimony" and Mr. Joseph Cohen, "The Law of Malpractice." The society was addressed, November 17, by Drs. Earle G. Brown, Topeka, on "Epidemiology of Infantile Paralysis"; James R. Elliott, Kansas City, Mo., "Management of Poliomyelitis During the Stage of Recovery," and Elam A. Reeves, Kansas City, "Placenta Praevia."——Dr. Russell E. Hobbs, Wichita, and other health officers conducted a discussion on "Immunization Measures and Demonstration of Schick Tests" before the Sedgwick County Medical Society, November 17, and Dr. Morton E. Brownell spoke on "Etiology and Treatment of Acute Iritis."

KENTUCKY

Society News.—The Hopkins County Medical Society was recently reorganized at Madisonville after several years of inactivity.——Members of the Daviess County Medical Society at a meeting in Owensboro, November 10, heard addresses by three Louisville physicians: Drs. James R. Stites, "Surgical Pathology of the Kidney"; Charles D. Enfield, "Urological Roentgenology," and Louis Wallace Frank, "Malignancy."——Dr. Hiram B. Weiss, Cincinnati, addressed the Campbell and Kenton County Medical Society, Dayton, November 19, on "Clinical Aspects of Coronary Disease."——At the fall meeting of the Fifth District Medical Society, Carrollton, November 12, speakers were three Louisville physicians: Drs. Philip F. Barbour, on "Pneumonia in Children"; Adolph O. Pfingst, "Fracture of the Skull as Related to the Eye," and Benjamin F. Zimmerman, "Encephalography and Ventriculography."

MAINE

Personal.—Dr. James A. Spalding, Portland, was given a complimentary dinner, September 25, by his associates. A portrait of Dr. Spalding was given to the Maine General Hospital in recognition of his service to that institution.

Society News.—The Penobscot County Medical Society was addressed, October 20, by Dr. Magnus F. Ridlon, Bangor, on surgical aspects of certain gynecologic conditions; two motion pictures with sound illustrated the talk.——Speakers who addressed the York County Medical Society, October 21, were Drs. Clinton N. Peters, Portland, on "Modern Urological Diagnosis"; Chester F. McGill, Portsmouth, N. H., "Posterior Occipital Presentation"; Lawrence R. Hazzard, Portsmouth, "Retrocecal Appendicitis," and George C. Wilkins, Manchester, "Uses of Radium."

MICHIGAN

Society News.—Dr. Raphael Isaacs, Ann Arbor, addressed the Wayne County Medical Society, Detroit, December 1, on "Present Status of Diagnosis and Treatment of Anemia."——The Oakland County Medical Society was addressed, November 19, in Pontiac, by Dr. Plinn F. Morse, Detroit, on "Comparative Anatomy and Development of the Kidneys and Their Clinical Application."

Personal.—Dr. Alvin H. Rockwell, for twenty-three years health officer and director of health and welfare of Kalamazoo, has offered his resignation, effective January 1.——Dr. William J. V. Deacon was elected president of the Michigan Public Health Association at its meeting in Lansing, November 11; Dr. John D. Monroe, Pontiac, vice president, and Miss Marjorie Delavan, Lansing, secretary.

Society Adopts Dime-a-Day Plan.—A sum of money will be donated to the Emergency Relief Fund of Detroit, through a dime-a-day plan recently adopted by the Wayne County Medical Society. A large box for contributions has been placed in the society's café, where an average of 100 members eat every day, and it is expected that more than $200 will be realized each month for donation to the fund.

Annual Clinic of Physicians' Club.—The sixth annual clinic of the Highland Park Physicians' Club was held at the Highland Park General Hospital, December 5. The program included papers by Drs. Carey Culbertson, Chicago, on "Management of Pelvic Infections, Acute and Chronic: Conservative and Operative Treatment"; Cyrus E. Burford, St. Louis, "Diagnosis and Management of Stone in the Kidney and Ureter"; John J. Moorhead, New York, "Practice of Traumatic Surgery"; Edwin M. Miller, Chicago, "Problems in Surgery in Children"; Harry S. Gradle, Chicago, "Etiology of Ocular Diseases"; Lee Wallace Dean, St. Louis, "Sinusitis in Children"; Albert Graeme Mitchell, Cincinnati, "Certain Phases of Nutrition in Childhood"; Marion A. Blankenhorn, Cleveland, "Neurological Aspects of Pernicious Anemia"; Frank H. Lahey, Boston, "Carcinoma of the Colon and Rectum: Its Diagnosis and Surgical Treatment," and Daniel L. Sexton, St. Louis, "Disorders of the Hypophysis." In the evening there was a stag buffet supper with entertainment.

NEW JERSEY

Society News.—The Essex County Medical Society held a demonstration clinic on syphilis at its meeting in Newark, November 12, in which the participants were Drs. Harrison S. Martland, Charles Englander, Francis J. McCauley, Newark, and Arthur J. Casselman, Camden.——Dr. Henry L. Bockus, Philadelphia, addressed the Camden County Medical Society, Camden, November 3, on diarrhea.——Dr. Nicholas M. Alter, Jersey City, addressed the Hudson County Medical Society, November 4, on "Practical Aspects of Nephrosis."——Dr. Mather Cleveland, New York, addressed the Bergen County Medical Society, Hackensack, October 16, on "Orthopedic Treatment of Poliomyelitis."——Dr. George M. Dorrance, Philadelphia, addressed the Cumberland County Medical Society, Bridgeton, October 13, on traumatic surgery.——Dr. Wells P. Eagleton, Newark, spoke on "Traumatism of the Frontal and Temporal Regions in Relation to Meningitis" before the Middlesex County Medical Society, Perth Amboy, October 21.——Dr. Henry W. Cave, New York, addressed the Passaic County Medical Society, Paterson, October 8, on "Difficulties Encountered in Operations on the Common Bile Duct."——Among speakers at the annual meeting of the Tuberculosis League of New Jersey, Trenton, October 16, were Drs. Donald B. Armstrong, New York, on tuberculosis in children, and John Bennett Morrison, Newark, "Rôle of the Physician in the Tuberculosis Fight."

NEW YORK

Grade B Raw Milk Abolished.—After July 1, 1932, grade B raw milk will be discontinued in New York. This grade was established in 1928 as a temporary measure to allow producers an opportunity to have their herds tuberculin tested. Its requirements were exactly the same as those for grade A raw milk except that such milk was not required to be from tested cows. In view of the fact that only a small amount of this grade of milk is now being sold, the Public Health Council, November 11, amended the sanitary code to eliminate it, effective July 1, 1932, thus allowing time for the testing of the remaining herds supplying this grade of milk.

County Society Celebrates One Hundred and Twenty-Fifth Anniversary.—The Medical Society of the County of Albany held its one hundred and twenty-fifth annual meeting at a dinner in Albany, October 28. Dr. George W. Crile, Cleveland, made an address on the evolution of the nervous system. Dr. Charles K. Winne, Jr., president of the society, gave an historical summary of the regulation of the practice of medicine in New York since the seventeenth century. Dr. William D. Johnson, Batavia, president of the Medical Society of the State of New York, and Mayor Thacher of Albany also addressed the meeting. Twelve former presidents of the society were present, including Dr. Frederick C. Curtis, Albany, who held the office in 1878.

Society News.—Dr. Royal H. Mayhew, among others, addressed the Franklin County Medical Society, Malone, October 28, on "Home Treatment Versus Sanatorium Treatment in Pulmonary Tuberculosis."——The twenty-fifth annual meeting of the fourth district branch of the Medical Society of the State of New York was held in Glens Falls, October 21-22. The speakers included the following: Dr. Wilder G. Penfield, Montreal, on "Neurology in General Practice—Early Diagnosis of Remediable Lesions"; Dr. Samuel T. Orton, New York, "Obstacles to the Development of Language Function in Children," and Dr. Walter J. Craig, Albany, "The State Orthopedic Program," and John R. Parker, Schenectady, "The Lawyer and Physician in Welfare Work."——Dr. Earl Dorland Osborne, Buffalo, addressed the Schoharie County Medical Society, Cobleskill, October 13, on "Common Skin Diseases, Exclusive of Eczema."——Dr. Arthur B. Soule, Jr., of the University of Vermont School of Medicine, Burlington, among others, addressed the Medical Society of the County of Washington, Hudson Falls, October 6, on "Studies of the Renal Function."——Dr. Clayton W. Greene, Buffalo, presented a paper on "The Medical Man's Attitude on the So-Called Acute Abdomen" before the Genesee County Medical Society, Batavia, October 26.——Four New York physicians presented a symposium on cancer at a meeting of the Yonkers Academy of Medicine, November 18, as follows: Drs. William P. Healy, "Diagnosis and Treatment of Cancer of the Female Genital Organs"; Ralph E. Herendeen, "Indications for Roentgen-Ray Therapy"; Frank E. Adair, "Treatment of Primary Operable Cancer of the Breast," and George T. Pack, "Melanomas and Pigmented Nevi."——A series of lectures on traumatic surgery was sponsored by the Wayne County Medical Society at Lyons during October and November, with the following speakers: Drs. Henry H. Ritter, New York, on injuries to the head; Henry M. Bergamini, internal injuries; David Goldblatt, burns; Emmett A. Dooley, infections and wounds of the hands, and Seth M. Milliken, common fractures.——Dr. Foster Kennedy, New York, addressed the Medical Society of the County of Nassau, Mineola, November 24, on "Head Injuries."

New York City

Faculty Changes at Columbia.—Dr. Allen O. Whipple has been appointed to the Valentine Mott professorship of surgery, which was recently established at the College of Physicians and Surgeons, Columbia University, and Dr. Israel S. Wechsler has been promoted to the professorship of clinical neurology. Dr. Russell A. Hibbs has resigned as professor of orthopedic surgery.

Personal.—Dr. Alfred F. Hess was recently elected to honorary membership in the German Pediatric Society.——Dr. William S. Ladd, formerly on the faculty of the College of Physicians and Surgeons, Columbia University, has been appointed assistant professor of medicine and associate dean of Cornell University Medical College.——Dr. Clyde Wilson Collings was made an honorary member of the French Urological Association in October, when he addressed the annual congress on "Relief of Bladder Neck Obstruction by Electrosurgery."

Gifts for Research.—New York University has recently announced the following gifts for medical research:

Commonwealth Fund, $5,000 for research in rheumatic fever under direction of Dr. William H. Park; $1,750 to Dr. Park for investigation on antipneumonia serum; $1.750 for the Clinical Pediatrics Research Fund in Pneumonia, under direction of Dr. Charles Hendee Smith.

Harriman Research Fund, $8,750 additional for that fund.

Anonymous donor, $10,000 for the Neurological Research Laboratory Fund.

R. T. Crane, Jr., $5,000 for the department of therapeutics.

International Committee for Study of Infantile Paralysis, $3,000 for study of infantile paralysis under Dr. Park.

Josiah Macy, Jr., Foundation, $3,000 for study of chorea under Dr. Smith.

Chemical Foundation, $1,000 for research on pneumonia.

Health Products Corporation, $1,000 for the Pernicious Anemia Fund.

Oxygen Penthouse.—A penthouse containing two oxygen chambers and a room for the treatment of dust asthma and hay fever has been completed on the roof of the Presbyterian Hospital. The oxygen chambers are equipped for the treatment of patients with pneumonia, cardiac failure and other diseases in which the lungs are affected. A dust filtering apparatus has been installed for the treatment of cases of asthma and hay fever. Oxygen is supplied from a central station, with a separate station for the use of carbon dioxide therapy in conjunction with oxygen therapy. The atmosphere is under thermostatic control. These rooms are for private and semiprivate patients, representing an addition to the oxygen chamber in the hospital proper. The chambers are the gift of Dr. Herman B. Baruch; the building itself was erected by the hospital.

Lectures on Social Problems of Tuberculosis.—The New York Tuberculosis and Health Association is sponsoring a series of lectures in cooperation with the New York School of Social Work on "Current Significance of Tuberculosis as a Social Work Problem." Lectures have been given by Louis I. Dublin, Ph.D., November 10, on trends in the past twenty-five years and possible effects of the present economic situation; Dr. Iago Galdston, November 19, etiology and immunity and different forms of tuberculosis; Dr. James Burns Amberson, Jr., November 24, diagnosis and complications of the disease and Dr. Grant Thorburn, December 1, treatment. Bailey B. Burritt, director, Association for Improving the Condition of the Poor, will speak, December 8, on "Tuberculosis and the Family"; Dr. Dwight Clifford Martin of the city department of health, December 15, "Administrative Control of Tuberculosis in New York City," and Dr. Linsly R. Williams, president of the tuberculosis and health association, December 22, on "Opportunity of the Social Worker to Help Control Tuberculosis."

NORTH CAROLINA

Hospital News.—Laurel Hospital, White Rock, in Madison County, has been closed by the Presbyterian Board of National Missions, after fifteen years' service. It was said that improvement in transportation and communication made the maintenance of a hospital in this once isolated region no longer necessary.——Physicians representing fourteen counties were guests of the Wayne County Medical Society, Goldsboro, at a meeting, October 3, at which Dr. Hubert A. Royster, Raleigh, spoke on treatment of wounds.

PENNSYLVANIA

Personal.—Drs. William H. Mayer, Pittsburgh, and Charles Falkowsky, Jr., Scranton, president and president-elect, respectively, of the Medical Society of the State of Pennsylvania, were guests of honor at a reception given by the Medical Club of Philadelphia, October 16.——Dr. James P. Roth has been appointed surgeon-in-chief of the Locust Mountain State Hospital, Shenandoah, succeeding the late Dr. Herbert H. Holderman.——Dr. Jesse L. Lenker, Harrisburg, was recently elected president of the Pennsylvania Heart Association.

Philadelphia

Society News.—Dr. Bernard Glueck, New York, addressed the Philadelphia County Medical Society, November 25, on "Principles of Psychoanalysis and the Practical Results That May Be Achieved Through This Procedure."——Dr. Basil R. Beltran delivered the postgraduate seminar of the Philadelphia County Medical Society, November 20, on "Surgery of the Vascular System." Dr. Robert G. Torrey gave the lecture, November 27, on tuberculosis.——The forty-fifth annual dinner of the Association of Ex-Resident and Resident Physicians of the Philadelphia General Hospital was held, December 1, at the Pennsylvania Hotel.

Personal.—Dr. Emily Lois Van Loon has been appointed acting head of the department of otolaryngology and bronchoscopy at the Woman's Medical College of Philadelphia, succeeding the late Dr. Margaret F. Butler.——Dr. David H. Bergey, formerly professor of hygiene and bacteriology, University of Pennsylvania School of Medicine, has been appointed director of research in biology for the National Drug Company.——Ernest Fullerton Cook, Pharm.M., of the Philadelphia College of Pharmacy and Science, was tendered a testimonial dinner, November 16, at which he was presented with the Remington Medal for 1931 (THE JOURNAL, August 1, p. 329). The dinner was given under the joint auspices of the New York and Philadelphia branches of the American Pharmaceutical Association.

Alvarenga Prize Awarded.—The Alvarenga Prize of the College of Physicians of Philadelphia for 1931 has been awarded to Dr. Edgar S. J. King, Melbourne, Australia, for an essay entitled "The Nature of the Stroma of the Ovary." The next award of this prize, which amounts to about $300, will be made July 14, 1932. Essays may treat any subject in medicine but must not have been printed previously or presented in competition for any prize. They must be sent without signature, marked with a motto and accompanied by a sealed envelop containing the name and address of the author. Entries must be received by the secretary of the college by May 1, 1932. Winners of the Alvarenga Prize in recent years have been Drs. H. A. Harris, University College Hospital, London; George M. Dorrance, Philadelphia; J. R. Paul and William U. McClenahan, Philadelphia.

TEXAS

Personal.—Dr. Lorenzo P. McCuistion, Paris, has been selected as the 1931 recipient of a certificate of distinction awarded annually by the Winfield F. Brown post of the American Legion at Paris to a distinguished citizen of the town. Dr. McCuistion, a native of Lamar County, was graduated from the Kentucky School of Medicine in 1889 and has spent all his professional life in Paris. In 1912, with other Paris citizens, he established the Sanitarium of Paris, of which he is physician in charge.

Society News.—Dr. Andrew G. Cowles, San Antonio, addressed the Bexar County Medical Society, October 1, on "Value of Complete Urologic and Gynecologic Examination."——Drs. Harry G. Walcott and Ben R. Buford, Dallas, addressed the Coleman County Medical Society, Coleman, October 1, on "Abdominal Conditions Producing Heart Symptoms" and "Heart Conditions Producing Abdominal Symptoms," respectively.——Dr. Waldo B. Lasater, Mineral Wells, among others, addressed the Palo Pinto County Medical Society, October 5, on "Resuscitation of the New-Born."

WEST VIRGINIA

Society News.—Dr. Raleigh R. Huggins, Pittsburgh, addressed the Ohio County Medical Society, Wheeling, November 20, on "The Present State of Conservatism in the Treatment of Salpingitis." Dr. George W. Crile, Cleveland, addressed the society, November 6, on "Emergencies in Medical and Surgical Practice."

Hospital News.—A new $100,000 hospital with a capacity of sixty beds was completed at Keyser in October. The new building, known as the Potomac Valley Hospital, is owned by Drs. Thomas E. and Robert W. Bess, replacing the old Hoffman Hospital. It is fully equipped for laboratory and roentgenray work and maintains a nursing school as well as a course for laboratory technicians.——St. Joseph's Hospital, Parkersburg, has recently taken possession of a new $500,000 building with a capacity of 100 beds, 12 more than in the old building.

GENERAL

Foundation to Advance Psychoanalysis.—The American Psychoanalytic Foundation has recently been formed in New York for the purpose of fostering psychoanalytic education and science in America. The foundation is incorporated in the state of New York and succeeds the Educational Trust Fund formed by the New York Psychoanalytic Society several years ago. The board of directors of the new organization includes Dr. Abraham A. Brill, chairman, Dr. Smith E. Jelliffe, Mr. Leo S. Bing, Mr. Sam A. Lewisohn and Dr. Clarence P. Oberndorf, 112 West Fifty-Ninth Street, New York, secretary. Mr. Alfred L. Rose is counsel for the foundation.

Annual Seal Sale for Tuberculosis.—The National Tuberculosis Association, through its 2,084 constituent state and local societies, began its twenty-fifth annual seal sale, Thanksgiving Day. Tuberculosis still causes the greatest number of deaths of persons between 15 and 45, the association's statistics show. The first sale of tuberculosis seals yielded only a little more than $3,000; the amount raised by this method in 1930 was $5,300,000. During this quarter century more than 500 sanatoriums have been constructed; clinics for early diagnosis and preventoriums for early care have been established; the tuberculin test and the diagnostic use of the roentgen ray have been brought to a high degree of efficiency, and methods of educating the general public have been developed.

Leslie Dana Medal Awarded.—The Leslie Dana Gold Medal, awarded annually for "outstanding achievements in the prevention of blindness and the conservation of vision," was presented to Edward M. Van Cleve, New York, principal of the New York Institute for the Education of the Blind, at a meeting in St. Louis, November 20. Mr. Van Cleve was selected by the National Society for the Prevention of Blindness in cooperation with the St. Louis Society for the Blind, through which the medal is offered by Leslie Dana, St. Louis. Mr. Van Cleve assisted in the formation in 1915 of the National Society for the Prevention of Blindness, sponsored by the Russell Sage Foundation, and became its first managing director, a position he held for nine years. At one time he was president of the Ohio State Commission for the Blind and, in 1907, was superintendent of the Ohio State School for the Blind. The medal was awarded last year to Dr. George E. de Schweinitz, Philadelphia.

Obstetricians Amend Constitution to Increase Membership.—At the third annual meeting of the Central Association of Obstetricians and Gynecologists in Chicago, October 28-31, the constitution of the association was amended to permit the admission to membership of physicians, resident in states which operate wholly or in part on Central standard time. Through this action physicians resident in Indiana, Michigan, Oklahoma, Ohio, North Carolina and Georgia become eligible to membership provided they (1) are in good professional standing, (2) have been graduated for five years or more, (3) have had special training in obstetrics and gynecology, and (4) have their major interests in the specialty. Dr. Rudolph W. Holmes, Chicago, was installed as president of the association at this meeting, and Dr. Percy W. Toombs, Memphis, Tenn., made president-elect; Dr. Jennings C. Litzenberg, Minneapolis, was elected vice president, and Dr. Everett D. Plass, Iowa City, reelected secretary.

Inventors of Respirator Receive Award.—Philip Drinker, assistant professor of ventilation and illumination, and Louis Agassiz Shaw, instructor in physiology, Harvard School of Public Health, Boston, joint inventors of the "Drinker respirator," received the John Scott Award administered by the

Philadelphia Board of City Trusts at a meeting at Franklin Institute, November 18. Each received a copper medal, and the honorarium of $1,000 was divided between them. The fund for the John Scott Award was given to the city of Philadelphia under the terms of the will of John Scott, a chemist of Edinburgh, Scotland, who died in 1816, to reward those whose inventions "add to the comfort, welfare and happiness of mankind." Among those who have received the award for medical work within recent years have been Drs. Afranio do Amaral of the Antivenin Institute of America, Alfred F. Hess, New York, and Francis Peyton Rous, New York, in 1927, and W. T. Bovie, Ph.D., professor of biophysics, Northwestern University, Chicago, in 1928. The Drinker respirator, which was perfected in 1930, has been used in the treatment of infantile paralysis, drowning, asphyxiation, electrical shock and drug poisoning. Mr. Drinker is the son of Henry S. Drinker, LL.D., Merion Station, Pa., former president of Lehigh University, and Mr. Shaw is the grandson of Louis Agassiz, famous educator and scientist.

Society News.—At the recent annual meeting of the Clinical Orthopedic Society, Dr. William Barnett Owen, Louisville, was elected president; Dr. Rexford L. Diveley, Kansas City, Mo., vice president, and Dr. Eugene B. Mumford, Indianapolis, reelected secretary. The next annual meeting of the society will be held in Chicago.——The American Society for the Study of Arthritis met in Pittsburgh, December 3-4. At an open meeting, December 3, Dr. Reginald Burbank, New York, discussed "Streptococcic Complement Fixation Test in Arthritis" and Dr. Henry Warren Crowe, London, England, "The Pathogen Selective Blood Test as Applied in Arthritis."——The Mid-South Post Graduate Assembly, formerly Tri-States Medical Association of Mississippi, Arkansas and Tennessee, will hold its next annual meeting in Memphis, February 9-12. Dr. Arthur F. Cooper, Memphis, is secretary.——The second annual meeting of the National Conference on Nomenclature of Disease will be held, December 14, at the New York Academy of Medicine, New York.——Dr. Lewis J. Moorman, Oklahoma City, was elected president of the Southern Medical Association at the annual meeting in New Orleans, November 18-20. The association will meet in Birmingham, Ala., in 1932.——The next session of the Inter-State Postgraduate Medical Association of North America will be held in Indianapolis, Oct. 24-28, 1932.

Yellow Fever Volunteers Receive Congressional Medals.—The gold medals authorized by Congress in 1929 for the recognition of the late Dr. Walter Reed and his associates in the famous yellow fever experiments of 1900-1902 have recently been dispatched to the fifteen volunteers who are still living and to the heirs of the seven who have died, according to press reports. Each medal bears the name of the recipient on one side and the words "Conquest of Yellow Fever" on the other. Posthumous awards were for Drs. Reed, Aristides Agramonte, James Carroll and Jesse W. Lazear, who made up the army commission, and for Edward Weatherwalks, Warren G. Jernegan and William H. Dean. Medals were also sent to the following men:

John H. Andrus, Elmira, N. Y
John R. Bullard, Cuba.
A. W. Covington, Cohocton, N. Y.
Wallace W. Forbes, Minneapolis
Levey E. Folk, Columbus, Ohio
Paul Hamann, East Moline, Ill.
James L. Hanberry, Denmark, S. C.
John R. Kissinger, Huntington, Ind.
William Olsen, Los Angeles.
John J. Moran, Mexico City.
Charles G. Sonntag, Jackson, S. C.
Clyde L. West, Toledo, Ohio.
Dr. Robert P. Cooke, Lexington, Va.
Thomas M. England, Washington, D. C.
James Hildebrand, Atlanta, Ga.

Pensions of $125 per month were granted at the same time to all those on the latter list and to the widow of Private Weatherwalks.

CANADA

Hospital Council Organized.—A federation of all provincial, interprovincial, religious and other hospital associations in Canada, to be known as the Canadian Hospital Council, was organized in September. The aims and objects as outlined in the constitution include the following: (1) to coordinate activities of hospital organizations in Canada, (2) to study hospital problems and the relationship of the hospital to the public, (3) to cooperate with other agencies, (4) to study hospital legislation in Canada and (5) to form a nucleus from which may be formed later a Canadian Hospital Association if such a development should be deemed advisable. Dr. Fred W. Routley, Toronto, was named president of the council and Dr. George Harvey Agnew, Toronto, secretary.

Health Regulations Changed.—The department of health of Ontario has recently rewritten the regulations concerning communicable disease, making them conform to recent concepts of epidemiology and bacteriology. Under the new regulations forty-five diseases are notifiable, in comparison with forty-two on the previous list. Goiter and pellagra were removed from the list and five diseases were added, as follows: ancylostomiasis, erysipelas, infectious or epidemic jaundice, undulant fever and trench mouth. Placarding is no longer required for chickenpox, German measles and mumps. The isolation period for measles was shortened to seven days and immunes from quarantined homes are now allowed to attend school. Poliomyelitis contacts are now quarantined for ten days. The isolation period was also increased for smallpox and reduced for scarlet fever. Other regulations deal with the handling of milk, burial and transportation of the dead, and disinfection.

FOREIGN

Lectures of College of Physicians.—Dr. John S. Fairbairn delivered the Bradshaw Lecture before the Royal College of Physicians, November 3, on "Medical and Psychological Aspects of Gynecology." The Fitzpatrick Lectures were delivered by Dr. James S. Collier, November 5 and 10, on "The Development of Neurology from the Commencement of the Nineteenth Century to the Present Time."

New Journal on Maternity Problems.—A new monthly journal, the *Boletín de la Maternidad*, has recently appeared as the organ of the Department of Maternity Hospitals and Prenatal Clinics of the Sociedad de Beneficencia Pública of Lima, Peru. Drs. H. Larraburc and N. Cavassa are the editors. The first and second issues, July and August, contain articles on obstetrics, infant mortality, infant psychology, mental hygiene, statistics of the maternity hospital of Lima, and general news.

Memorial to Sir Charles Hastings.—The British Medical Association has opened a fund to establish a memorial to its founder, Sir Charles Hastings, in celebration of its centenary, which occurs in 1932. A stained glass window in his honor will be placed in the cathedral at Worcester, the city with which Hastings was most closely identified; a tablet will be placed on the house in Worcester where he practiced, and his grave in the Astwood cemetery in that city will be restored and cared for. Any balance remaining after these objects have been attained will be turned over to the Sir Charles Hastings Fund, the income of which is distributed for the benefit of members of the medical profession and their dependents according to the discretion of its trustees. The opening ceremony of the centenary meeting of the association will be a pilgrimage to Worcester, July 24, 1932, when the memorial window and plaque will be unveiled.

Course in Ophthalmology.—The ninth graduate course in ophthalmology given under the auspices of the American Medical Association of Vienna will be offered between Oct. 1 and Dec. 6, 1932, at the I and II Eye Clinic of the Allgemeines Krankenhaus, Vienna. Lectures will be given by Prof. Josef Meller and Prof. Karl Lindner, chiefs of the clinics, as well as other members of the staff. Members of other departments will lecture on their respective subjects, including roentgen rays, the hypophysis and sinuses, endocrine disturbances, radium treatment, embryology and the modified West operation. This course, which was originated ten years ago at the suggestion of Dr. Edward Jackson, Denver, is given in English for a minimum of ten and a maximum of seventeen physicians, at a fee of $250 each. A preliminary knowledge of ophthalmology is presupposed. Applications with a certified check for $100 should be sent to Dr. Adalbert Fuchs, Vienna VIII, Skodagasse 13. Further information may be obtained from Dr. Fuchs or from the American Medical Association of Vienna, Alserstrasse 9, Café Edison.

Society News.—Physicians who wish to participate in the International Congress of Tropical Medicine to be held in Amsterdam, Sept. 12-17, 1932, are requested to notify the secretary, Dr. E. P. Snijders, Institute for Tropical Hygiene, Amsterdam, not later than December 31.——The Third International Congress of Sanitary Technics and Urban Hygiene will be held at Lyons, France, March 6-9, 1932. Information may be obtained from M. le Docteur Garin, Conseiller Municipal, Rue Ménestrier, Lyons.——The Ninth International Congress of the History of Medicine will be held in Bucharest in September, 1932. The principal subjects for discussion will be the evolution of medicine in the Balkan states and the protection of Europe against bubonic plague. Those wishing to contribute papers are requested to forward the title and a summary of the paper to the office of the congress, Str. Stirbey Voda, 86, Bucharest II, without delay.——The ninth congress of the International Society of Surgery will be held in Madrid, March 15-18, 1932, under the presidency of Dr. Quervain. Topics for discussion will be: diagnosis and treatment of intraspinal tumors, nontuberculous suppurations of the lung, surgery of the esophagus, and recent progress of anesthesia in surgery.

Government Services

Col. Skinner Wins Wellcome Medal

The Henry S. Wellcome medal and prize of $500 have been awarded to Col. George A. Skinner, chief surgeon, seventh corps area, U. S. Army, Omaha, for a paper on "The Influence of Epidemic Disease on Military Operations in the Western Hemisphere." The award was to be made during the annual meeting of the Association of Military Surgeons of the United States, New Orleans, November 30-December 2. The Wellcome award was established in 1916 to encourage study and research on problems connected with the health of armies and the efficiency of the medical services. The competition is open to all medical officers, former medical officers, acting assistant and contract surgeons of the army, navy, health service, national guard, volunteers and reserves and commissioned medical officers of foreign military services.

Annual Report of Surgeon General of Army

Automobiles were the leading cause of death in the United States Army in 1930, according to the annual report of Surg. Gen. Robert U. Patterson. If it had not been for the material increase in the number of deaths from automobile accidents, the mortality rate for the year would have been the lowest on record. All but eleven of the seventy-two deaths from this cause occurred in privately owned cars. Suicides, which, during eight of the preceding nine years, had led the list, were second, and tuberculosis was third, with drowning and cancer in fourth and fifth positions. The average daily strength of the army was 137,299. There were 50,910 enlistments in 1930 as compared with 61,898 in 1929. The annual hospital admission rate from all causes (608 per thousand men) was the lowest recorded in the history of the army. The most notable advance was in the control of communicable diseases, and especially of those transmitted through the gastro-intestinal tract: typhoid, diarrhea and dysentery. The leading causes of admission were bronchitis, gonorrhea, acute tonsillitis, athletic exercises and chronic tonsillitis. The number of malarial fevers was reduced to less than 800 in each hundred thousand men. During the year, 1,546,786 days were spent by the military personnel on sick report, as compared with 1,551,915 in 1929. Of the average 6,815 patients in hospital each day, 62 per cent were in general hospitals, the cost per patient day having been $5.07, a decrease of $0.14 as compared with that of the previous year. The average daily noneffective rate from disease was 30.9 as compared with 31.3 in 1929 and 30.2 in 1928, and the leading causes were gonorrhea, tuberculosis, syphilis, athletic exercises and automobile accidents. The leading causes of disability were dementia praecox, tuberculosis, constitutional psychopathic state, mental deficiency and pes planus. The admission rate (47.7) for venereal diseases was the lowest in the history of the army; the group caused 7.9 per cent of all admissions to hospitals and quarters, 16.3 per cent of the loss of time on account of sickness, 4.6 per cent of the discharges for disability, and about 2 per cent of the deaths. Since the inauguration of the campaign for the prevention of venereal disease in 1909, the army rate has been reduced 73 per cent. The rate for influenza was the lowest recorded since 1888. The report exhibits the vital statistics of the regular army for the calendar year ended Dec. 31, 1930, and covers the general activities of the medical department for the fiscal year ended June 30, 1931.

Typhoid at Fort Des Moines

The first explosive outbreak of typhoid in the United States Army since the close of the World War occurred during October in Battery E, Seventeenth Field Artillery, Fort Des Moines, Iowa, according to the surgeon general's monthly review of the health of the army. Between September 22 and October 31, twenty probable cases of typhoid were admitted to the hospital. Specimens for examination were sent to the Sixth Corps Area laboratory at Fort Sheridan, Illinois, and to the Army Medical School. A report, November 7, showed eighteen cases diagnosed as typhoid and two as fever undiagnosed. All the patients had been inoculated. No deaths had occurred up to the time of the report.

Vitamin Standards and Units

A conference of scientific investigators has been held in London under the auspices of the health organization of the League of Nations to consider the establishment of an international standard for the vitamins, defining for each vitamin an arbitrary unit of activity and methods of testing. The members of the conference were drawn from several European countries and the United States. The first question was whether to define in terms of a biologic test or a standard substance. The latter was unanimously adopted.

VITAMIN D

The preparation of irradiated ergosterol (viosterol) already issued from the National Institute of Medical Research was chosen as the international standard for vitamin D. This has been used for more than a year as vitamin D standard in Great Britain. At room temperature it loses potency, but it has been found to remain stable for two years when preserved at 0 C. in the absence of air. The method of preparing the standard solution was defined, and it was agreed that when renewal became necessary laboratories in different countries should cooperate in comparing the new standard solutions with the old so as to insure equivalence. The unit of vitamin D was defined as the activity of 1 mg. of the international standard solution of irradiated ergosterol. If the vitamin is isolated in pure crystalline form during the next few years, the international unit can be redefined in terms of this form.

VITAMIN A

Two substances suggested themselves as standards for vitamin A—cod liver oil and carotene. The fact that the oil, particularly when first expressed, undergoes a loss of vitamin A from oxidation impairs its suitability as a standard. But after a few years further change is slow. Pure carotene, which is transformed into vitamin A in the liver, produces the physiologic effects of vitamin A when given in very small doses. Little is known as to the stability of carotene in respect to its vitamin A action. The fact that it consists of two isomers is of little importance, for they have been found to possess almost similar biologic activity. The conference recommended the adoption of carotene temporarily as an international standard for vitamin A, with a selected sample of cod liver oil as a second provisional standard. Further investigation will be necessary before the permanent reliability of carotene is assured. The carotene is to be made from a number of pure samples prepared in certain specified laboratories by Willstater's method. The unit is the vitamin potency of 0.001 mg. of the resulting mixture.

VITAMIN B

The absorption product prepared in the Medical Laboratory, Java, by the method of Seidell is to be the standard for the antineuritic vitamin B. It is made by extracting rice polishings with dilute sulphuric acid and treating with fullers' earth. The earth with the vitamin adsorbed forms the standard substance. As far as is known, loss of antineuritic vitamin does not occur even when the dry preparation is kept at room temperature for some years. But moisture must be avoided or bacterial decomposition will take place. The material has the disadvantage of being a complex substance and probably contains other B vitamins. The unit is the antineuritic value of 10 mg. of the adsorption product.

VITAMIN C

A suitable standard of reference for vitamin C appears to exist ready made. It has been found that the juice of oranges and lemons varies little in vitamin C potency from year to year. The unit is the activity of 0.1 cc. of fresh juice of the lemon, Citrus limonum.

METHODS OF BIOLOGIC ASSAY

The merits of the different methods of biologic assay were not discussed at any length. The substance under examination and the standard preparation are tested simultaneously by the same method. The test substance should therefore show the same value in terms of the standard, whatever the technic. Thus, for vitamin D tests the conference decided that the "line" test, roentgen examination and determination of bone ash are all equally reliable.

The Evils of Medical Socialism

The scheme of the British Medical Association for a national medical service that would provide treatment for every class and cover the whole field of preventive and curative medicine was described in a previous letter (The Journal, May 17, 1930, p. 1612). After the crushing defeat of the socialists in the general election and with the stringent economy and overtaxation rendered necessary by their prodigal expenditure, such extension of the medical socialism of the insurance act is not to be feared for the present. In an address to the Windsor and District Medical Society, Sir Ernst Graham-Little, dermatologist and member of parliament for London University, criticized the association's scheme. He said that it would perpetuate and indeed aggravate the radical defect of the present insurance act—the restriction of insurance benefits to what was described in the act as "general practitioner treatment." This was one of the principal reasons for the dissatisfaction of the insured with the service supplied. Sir Arthur Newsholme, formerly principal medical officer to the local government board, obviously no unfriendly critic, described that service in a recent address as "representing in many ways an obsolete ideal of medicine." The drastic reduction of the capitation fee of panel physicians has been described in previous letters. The medical profession had been able to meet this cut with something like equanimity, because panel practice was not the sole resource of the majority of practitioners. "The problem of the outpatient at the voluntary hospitals" had arisen. Partly as the result of dissatisfaction of insured persons with the national insurance service, the number of outpatients at all the hospitals throughout the country has risen continuously during the last decade, and the remarkable position has come about that, notwithstanding a health insurance involving compulsory contributions and therefore no expense on receiving treatment, which was confidently expected to deplete our outpatient departments, the attendance has risen continuously since 1920 until it now exceeds the figure before the act came into operation. The suggestion that the hospitals should receive only such patients as were countenanced by physicians acting under the orders of the British Medical Association was a complete misapprehension of the situation. As the expenses of the hospitals were met by the general public, such an assumption of authority would not recommend itself to those who supported the institutions, who were now largely the working classes themselves.

London's Biennial Epidemics of Measles

It is curious that epidemics of measles occur regularly in London at intervals of two years. They begin in the late autumn, reach a maximum in March, and take some six or seven months to complete the circle of London. Sporadic cases occur the interepidemic periods, especially in centers of overcrowdg, but not until sufficient susceptible material has accumulated are the conditions ripe for starting a new epidemic. The last one occurred in the autumn and winter of 1929-1930 and the next is therefore due this autumn. In each epidemic, no fewer than 50,000 children are attacked. As this number is too great for hospital treatment, the public health committee of the London county council encourages home nursing when it can be carried out under favorable conditions. Indeed, it is difficult to say at the moment whether the council will have at its disposal sufficient accommodation in its fever hospitals to cope with the cases that may require hospital treatment. If not, it will be necessary to call on the general hospitals for assistance during the period of greatest pressure, February to April, 1932. The committee points out that in spite of such propaganda in recent years the belief still prevails that the disease can be lightly regarded and can be treated without medical advice or skilled nursing. The fact is that in the past four years, measles has caused eight times as many deaths as scarlet fever and one and one-half times as many as diphtheria. The London county council and the metropolitan borough councils are taking every precaution to cope with the imminent epidemic. The following advice has been issued: 1. Every effort should be made to postpone the contraction of the disease until after the third or preferably the fifth year, for the younger the child the greater the danger of serious complications. 2. Adequate medical, nursing and hygienic care are the most important means for preventing the complications and a fatal issue. 3. The disease is particularly fatal among children undernourished and living under unfavorable conditions. Special methods of control must be applied to prevent or ameliorate the disease in such children. The *Times* suggests that the best way to prevent infection of young children is to exclude those under the age of 5 years from Christmas or other parties, except perhaps family parties. Infection usually has its headquarters in the school. When school children come in association with infants, for example at Christmas time, the infection epidemic gathers force. If young children must go to parties they should associate only with those of the same age, under the school age.

PARIS

(From Our Regular Correspondent)

Oct. 28, 1931.

The French Congress of Hygiene

Among the topics on the program of the eighteenth French Congress of Hygiene this year was the protection of civil populations, in time of war, against war gases. Sieur, *médecin inspecteur général,* did not hesitate to say that, in spite of solemn agreements entered into by the nations of the world, it was likely that they would have recourse to the use of these gases, in case of war, without the least scruples. In the countries bordering on France, there are no doubt large supplies of gas shells—likewise in Russia. The accident that occurred in a Hamburg plant, a few years ago, costing the lives of some thirty persons, through the escape of phosphine gas, is evidence of the fact. Furthermore, all the chemical manufacturing plants that produce nitrogen compounds to be used as fertilizers can be equipped within a few hours for the intensive production of war gases. Professor Messerli of Lausanne projected some interesting illustrations, taken from German and Russian magazines, showing the drills to which the civil populations are periodically subjected in order to become accustomed to the wearing of masks for protection against war gases. Colonel Laure, representing le maréchal Pétain, explained a system of preventive measures to be adopted in case of a gas attack: rapid evacuation of the population, creation of shelters supplied with properly filtered air, masks of various kinds, special hospitals for the treatment of gassed persons, and the like. Mr. Marcelle presented a new style of mask. Professor Parisot of Nancy gave an account of a gas mask drill that was recently held in that city for the purpose of accustoming the population to the wearing of a gas mask. He recommended that police officers, firemen and hospital nurses be given, in time of peace, special instruction that would enable them to render intelligent aid to victims. There were also long discussions on the rôle of hygienists in connection with the new law pertaining to social insurance. Mr. Dequidt, *inspecteur général,* Professor Parisot, Dr. Boulangier, Dr. Pigot and Mlle. Chaptal presented communications dealing with the topic. Dr. Cuvier spoke on the collective organization of donors for blood transfusion. Dr. Grasset discussed the question of antityphoid serotherapy. Carrieu and Pappas spoke on the rôle of mollusks and other shell fish in the transmission of typhoid. The congress was prolonged in order to afford the conventionists an opportunity to inspect carefully the pavilions of the Colonial Exposition, where were displayed many documents pertaining to colonial hygiene and to the crusade against tropical diseases.

The French Gynecologic Congress

The congress of the Association des gynécologues et obstétriciens de langue française met recently at Bordeaux under the chairmanship of Prof. Jean-Louis Faure. In his inaugural address, Professor Faure urged his colleagues to seek to simplify the technic of important gynecologic operations and to improve the instrumentation so as to reduce to a minimum the number of aids and assistants that a surgeon requires. Mr. Cotte of Lyons presented a paper on radiologic diagnosis in gynecology, the first question on the program, considering in turn pneumoperitoneum and the injection of iodized oil into the uterus and the tubes. He considers the last-mentioned method valuable for the testing of tubal patency and the diagnosis of sterility in women. Inflammatory accidents of the tubes constitute 0.43 per cent. Injections into a hemorrhagic uterus should be avoided for fear of embolism. The second paper was that of Mr. Henrotay of Antwerp, who spoke on obstetric roentgen diagnosis—roentgen pelvimetry, which is difficult and does not permit the measurement of the fetal head; early diagnosis of pregnancy, which is possible only with the beginning of the fifth month but which is of great value from the medicolegal point of view; diagnosis as between pregnancy and tumor, which is often useful; diagnosis of a twin pregnancy, only with the beginning of the sixth month; diagnosis of the death of the fetus through demonstration of overlapping of the bones of the fetal cranium; and ectopic pregnancy associated with the injection of iodized oil. In the discussion that followed, Mr. Douay of Paris, who has made 709 explorations with iodized oil and 576 insufflations, declared that the results are essentially the same with the two methods. Each gave him from 8 to 10 per cent of pregnancies during the year that followed the examination. The only danger is infection in case of hydrosalpinx. A third paper was furnished by Hamant of Nancy and Koenig of Geneva, on the social means of discovering cancer of the uterus. In the treatment of this form of cancer great progress has been made. Unfortunately, in 50 per cent of the cases the patients do not consult a physician until the lesions are too far advanced. Ordinarily, it may be said that uterine cancer is incurable after the lapse of from five to six months after the appearance of its first signs. The essayists recommended that physicians familiarize themselves with the early signs of uterine cancer and advised every woman more than 30 years of age to be examined at least every year—better would be every six months. Especially women who have presented, since confinement, lacerations of the cervix, and those who have had numerous pregnancies, should be examined periodically, for which purpose convenient anticancer centers should be created and the attention of the public called to them.

A fourth paper, on "Late Hemorrhages of the Postpartum Period," consisted of two parts, one part being presented by Anderodias and Péry of Bordeaux, and the other by Professor Couvelaire of Paris. Grave hemorrhages are caused chiefly by an infection. Others yield to ergotine, hot intra-uterine injections and uterine massage. Couvelaire considers curettage dangerous or ineffective. He prefers medical treatment, local or general vaccines, and, if need be, hysterectomy, which results, it is true, in 50 per cent of mortality; but it is resorted to only in cases that would otherwise result fatally. Mr. Keller of Strasbourg recommends, as a prophylactic measure, careful examination of the uterine cavity after every confinement. Numerous unofficial communications were then presented—on the examination of the urine for the presence of the hypophyseal hormone as a method for early diagnosis of pregnancy; on the use of the B C G vaccine in normal new-born children, on the use of diathermy in gynecology, and others.

The French Society of Gynecology

Every year the Société française de gynécologie holds a plenary session at which many important questions are discussed, with the aid of foreign scientists. The first paper was presented by Mr. Ulrich on "The Chemism of the Vagina and Its Physiologic Significance." He pointed out that, in the whole economy, only the stomach and the vagina supply acid secretions, the vaginal secretion containing lactic acid. He then took up the dosimetric methods by which the vaginal acidity can be quantitatively determined; discussed the rôle that such acidity plays with respect to the vaginal microbic flora, and the origin and behavior of vaginal acidity during the life of the woman. He gave then one theory as to the genesis of this acidity and pointed out in closing that temporary or lasting constitutional hyperacidity of the vagina may be the cause of sterility.

In another paper, Mr. C. O. Guillaumin considered the best chemical conditions for the development of various germs in the vaginal secretions. In a third paper, Mr. Martin of Angers discussed the indications for various surgical interventions in the treatment of nontuberculous chronic salpingitis. He stated that gynecologists had become, in this field, much less inclined to operate than formerly—since cures had begun to be effected by diathermy, and radioscopic examination of the tubes into which iodized oil has been injected has made possible the determination of their patency. Among the unofficial communications presented, mention may be made of those that favor the return to vaginal hysterectomy (Violet); the criterion of recovery from gonorrhea in the woman (Bender); the treatment of colibacillary manifestations in the woman (Colanéri), and phlebitis and periphlebitis of uterine origin (Maurice Fabre).

The Thirty-First French Congress of Urology

The thirty-first Congrès français d'urologie was held, October 6, at the Faculté de médecine, under the chairmanship of Dr. Gauthier of Lyons. A single topic was on the program: "Postoperative Acidoses." Dr. Chabanier, in collaboration with Dr. Lobo-Onell of Santiago, Chile, presented a comprehensive introductory paper. After general statements on the notions of acidosis, the paper took up keto-acidosis in persons with true diabetes, keto-acidosis in persons without diabetes, and postoperative acidoses without ketosis. Christol of Montpellier and Chauvin of Marseilles presented their individual opinions on various questions. A large number of communications on various questions of urology were discussed at length.

Session of the Academy Devoted to Colonial Medicine

October 13, the regular session of the Academy of Medicine was devoted entirely to colonial medicine, in connection with the Colonial Exposition, which will soon close. The governors of the various colonies, present in Paris at the time, were on the platform in full dress; also several foreign scientists:

Sanarelli of Rome, Cantacuzène of Bucharest, Ricardo Jorge of Rio de Janeiro, Henrijean of Liége, and Madsen of Copenhagen. Professor Marchoux of the Institut Pasteur delivered an address on the present status of the question of malaria, with the indications for new drugs proposed to take the place of quinine, plasmochin and Fourneau 710. Mr. Mathis discussed the question of spirochetoses occurring in French West Africa. Mr. Mesnil spoke on trypanosomiasis, or the sleeping sickness. Mr. Dinguizli Bachir of Tunisia gave an account of the progress in that country in health work since the creation of a bureau of social hygiene.

International Congress of Women Physicians

The International League of Women Physicians, which draws its membership from twenty-six countries, assumed the task of studying some sociohygienic problems that women physicians regard as their special field of investigation. The International Congress of Women Physicians, held in Vienna under the chairmanship of the French woman physician Dr. Thuillier-Landry, attracted 200 participants. One of the topics was "The Work of the Woman Physician in Tropical Countries." Forty woman physicians from India, Persia, China, Japan, Egypt, Palestine and Africa submitted replies to the questionnaires sent out. The papers of Dr. Balfour of India and Dr. Garnier of Algeria gave an insight into the terrible hygienic conditions under which women live in tropical countries. As women physicians inspire great confidence almost everywhere, so long as they do not antagonize too sharply religious customs, a wide field of action is opened to them, particularly through the creation of consultation centers for mothers, maternity hospitals, eye policlinics, training of nurses and education of the people in hygiene.

LAWS FOR THE PROTECTION OF WORKING WOMEN

The papers of the second day, on "Laws for the Protection of Working Women," presented by Dr. Sorrentini of Rome, Dr. Bang of Oslo and Dr. Adler-Herzmark of Vienna, led to a lively discussion. The Scandinavian physicians and a portion of the English and American physicians, who support the "open-door" movement, are fighting, above all things, for the principle of equal rights for women, and therefore reject special protection through legislation. They contend that women with, for example, better pay for night work should look out for the preservation of their health themselves. The need of protecting pregnant women is not denied; but the period of protection should be regarded as a period of sickness and the sick benefits should be paid by the sick benefit associations. The better standard of living of the Nordic peoples has doubtless led to this attitude. According to the German conception, the protection of mothers is one of the chief forms of protection for working women, since without such protection they become worn out early in life through the double burden of the household and the work in a factory and are liable to become permanent invalids, and furthermore because certain industrial poisons, such as lead and benzene, injure the child in utero. Two German industrial women physicians (Krüger of Dresden and Rosenthal-Deussen of Magdeburg) called attention to the fact that the time is past when, for the sake of the principle of equal rights, the physiologic peculiarities of woman are denied. In view of the constraining force exerted by present economic conditions, it is the duty of women physicians to prevent selfish interests from exploiting the health and strength of women.

Since the greater percentage of working women are married, they take care of the home and the children. It is impossible for them to secure adequate rest. How is the pregnant textile worker to protect herself when the inexorable movements of the loom prevent her from resting between the tiresome bending and lifting? How is she to protect herself when constantly new machines and new poisons make their appearance in the industries? In view of the modest demands that women make on industry, there is danger that labor forces may be drawn into those countries that are most backward from a sociopolitical and sanitary point of view.

In closing, a resolution was adopted demanding the creation of uniform, international laws for the protection of labor; furthermore, supervision of industrial plants by specially trained industrial physicians, compulsory instruction of students in industrial hygiene and occupational diseases, far-reaching control of home work as it concerns men and women, and the carrying out of the principle of "Equal pay for equal work for men and women."

Retrenchment in Child Welfare Societies

The Deutsche Gesellschaft für Kinderheilkunde, filled with anxiety concerning the dire effects of threatened retrenchments in children's aid made necessary by the stringent economic conditions, issued at its recent meeting the following proclamation:

> With great anxiety German pediatricians look forward to the future of the German people. Already they observe in Germany and Austria conditions similar to those seen during the worst years of the war and postwar period: general debilitation, reduced resistance to disease, and increase of tuberculosis. As a result of economic distress, the birth rate has declined considerably. But—worse still—the small number of children born are seriously threatened in their development. And under these conditions, the organizations that have been slowly and laboriously built up to supply aid to sick children are to retrench? Are also hospitals to be closed; are sick children to be dismissed from hospitals before they are well, and are welfare centers to be abolished? In the face of such threatened action, the Deutsche Gesellschaft für Kinderheilkunde cannot remain silent. It warns against the great dangers that threaten the life and health of our children, and protests most decidedly against any ill planned restrictions on the aid to be given children in need. To be sure, retrenchments will be necessary; but they must not be introduced at the expense of our children, in whom lies the hope of the German people.

Suicide and Economic Conditions

It is recognized today that a large proportion of the cases of suicide are due to mental disease or to abnormal predispositions. In many countries there has been an increase of suicide since the end of the war, especially in the cities. Recent statistics represent Switzerland as having the highest percentage of suicide: 2.6 per 10,000 inhabitants; Germany with 2.5 suicides per 10,000 of population; Japan, 2.1; France, 1.9; United States, 1.6; England, 1.2, whereas in Italy, the Netherlands, Norway and Spain there is not 1 suicide per 10,000 of population. The percentage of men committing suicide has always been greater than that of women; but of late the percentage of women has been increasing, which may be due to the fact that women are more frequently engaged in occupational activities. Aside from the mental disposition of the population, no doubt the economic situation plays an important part, as Dr. Hans Dornedden, with the federal bureau of health, has emphasized in a recent number of the *Deutsche medizinische Wochenschrift.* The influence of the density of the population manifests itself in the fact that the suicide rate in the large cities is higher than elsewhere. Of especial significance was the trend of events after the war. In 1918, suicide among males of the wage-earning age groups dropped to half that of the last prewar year. The year of inflation (1923) brought a great many suicides among persons in the seventies, who through the depreciation of money values lost their means of subsistence. Later, however, suicide among aged persons became less than before the war, because the public welfare departments rendered aid to the aged. During the years 1926 and 1929, the frequency of suicide among men and women of wage-earning age was augmented because of the increased difficulty of securing employment. Thus, the statistics on suicide are, in a sense, a barometer of the economic conditions. But the typical curve of the suicide months, which reaches its apex in the spring and drops, toward the end of the year, to about two thirds of the maximum, is yet to be explained. While it is true that the suicide rate shows an increase as employment becomes more difficult to secure, there are other factors that are more stable than the fluctuations of economic life. For example, after the economic crisis of 1876-1885 it was observed that the high suicide rate did not decline when conditions improved, doubtless because the habit of seeking escape in this manner from the struggles of existence had first to be overcome. On the other hand, the lack of employment in 1931, even at its worst, has not affected the mentality of the people in such a manner that suicide has shown any great increase. It appears rather that the great difficulties have aroused the courage of the people and fitted them to struggle with unfavorable conditions. In this connection, it is observable that misfortunes and distress that rest more or less uniformly on all the people do not commonly bring about an increase of suicide. Individuals feel, under such circumstances, that they are part of an inseparable whole and are more inclined to resist the temptation to end their lives.

CAPE TOWN

Oct. 14, 1931.

The Annual Medical Congress

The twenty-fifth annual medical congress, the fourth held under the auspices of the Medical Association of South Africa, was opened at Johannesburg, September 14, and was attended by about 400 physicians from all parts of the Union and by delegates from Rhodesia, Kenya and the Congo. These annual medical meetings, first started in 1893 and now popular features of our medical life, are less scientific gatherings than social reunions of which advantage is taken by all medical men who can afford to take a holiday. Owing to the vast distances to be traversed and the difficulties of railway traveling the attendance is not usually representative, but this year's meeting may be said to have been fully representative both of the profession and of the medical association, in that 25 per cent of the association members turned up. As the association represents nearly 88 per cent of all practicing physicians in South Africa, this proportion is highly satisfactory. Translated into relative American figures, it would mean that some 40,000 medical men attended such a meeting in the United States. This success is largely due to the lure that Johannesburg has. It is the fourth time that the congress assembled there, the first meeting having been in the troublous time immediately succeeding the year of the Jameson raid, and the last in 1922. The first Johannesburg meeting is still talked of with enthusiasm by old members, for those were the days when it was still a city of adventure and romance. Today it is more sober, but none the less conscious that it is the economic and industrial hub round which the rest of South Africa turns. It does things on the grand scale, and the congress was no exception, for the program was so full that most of the members were utterly fatigued before the middle of the week was reached.

THE PRESIDENTIAL ADDRESS

The president of the congress was Dr. Francis Napier, one of the oldest and most respected specialists in the country, who in the past has done excellent service as a legislator. His subject for the presidential address was a highly controversial theme, "A State Medical Service," and opinions differ widely on the desirability of saying what he had the courage to say. He pointed out that there was a tendency to become too individualistic in the profession and that such rampant individualism constituted a danger to the public. His frank opinions have given rise to considerable discussion and some resentment. Many feel that some such pronouncement should be made in the interests of all concerned. We are now training our own medical men, and it is possible that we are trying far too much to train them in the direction of making immature specialists out of them instead of endeavoring to shape them into good general practitioners. In isolated rural areas the general practitioner must undertake emergency operative work when he is faced with it, but unfortunately many general practitioners do major operations for which they have neither the experience nor the training. The adumbration of a state medical service is hardly a fit subject for such an oration, but the choice may be excused because the profession has been much intrigued by the various proposals made to give adequate medical services to the rural and native areas. In a former letter I mentioned the memorandum which had been drawn up on the subject by the federal council of the association. This has now, with some slight modifications, been presented to the minister of public health, who is already dealing with the program of activities recommended by Professor Swellengrebel in his report on malaria. The association, briefly, supports an extension of the existing system of district surgeons, a system that took root in the Cape Province but has never been popular in the other provinces. Dr. Napier pleads in his presidential address for the institution of a state medical service, modeled apparently on the system now existing in Basutoland. Both the government and the lay public are keenly interested in the subject. With the proposal to do away with the present provincial system of political control of education, public health and roads there is a desire on the part of the public to have some concrete suggestions for improving the present position as regards medical aid. Possibly some measure of devolution will be favored, and something similar to the Canadian system of rural medical officers may come up for consideration. Conditions in some rural districts are so bad that there is practically no private practice, and the practitioners live on what they obtain from the state. In such areas there is already, for all practical purposes, a state medical service, although it exists under conditions which are irksome to the practitioner and of little benefit to the public. Dr. Napier's frank discussion of the pros and cons will at least enable the public to see that the medical profession is not afraid to contemplate the possibility of a state medical service, provided the conditions of service are such as to satisfy both sides.

SCIENTIFIC PAPERS

There was no paper of outstanding importance read at the congress. The committee rightly tries to make these meetings attractive and instructive to the general practitioner, and ultrascientific papers that need for their discussion intimate specialized knowledge are discouraged. Many papers of general interest were read. Perhaps the most important discussion was that initiated by Dr. Lance Impey of Cape Town, on "Medical Attendance in Pregnancy and the Puerperium." In the discussion the need for specialist attention, for intelligent examination of the pregnant mother, and for equally skilled antenatal treatment was stressed. Dr. Marchand gave an interesting paper on "Obstetrics Among South African Natives." The initial paper, on constipation, introduced a brisk discussion in which various speakers emphasized the fact that constipation was as common among natives as among whites, and that the evils due to intestinal stasis were probably due more to mechanical than to toxic causes. Before the section on medicine the Phthisis Bureau of Johannesburg contributed a paper on the number of tuberculosis and silicosis cases, explaining the difficulties of the definite diagnosis of pulmonary tuberculosis with x-rays. In the section on surgery the opening session was devoted to a discussion on appendicitis, but the paper that roused the greatest interest was that of Dr. Lee Macgregor on the surgery of the sympathetic nervous system. The public health section had one paper of outstanding interest, Dr. Sampson's admirable discussion of the etiology of blackwater fever and its relation to malaria. Considerable interest also was aroused by a preliminary report by Dr. Scroggie, medical officer of health for Port Elizabeth, on a new type of fever with some resemblance to typhus fever, observed in his area; the probability is that the disease is due to a Rickettsia body, but further bacteriologic and clinical research is required before it can be accepted as a clinical entity. The public health section held a combined meeting with the psychiatric section in which the subject of the sterilization of the unfit was discussed. The introducer, Dr. Dunston, commissioner for mentally disordered persons in the Union, made a strong plea for the compulsory sterilization of mental defectives, but an equally strong case against such sterilization was made out by his opponents. The public is interested in this subject, largely owing to the provocative statements that are made in the lay press about the high percentage of mentally defective juveniles in the population. There has been no authoritative survey of mental defectiveness in the Union and the percentages are more or less guesswork, for many of the statistical data are derived from the results of intelligence tests. The work in the other sections presented nothing of particular interest.

The Cancer Conference

A conference on cancer, convened by the administrator of the Transvaal Province at the instance of the Johannesburg Hospital Board, was held immediately after the congress and was well attended, although interest waned after the first day. The conference discussed the advisability of founding a national society for fighting cancer and decided on its establishment. The society is to be affiliated with the Imperial Cancer Research, and its work will be mainly to educate the public. Originally it was intended that the conference should also authorize the establishment of a cancer research institute, but the idea has been deprecated, as it is argued that cancer is not a disease of immediate economic importance in South Africa and that, in comparison with malaria, tuberculosis and rheumatic fever, its urgency is of less importance. The conference took no resolution on this subject or on the matter of the purchase of a radium bomb for distant treatment. The enthusiasm of the conveners had lessened by the time the conference met, and the only practical result of the meeting was the establishment of a South African anticancer society, which will probably have as long and as uneventful a life as the antimalaria societies in the past. The fact is that while the public has a reasonably active interest in cancer, it feels that there are other diseases of far greater importance in this country, which stand in need of investigation, and that we already have an excellent research institute at Johannesburg in the South Africa Institute for Medical Research, which is financed partly by the mining industry and partly by the government and is under the able directorship of Sir Spencer Lister.

Research on Malaria

The institute has just published a report by Professor Swellengrebel and his co-workers on the incidence of malaria in the Union. Professor Swellengrebel's report to the government was written in simple, popular language, and has resulted in the government taking action. Most of the recommendations which he suggested will be adopted. A malaria research institute, in charge of Dr. Annecke, is being established in the low veld, and adequate provision is being made for the treatment of malaria cases in rural areas. Professor Swellengrebel in a carefully written scientific report discussed the question of the relative immunity or toleration possessed by the aboriginal native living in malarious areas. He and his co-workers have carefully examined both the adult and the juvenile population in some of the locations situated in the most fiercely endemic districts, and have come to the conclusion that natives in such areas possess a real tolerance which is of industrial and economic importance. The report is one of the most interesting papers on malaria that have been published on this side.

JAPAN

(From Our Regular Correspondent)

Sept. 26, 1931.

Personals

Prof. Dr. Yokota, who retired as chief of hygiene in the medical department of the Tokyo Imperial University, was succeeded by Dr. Tamiya, professor in the university and a member of the Government Institute for the Study of Infectious Diseases. He had a scholarship in the Rockefeller Institute for the years 1914-1916.

Dr. Sato left Yokohama for Europe by way of America, July 16. He is a member of the lower house of the imperial diet, elected from Fukuoka prefecture, and was to attend the international conference of national representatives in Budapest in October.

Dr. Professor Kitajima, chief of the Keio Medical College and president of the Japan Physical Association, has been appointed medical superintendent of the Saiseikai Charity Foundation, succeeding the late Baron Dr. Kitasato.

Dr. Tomura, who had been chief of the health bureau of Tokyo, resigned from his post and was succeeded by Mr. Ishibashi, secretary of the bureau.

Owing to the death of Baron D. Kitasato, founder and director of the Kitasato Institute, Dr. Kitashima, former vice director, was unanimously elected director, and Dr. S. Hata was elected vice director.

Dr. Rajchman of the League of Nations arrived in Tokyo, September 10, on his way to inspect health conditions in China.

Dr. Takayama, professor in the Kyushu Imperial University, who resigned, has been appointed an emeritus professor of the university.

Dr. Miyajima, permanent commissioner of the narcotic section of the League of Nations, will be in Tokyo in the middle of November after visiting America on his way home.

Professor Gann of the Rockefeller Foundation, who recently arrived in Tokyo, visited the health bureau of the home ministry to talk over the proposed establishment of the health center and school of public health and hygiene in this country. August 6, he visited the government dietetic institute and other places, and attended the dinner party given in his honor by Mr. Adachi, home minister, in the evening.

Dr. Johnson of the University of Pittsburgh School of Medicine, who came to this country as a representative of the American Eugenic Society, was welcomed by the Japan Physical Hygienic Association at the Hitotsubashi Club at Kanda, Tokyo, July 25. At this meeting he gave a lecture on the practice of sterilizing feebleminded persons in America. His schedule for the two months' stay in this country was arranged and the home ministry gave an order that he could lecture without inconvenience at the places where he would go.

Sanatoriums and Asylums

The Yamaguchi branch of the Japan Red Cross Society is going to establish a new sanatorium at the town of Onoda. It will contain forty beds when completed.

The Wakamatsu Sanatorium, which is in Kanazawa City and has sixty beds at present, is also going to enlarge the capacity by twenty beds.

The Satojima Leprosy Asylum, which has accommodations for 550 patients at present, is going to enlarge the capacity by 450 additional beds.

Infectious Diseases in Dormitories

The educational ministry has conducted an investigation of the number of cases of infectious diseases that broke out among the students in the dormitories in this country. The cases of dysentery were the largest in number, there being eighty-seven; next came the eighty-two cases of typhoid; then twenty-two cases of paratyphoid fever, then five cases of diphtheria, and lastly two cases of scarlet fever. The number of cases for five years and the deaths are as follows:

Year	Number of Dormitories	Number of Cases	Deaths
1927	110	235	7
1928	120	254	7
1929	81	151	8
1930	94	187	8
1931	113	208	8

New Regulations for Narcotic Drugs in Taiwan

The government of Taiwan (Formosa) has issued new regulations for opium and other narcotic drugs this year. Opium is not allowed to be handled except by licensed pharmacists and druggists. A person who is suspected of being an opium eater shall be detained in an opium eaters' hospital for observation. In using any preparations of narcotic drugs, physicians must obtain licenses from the local governor whenever in need of them for their patients.

Epidemic of "Dengue Fever"

An epidemic of "dengue fever" which broke out in the Loochoo Islands last July was reported by the local government to the effect that there were 13,969 cases, 136 of which terminated fatally, between July 13 and 19. The authorities concerned on the islands did their best in killing the mosquitoes. The symptoms are reported to be like those of influenza at first; then come typical states of fever accompanied by eruption. Some patients improved after two or three days of pain in the joints, and eruption; others continued to suffer for a week or more.

Cholera

Dr. Katsumata, health officer of the department of the interior, returning from Shanghai in August reported the health conditions there to be very good because of the inoculations against cholera made among the inhabitants. August 24, however, two cases were found on board the British steamer which had touched at Shanghai on the way to Kobe. The patients had been infected in Shanghai, and the next day another case was found. September 7, a case was reported at Fukuoka, Kyushu, in a Chinese who had just arrived from his native country.

Marriages

James C. Owings, Baltimore, to Miss Constance Macgill Carey of Riderwood, Md., at Ruxton, November 14.

Edwin Foster Gouldman, Colonial Beach, Va., to Miss Margaret Reid of Washington, D. C., October 13.

George Preston Nowlin, Charlotte, N. C., to Miss Mary Ann Jones of Lynchburg, Va., October 10.

James Winston Watts, II, of Chicago, to Miss Julia Meem Harrison of Lynchburg, Va., in October.

Clabe Webster Lynn to Miss Grace Lunsford Friend, both of Petersburg, Va., October 17.

James Bannister Stone to Miss Janet Watkins, both of Richmond, Va., November 3.

Jacob Goldberg to Miss Rose D'Vorkin, both of Long Branch, N. J., November 5.

DeWitt C. Dever to Miss Dorothy L. Fraley, both of Seattle, October 29.

Deaths

Louis D. Brose ⊕ Evansville, Ind.; University of Pennsylvania School of Medicine, Philadelphia, 1881; member of the American Academy of Ophthalmology and Oto-Laryngology and the American College of Surgeons; past president of the Vanderburgh County Medical Society; delegate to the Pan-American Medical Congress in Washington, D. C., in 1893, the International Medical Congress in Berlin in 1900 and the International Otological Congress in Boston in 1912; demonstrator and professor of anatomy, Evansville Medical College, until it dissolved in 1885; for many years oculist and aurist to St. Mary's Hospital; aged 72; died, November 15, of hypostatic pneumonia.

Norton Luther Wilson ⊕ Elizabeth, N. J.; Bellevue Hospital Medical College, New York, 1884; past president of the Medical Society of New Jersey and the Union County Medical Society; formerly member of the board of health; member of the American College of Surgeons; senior ophthalmologist and otolaryngologist to the Elizabeth General Hospital and consultant to St. Elizabeth's and Alexian Brothers' hospitals; formerly member of the board of managers of the Bonnie Burn Sanatorium, Scotch Plains; aged 70; died, November 13, of heart disease.

Archibald Mercer, Newark, N. J.; College of Physicians and Surgeons in the City of New York, 1871; member, past president and for thirty years treasurer of the Medical Society of New Jersey; secretary, 1878-1906, and president in 1906, Essex County Medical Society; police surgeon, 1881-1883; medical superintendent, visiting surgeon and on the staff of the St. Barnabas Hospital, 1880-1921; surgeon to the New Jersey Home for Disabled Soldiers, 1891-1897; aged 82; died, November 3, of chronic interstitial nephritis and cerebral hemorrhage.

Frederick Asser Asserson ⊕ Medical Inspector, Commander, U. S. Navy, retired, Newport, R. I.; University of Virginia Department of Medicine, Charlottesville, 1899; member of the American College of Surgeons and the New England Surgical Society; entered the Navy in 1901 and retired in 1920 for incapacity resulting from an incident of service; aged 52; on the staff of the Newport Hospital, where he died suddenly, November 6, of heart disease.

Carter Slocum Fleming, Fairmont, W. Va.; College of Physicians and Surgeons, Baltimore, 1914; member of the West Virginia State Medical Society, and the American College of Surgeons; past president of the Marion County Medical Society; gynecologist and obstetrician to the Cook Hospital; aged 40; died, in November, at the Walter Reed General Hospital, Washington, D. C., of a self-inflicted bullet wound.

Lemuel Fox Woodward, Worcester, Mass.; Harvard University Medical School, Boston, 1882; member of the Massachusetts Medical Society, and the American College of Surgeons; consulting surgeon to the Worcester City and Memorial hospitals, Worcester, and the Hospital Cottages for Children, Baldwinsville; aged 74; died, November 12, of arteriosclerosis and cerebral hemorrhage.

Lawrence Evans Chapman, Galveston, Texas; University of Texas School of Medicine, Galveston, 1915; member of the State Medical Association of Texas, and the American College of Physicians; associate professor of clinical medicine at his alma mater; on the staff of the John Sealy Hospital; aged 44; died suddenly, October 21, of coronary occlusion.

Edward Dunaway Allgaier ⊕ Cincinnati; Medical College of Ohio, Cincinnati, 1908; formerly instructor in clinical pediatrics, and clinical otolaryngology, University of Cincinnati College of Medicine; on the staff of St. Francis Hospital; aged 48; died, November 6, in the Deaconess Hospital, of injuries received in an automobile accident.

Robert James Talbot ⊕ Niagara Falls, N. Y.; Baltimore Medical College, 1909; member of the American College of Surgeons; physician to the Niagara University; formerly health officer of Niagara Falls; on the staffs of St. Mary's and Niagara Falls Memorial hospitals; aged 49; died, October 30, of tuberculosis of the throat.

Marvin R. Stone, Parkersburg, W. Va.; College of Physicians and Surgeons, Baltimore, 1908; member of the West Virginia State Medical Association; past president of the staff of the City Hospital and a member of the staff of St. Joseph's Hospital; aged 53; died, September 4, of coronary occlusion.

Newton Whitney Wear, Bellingham, Wash.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903; member of the Washington State Medical Association; county coroner; aged 52; on the staff of St. Joseph's Hospital, where he died, September 8, of leukemia.

Edmund Farnham Curry ⊕ Fall River, Mass.; Harvard University Medical School, Boston, 1896; member of the New England Pediatric Society; formerly on the staff of the Fall River General Hospital; aged 58; died suddenly, October 29, in the Union Hospital, of coronary occlusion.

Leonard Reu, Buffalo; University of Buffalo School of Medicine, 1904; member of the Medical Society of the State of New York, and the American Roentgen Ray Society; aged 52; died, November 2, of miliary and pulmonary tuberculosis, chronic endocarditis and mitral insufficiency.

James Patton Taylor, Wartrace, Tenn.; Vanderbilt University School of Medicine, Nashville, 1896; member of the Tennessee State Medical Association; aged 63; was instantly killed, November 1, when the automobile in which he was driving was struck by a train.

Thomas Carr Avary, Portland, Ore.; Southern Medical College, Atlanta, 1889; member of the Oregon State Medical Society; for many years health officer of Skamania County, Wash.; aged 72; died, October 25, in the Good Samaritan Hospital, of lobar pneumonia.

Marcus F. Squier, Harrison, N. J.; College of Physicians and Surgeons in the City of New York, 1872; member of the Medical Society of New Jersey; formerly member of the board of health; aged 80; died, November 1, of angina pectoris and myocarditis.

Harlin H. Smith, Calico Rock, Ark.; University of Arkansas School of Medicine, Little Rock, 1906; member of the Arkansas Medical Society; aged 50; died, October 14, in the Baptist State Hospital, Little Rock, of cerebral hemorrhage.

Manley Arphew Siske, Kings Park, N. Y.; University of Virginia Department of Medicine, Charlottesville, 1927; senior assistant physician on the medical staff of the Kings Park State Hospital; aged 34; was accidentally drowned, October 20.

Joseph Amidee Charest, Nashua, N. H.; Tufts College Medical School, Boston, 1896; member of the New Hampshire Medical Society; on the staffs of St. Joseph's Hospital and the Nashua Memorial Hospital; aged 64; died, October 20.

Harold Lowell Reinhard ⊕ Portsmouth, Ohio; Ohio State University College of Medicine, Columbus, 1927; aged 32; on the staffs of the Mercy Hospital and the Portsmouth General Hospital, where he died, November 3, of spinal meningitis.

William Baird Henderson ⊕ Philipsburg, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1886; member of the American College of Surgeons; chief of the staff of the State Hospital; aged 71; died, October 30.

Henry Hamilton Taylor, San Saba, Texas; Memphis (Tenn.) Hospital Medical College, 1902; member of the State Medical Association of Texas; president of the school board; county health officer; aged 51; died, October 11.

Thomas Brinsley Foley, Boston; Queen's University Faculty of Medicine, Kingston, Ont., Canada, 1903; member of the Massachusetts Medical Society; aged 52; died, November 12, of carcinoma of the rectum and bladder.

William Martin Bradley, Mayesville, S. C.; Baltimore University School of Medicine, 1900; member of the South Carolina Medical Association; aged 57; died, October 28, of myocarditis following influenza and pleurisy.

Emma J. Batchelor, Cincinnati; Presbyterian Hospital and Woman's Medical College, Cincinnati, 1894; member of the Ohio State Medical Association; aged 77; died, November 4, of coronary embolism and arteriosclerosis.

Frederick John Mitchell, St. Paul; Hahnemann Medical College and Hospital, Chicago, 1903; Northwestern University Medical School, Chicago, 1909; aged 52; was accidentally shot and killed, October 18, while hunting.

William L. Cuddeback, Port Jervis, N. Y.; Bellevue Hospital Medical College, New York, 1876; member of the Medical Society of the State of New York; formerly bank president; aged 77; died, October 31.

Joseph Jackson Skelton, Huntington, W. Va.; University of Louisville (Ky.) School of Medicine, 1902; aged 67; was instantly killed, October 18, when the automobile in which he was driving was struck by a train.

Henry Howard Mason, Butler, Ala.; University of Alabama Medical Department, Mobile, 1903; member of the Medical Association of the State of Alabama; aged 58; died, October 29, of cerebral hemorrhage.

Walter Tracy Fuller, Boston; Boston University School of Medicine, 1895; member of the city health department; aged 68; died, October 29, in the City Hospital, of intestinal obstruction and chronic myocarditis.

Edward Gustine Higgins, Melrose, Wis.; Milwaukee Medical College, 1904; member of the State Medical Society of Wisconsin; aged 55; died, October 28, in Rochester, Minn., of carcinoma of the rectum.

William Hanford Todd, Dobbs Ferry, N. Y.; Medical Department of Columbia College, New York, 1890; at one time health officer of the villages of Dobbs Ferry and Irvington; aged 70; died, October 21.

James Henry Meek, Bellaire, Ohio; Ohio Medical University, Columbus, 1898; member of the Ohio State Medical Association; formerly on the staff of the City Hospital; aged 69; died, October 24.

Roy B. Leach ⊕ Joliet, Ill.; Rush Medical College, Chicago, 1901; aged 55; on the staffs of St. Joseph's Hospital and the Silver Cross Hospital, where he died, November 1, of chronic myocarditis.

William August Ocker, Indianapolis; Cincinnati College of Medicine and Surgery, 1897; director of physical education in the public schools of Indianapolis; aged 61; died, November 13, of heart disease.

Wesley Van Nette, Clyde, Ohio; Northwestern Ohio Medical College, Toledo, 1890; member of the Ohio State Medical Association; aged 75; died, November 5, of a sarcoma in the left groin.

Robert Coltman, Jr., Washington, D. C.; Jefferson Medical College of Philadelphia, 1881; aged 69; died, November 3, of chronic interstitial nephritis, myocarditis and acute dilatation of the heart.

William Sherman Warren, Jacobsburg, Ohio; Starling Medical College, Columbus, 1896; member of the Ohio State Medical Association; aged 54; died, November 8, of cerebral hemorrhage.

George W. Bogart, New York; Medical Department of the University of the City of New York, 1890; member of the Medical Society of the State of New York; aged 72; died, October 31.

Oscar William Lowery, Des Moines, Iowa; College of Physicians and Surgeons, Keokuk, 1873; member of the Iowa State Medical Society; Civil War veteran; aged 86; died, October 18.

W. D. Foster, Gravette, Ark. (licensed, Arkansas, 1903); formerly mayor of Gravette and justice of the peace; aged 78; died, October 29, in Topeka, Kan., of influenza and bronchopneumonia.

William Fleming Shellhorse, Jacksonville, Fla.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1916; aged 55; died, October 30, of diabetes mellitus, carbuncle and lobar pneumonia.

Herbert Nelson Leete ⊕ Twin Falls, Idaho; Rush Medical College, Chicago, 1904; aged 57; died, October 1, in the County Hospital of septicemia following a surgical infection of the hand.

Edward Pisko ⊕ New York; University of Vienna Faculty of Medicine, Vienna, Austria, 1888; on the staff of the Hospital for Joint Diseases; aged 69; died, November 11, of heart disease.

Robert Wesley Frey, Trenton, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1887; member of the Kentucky State Medical Association; aged 70; died, October 10.

Miram Gardner, Cedar Falls, Iowa; University of Michigan Medical School, Ann Arbor, 1886; member of the Medical Society of the State of New York; aged 79; died, September 17.

Elinor Van Buskirk Cummins, New York; Boston University School of Medicine, 1907; University of Vienna Faculty of Medicine, Vienna, Austria, 1908; aged 53; died, October 20.

William E. Howley ⊕ New York; Medical Department of the University of the City of New York, 1891; aged 65; on the staff of St. Francis Hospital, where he died, September 28.

Maxwell Lewis Volk, New York; Columbia University College of Physicians and Surgeons, New York, 1905; aged 47; died, September 18, of cerebral hemorrhage and edema.

John Douglas Simpson, Minneapolis; Chicago Medical College, 1881; an affiliate Fellow of the American Medical Association; aged 73; died, October 18, of chronic endocarditis.

Arthur Allison Howard, Boston; Harvard University Medical School, Boston, 1909; aged 52; died, October 7, in the City Hospital, of arteriosclerosis and chronic myocarditis.

Albert Lodge, Detroit; University of Michigan Homeopathic Medical School, Ann Arbor, 1879; aged 79; died, November 4, of myocarditis, uremia and interstitial nephritis.

George Edgar Mulford, Morristown, N. J.; College of Physicians and Surgeons in the City of New York, 1882; aged 76; died, November 1, of a self-inflicted bullet wound.

George William Compton, San Diego, Calif.; Denver Homeopathic College, 1898; aged 65; died, October 21, of acute dilatation of the heart and chronic myocarditis.

Benjamin F. Collins, Steubenville, Ohio; Columbus Medical College, 1892; formerly on the staff of the Ohio Valley Hospital; aged 62; died, November 8, of myocarditis.

Charles A. Isbell, Paducah, Ky.; Howard University School of Medicine, Washington, D. C., 1891; aged 66; died, June 9, in Detroit, of cerebral hemorrhage.

Flora Hubbard Ruch, Lansing, Mich.; University of Michigan Medical School, Ann Arbor, 1882; aged 80; died, November 5, in Binghamton, N. Y., of nephritis.

Herman Andrew Reque ⊕ Brooklyn; Rush Medical College, Chicago, 1906; on the staff of the Norwegian Hospital; aged 57; died, November 4, of pneumonia.

Frederick James Carley ⊕ North Attleboro, Mass.; Tufts College Medical School, Boston, 1906; aged 53; was found dead, November 10, with a bullet wound.

William E. Witter, Rochester, N. Y.; Chicago Homeopathic Medical College, 1890; formerly a missionary; aged 78; died, November 5, of arteriosclerosis.

Robert Victor Swanton ⊕ Pittsburgh; Western Pennsylvania Medical College, Pittsburgh, 1901; aged 53; died, November 5, of chronic myocarditis.

Julia Thomas, Toronto, Ont., Canada; Trinity Medical College, Toronto, 1891; Victoria University Medical Department, Coburg, 1892; died, June 28.

Romeo Arsborne Johnston, Columbus, Ohio; Ohio State University College of Medicine, Columbus, 1909; aged 47; died, October 11, of heart disease.

Jennie Fuller, Hartland, Maine; Boston University School of Medicine, 1882; aged 79; died, July 9, in Portland, of coronary thrombosis and myocarditis.

Gerry Elbridge Emanuel, Edgerton, Ohio; Rush Medical College, Chicago, 1884; aged 68; died, October 24, of cerebral arteriosclerosis and nephritis.

Charles Jefferson Stewart, Heiberger, Ala.; University of Alabama Medical Department, Mobile, 1891; aged 66; died, October 4, of heart disease.

James Harvey Stallard, Geuda Springs, Kan.; Barnes Medical College, St. Louis, 1901; aged 73; died, July 7, of carcinoma of the liver.

James M. Henry, Notus, Idaho; College of Physicians and Surgeons, Chicago, 1885; aged 74; died, September 21, of intestinal hemorrhage.

John B. Zabriskie, Nice, France; Long Island College Hospital, Brooklyn, 1894; aged 61; died, October 28, of cerebral thrombosis.

James Borthwick Hutton, Ceylon Station, Sask.; Queen's University Faculty of Medicine, Kingston, Ont., 1909; aged 43; died, August 2.

David Brownlee Lazier, Fraser Lake, B. C., Canada; Queen's University Faculty of Medicine, Kingston, Ont., 1901; died, August 3.

William Arthur Stenning, Sherbrooke, Que., Canada; McGill University Faculty of Medicine, Montreal, 1894; died, September 2.

Samuel Addison Marable, Palmyra, Tenn.; Vanderbilt University School of Medicine, Nashville, 1882; aged 77; died, October 30.

Richard Smith Conboy, Toronto, Ont., Canada; Medical Faculty of Trinity University, Toronto, 1903; aged 51; died, October 24.

Frank M. Boyce, Houston, Texas; Albany (N. Y.) Medical College, 1872; aged 80; died, November 2, of gangrene of the foot.

James Pickett Colvin, Lincoln, Ala.; Kentucky School of Medicine, Louisville, 1891; aged 67; died, November 1, of uremia.

David Gross, Glenwood, Iowa; Creighton University School of Medicine, Omaha, 1929; aged 26; died, November 5, of heart disease.

Granville Warburton, Brooklyn; Bellevue Hospital Medical College, 1883; aged 75; died, August 26.

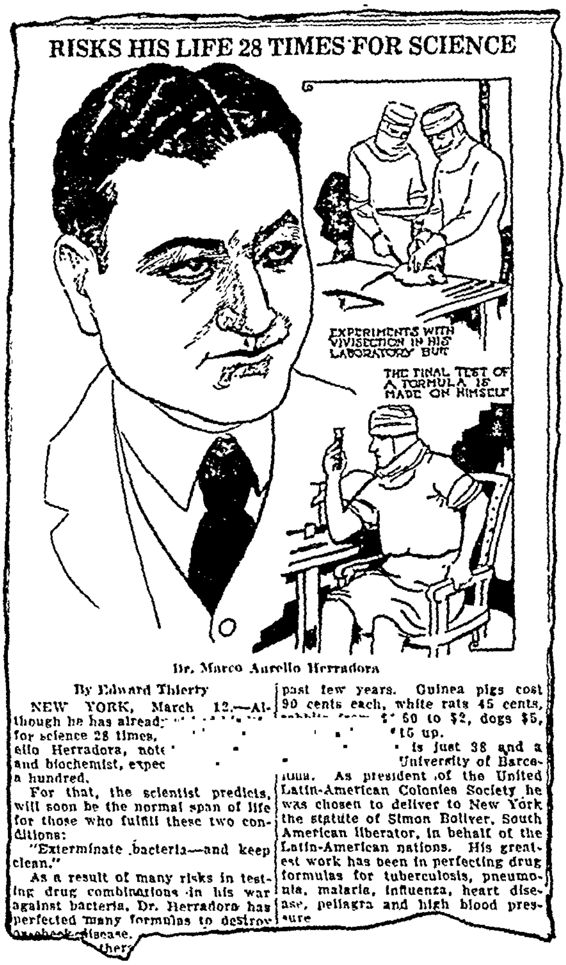
Bureau of Investigation

MARCO AURELIO HERRADORA

And Some Preparations of a Specialist in "Research Regarding Therapeutics"

Marco Aurelio Herradora, according to the 1931 New York City telephone directory, is at 43 West 16th Street, telephone Chelsea 3109. At the same address and with the same telephone number is the "Spanish Biochemical Institute" and the "*Unité Pharmaceutique Française.*"

Early in 1923, newspaper puffs of a syndicated article on Marco Aurelio Herradora were published, accompanied by pictures of this person and describing him as a "noted therapeutist and biochemist" who expected to live to be a hundred. Herradora was described in this article as a graduate of the University of Barcelona and as president of the United Latin-American Colonies Society. The newspaper article ended with the statement:



RISKS HIS LIFE 28 TIMES FOR SCIENCE

EXPERIMENTS WITH VIVISECTION IN HIS LABORATORY BUT
THE FINAL TEST OF A FORMULA IS MADE ON HIMSELF

Dr. Marco Aurelio Herradora

By Edward Thierty

NEW YORK, March 12.—Although he has already for science 28 times, ello Herradora, note and biochemist, expec a hundred.

For that, the scientist predicts, will soon be the normal span of life for those who fulfill these two conditions:

"Exterminate bacteria—and keep clean."

As a result of many risks in testing drug combinations in his war against bacteria, Dr. Herradora has perfected many formulas to destroy or check disease.

past few years. Guinea pigs cost 90 cents each, white rats 45 cents, 60 to $2, dogs $5, 15 up.

is just 38 and a University of Barcelona. As president of the United Latin-American Colonies Society he was chosen to deliver to New York the statute of Simon Bolivar, South American liberator, in behalf of the Latin-American nations. His greatest work has been in perfecting drug formulas for tuberculosis, pneumonia, malaria, influenza, heart disease, pellagra and high blood pressure

Photographic reproduction (reduced) of a syndicated article on Herradora that appeared in various newspapers in 1923.

> "His greatest work has been in perfecting drug formulas for tuberculosis, pneumonia, malaria, influenza, heart disease, pellagra and high blood pressure."

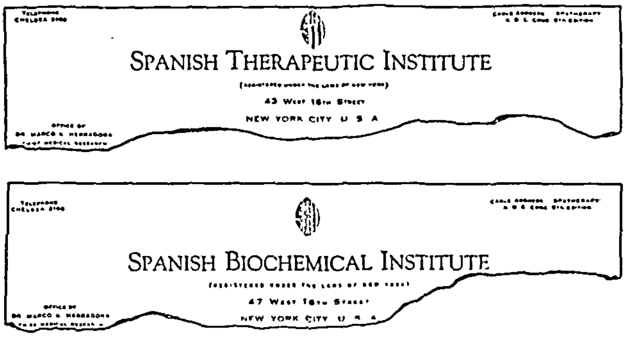
In 1922, "Marco Aurelio Herradora, M.D.," was described as president of the Scientific Chemical Company of New York, which at that time put out a line of preparations for intravenous use. These products were submitted to the Council on Pharmacy and Chemistry, which after careful consideration refused to accept any of them. The Council declared that the preparations were fundamentally irrational and that the advertising matter indicated that the firm was much more interested in persuading the unthinking to use its specialties than it was in scientific therapy. The report, which occupied nearly two pages of The Journal, appeared in the issue of April 23, 1923, after a year had been devoted to a consideration of the products.

The Journal for November 21, 1925, again reported briefly on the Herradora products and again reminded physicians that these products were unacceptable because of unwarranted and unsubstantiated statements and because of the complex and indefinite mixtures of drugs represented by the Herradora preparations.

In 1925, a questionnaire on stationery headed "Marco A. Herradora, M.D.," was sent to osteopaths, who were addressed as "Dear Doctor." One of the questions propounded to those osteopaths who received Herradora's questionnaire was whether they considered that osteopaths who had the M.D. degree, in addition to the "D.O." degree, had benefited either themselves or the osteopathic "profession."

In 1930, Herradora was reported as having sent a letter to a physician asking him if he would appreciate the opportunity of becoming "one of the physicians of a new Club" which he (Herradora) was helping to organize. The doctor who *would* appreciate such an opportunity would have "to contribute $1,000 as a small part toward organization expenses and equipment of the medical division."

The *Unité Pharmaceutique Française* was incorporated under the laws of Delaware, and the public has been solicited to purchase stock. The stock-selling scheme was of the familiar type—a bonus of shares of common stock to be given free to those who purchased five shares of the "7 per cent cumulative preferred at $20 a share." The *Unité Pharmaceutique Française* puts out a line of "patent medicines": "Sonedine" for rheumatism, neuralgia and gout; "Exhaline" for asthma; "Rubiline" for gallstones; "Antisol," to "aid in keeping the kidneys clean"; "Conchaline" for the sexual rejuvenation of elderly people; "Dodgeline" for tonsillitis; "Madreline" to purify the blood, and "Jenniline" for nasal catarrh and sinusitis.



SPANISH THERAPEUTIC INSTITUTE
43 West 16th Street
NEW YORK CITY U S A

SPANISH BIOCHEMICAL INSTITUTE
47 West 16th Street
NEW YORK CITY U S A

Photographic reproduction (reduced) of the letterheads of the Spanish Therapeutic Institute which later became the Spanish Biochemical Institute. This concern puts out "Vitamineralis" described as "The material from which life is created."

Herradora is described on some of the letterheads, as "Chief Medical Research" of the "Spanish Biochemical Institute," which was earlier known as the "Spanish Therapeutic Institute"—a name which violated local laws and had to be changed. The Spanish Biochemical Institute puts out "Vitamineralis," which is said to be "the Material from Which Life is Created." According to an advertising circular:

> "Vitamineralis is a combination of *sterolized minerals* similar to those entering the composition of the human body. Due to the fact that *Vitamineralis* contains *calcium, phosphorus, fluorine, potassium, sulphur, silicon, iodine, magnesium, iron, sodium, manganese, chlorine* and other minerals, it beneficially influences daily replenishment and reconstruction of the body. These minerals by renovating organic forces protect the individual constitution from decay that comes from exhaustion and diminishment of these life substances in the human economy." [Italics in the original.—Ed.]

The circular then goes on to describe the "Function of Minerals" in "preserving life." The circular states that such minerals should "never be given separately, alone, but in combination with the others, *simultaneously, in adequate proportions, at the same time.*" [Italics as in original.—Ed.]

The reader is then given some interesting alleged information regarding certain elements, a paragraph being given to each element. We can quote from but part of this material:

> "*Fluorine* . . . When the feet and arm pits produce disagreeable odors, it will be an evidence of the need of *fluorine in the system.* Carbon counteracts fluorine, calcium and iron."
>
> "*Potassium* . . . Its exhibition in the body will prevent constipation, nervous disorders, general weakness."
>
> "*Sulphur* . . . Through its purifying qualities it clears the skin, preserving same from infection. Carbon controls sulphur."
>
> "*Silicon* . . . *is necessary to those doing mental* work. Carbon counteracts silicon."
>
> "*Magnesium* . . . When the system is lacking in magnesium, insanity, neurasthenia and hysteria may be the consequences."
>
> "*Iron* . . . Yes, iron will help blood forming organs but unless properly *vitaminized and sterolized* it will not be properly assimilated *by the body* and *may also perturb the kidney* function very severely. . . . It is a brain food very necessary to people doing mental work. . . . Its indiscriminate use causes stupidity, atrophia, plethora and many functional derangements such as hemorrhages and others."
>
> "*Sodium* . . . used without due control will cause the same effect to the circulatory vessels as sea water does cause to an iron rod."
>
> "*Manganese* . . . acting like the dark chamber of a photographic studio is the connecting element of the organism of brain matter serving as a point of contact to its dynamic emanation. It flashes thoughts as a regenerative constructive power of brain transmission . . . It helps to give stamina and determination of character."
>
> "*Chlorine* . . . arrests the progress of muco-purulent formations and catarrh, albuminuria, obesity and protects the nervous system. Chlorine is controlled by hydrogen, nitrogen and carbon."
>
> "*Carbon* . . . Used indiscriminately it interferes with iron assimilation, causing an acid reaction that is damaging to the teeth, bones, brain and digestion producing auto-intoxication, goitre, heart involvement and serious impairments of mental forces. When deficient it causes enduration, *atrophy, eczema.*"

In view of the marvelous effects that are to be expected from the use of this latest addition to the field of catholicons, it is interesting to learn that "Vitamineralis is now served at the best homes of learned intelligent people and will enter the high-class soda fountains as a wholesome good habit."

A few weeks ago, an inquiry came in to the Bureau of Investigation regarding the Spanish Biochemical Institute, reading in part as follows:

> "Do you have an acquaintance with the activities of the Spanish Biochemical Institute, which is located at 47 West 16th Street, New York, N. Y.? If so, we will be very appreciative of all the facts that you can supply. The Spanish Biochemical Institute is introducing commercially a product, baptized 'Vitamineralis,' said to be 'the life substance,' which is described at length, in quaint style, in the enclosed circular. It is reported that the literature of the Spanish Biochemical Institute is now being distributed among food manufacturers and especially among carbonated beverage producers. Letters from the Spanish Biochemical Institute are usually signed by Marco A. Herradora, Director."

Our correspondent further stated that his inquiry was prompted by a letter that Herradora had written to a business concern in connection with the use of Vitamineralis, and that in his letter, Herradora had thus described himself:

> "'In regards to the writer's [Herradora's] qualifications, you will find his name listed in the enclosed booklets as a member in good standing of the Medical Association of the Greater City of New York, affiliated with the Academy of Medicine, also as the Chairman of the Hospital Committee of the International Association of Physicians, Surgeons and Dentists, member in good standing of the Yorkville Medical Society. This in no way should be construed as the writer doing clinical medical work, but exclusively devoted to medical research. . . . The undersigned, who has devoted more than twenty years of study and research to subjects of this nature, is prepared to furnish to you unquestionable references as to his integrity and scientific standing.'"

Herradora's claim, that he is a member in good standing of the Medical Association of the Greater City of New York, astonishing as it may seem, is correct. This in spite of the fact that that organization has been advised of Herradora's past and present activities in the nostrum field and has been sent a photostatic copy of a letter from the Rector of the University of Barcelona, who, in response to an inquiry from the American Medical Association, declared definitely that no man by the name of Marco Aurelio Herradora was a graduate in medicine of the University of Barcelona.

In January, 1931, Herradora was brought into court on the charge of unlawfully practicing medicine. Evidence was submitted by an investigator for the State Department of Education of New York that Herradora examined her, gave an alleged diagnosis, and prescribed a bottle of Sonedine, one of the "patent medicines" put out by the *Unité Pharmaceutique Française*. Herradora testified, on the other hand, that he made no examination or diagnosis, but merely sold the woman a bottle of Sonedine. His testimony was supported by that of two of the employees. After hearing all the evidence, which was given before three justices—Walling, Voorhees and Direnzo—the verdict was:

"A majority [two out of three] of the court has a doubt and the defendant is acquitted. Mr. Justice Voorhees dissents."

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

BACTERIAL ENDOCARDITIS

To the Editor:—When a girl, who is now 12, was 3 years of age, her mother was told that the child had a heart murmur. At the age of 9, the tonsils were removed. The patient has never had a definite attack of rheumatic fever but has had indefinite pains in the joints. The past history otherwise is negative. About the middle of July, 1931, the patient was caught in a severe electrical storm about half a mile from her home. Being frightened, she ran as fast as she could to her home. From that time until I saw her, she became listless and pale. When I saw her, Aug. 6, 1931, she was a well nourished, well formed child, up and around the house. She had a temperature of 101, a pulse of 130 and a loud systolic murmur at the apex. She was decidedly anemic. There was a definite moderate enlargement of the right side of the heart. I made a diagnosis of an acute attack of chronic endocarditis, with acute dilatation probably induced by the exertion. I put her to bed, gave her salicylates with alkali, plenty of sugar, citrus drinks and water. I started her on iron and gave bromides at night. An ice cap over the heart quieted the uneasy pain present there. About ten days after this, I noticed a new murmur, systolic, over the aortic area. Since the onset, the temperature has been decidedly septic, at times returning to normal. Small ecchymotic areas have developed all over the abdomen and the upper portion of the chest. The spleen is now definitely enlarged and tender. The liver margin is not enlarged but is somewhat tender. At first, the patient was nervous and subject to trembling, but now she has attacks of moderate stupor. The urine contains some albumin and numerous bacteria. I had an internist see her, and he suggested small doses of digitalis and liver extract. He would give me no prognosis. The picture now is one of much discouragement. The pulse stays rapid but regular. The patient does not have any edema of the extremities but does have transient indefinite puffiness of the face. The temperature shows no intent to return to normal. There is no blueness of the lips, cheeks or fingernails, but the anemia is not getting any better; in fact, it appears worse. The patient is losing some weight despite my attempts at a nourishing diet. The bowels are regular, but the appetite is poor. The parents, who are of limited means, are naturally much worried over the course of this attack. I realize that these cases sometimes take months to show recovery, even with absolute bed rest. Will you please tell me of anything else that I can do? Do you think this child will recover? If you do, to what extent do you think that her heart will be permanently crippled? Have you any idea as to how long this acute septic process with fever is going to last? She has had some moderate pains in the joints and swelling since I have been seeing her. The murmurs are loud and distinct. When the temperature goes down to near normal, the pulse gets much weaker and the child more stuporous. Please omit name.

M.D., New York.

Answer.—The history and observations as given are indicative of a bacterial endocarditis which is probably more than subacute. From the evidence there can be little doubt in regard to the diagnosis. The overexertion probably had little to do with the onset. The enlargement of the heart is due to infection and not to dilatation from overexertion. About three fourths of such cases occur in patients who have previously had rheumatic fever, and in this case the history of definite pains in the joints is probably indicative of rheumatic infection at that time. Becoming wet and chilled at the time of the storm might have predisposed to an infection of the upper respiratory tract, which later localized itself in an already damaged heart.

The prognosis is practically hopeless. There are cases of subacute bacterial endocarditis in which recovery is made, but these constitute a small percentage, and they are usually the milder forms. In the cases in which the observations are as they are here, the mortality is 100 per cent.

No medicine or treatment known at present will have any effect on the progress of the disease. There is no treatment except absolute rest in bed, and quiet, and time. All that can be done is to make the patient as comfortable as possible and to employ symptomatic treatment if this is necessary. There is no especial reason for the digitalis and it is doubtful whether the liver extract is of any value.

There is no possible way of giving an estimate as to how long this will continue. The symptoms in the joints are moderately frequent in subacute bacterial endocarditis.

DIAGNOSIS AND TREATMENT OF SYPHILIS

To the Editor:—A woman, aged 22, was found about three years ago in the course of exhaustive examinations to determine the cause of a marked nervousness to have a 3+ Wassermann reaction, and her mother recalled that as an infant under the care of a colored nurse girl she had developed skin manifestations which probably were secondaries. Treatment carried out to cure her syphilis since the positive Wassermann has failed to change the reaction. She recalls no recurrences of active early lesions of syphilis, and is apparently perfectly well. Will you please answer the following: Should further treatment be persisted in? If so, what other than the arsenicals and mercury? What can I tell the patient about her 3+ Wassermann reaction? Is she infectious? Can she marry without running the danger of transmission of the infection? In taking her blood for a Wassermann test, am I running the chance of an infection? Should a case of this type, without any signs of lesions or ill health and with only the 3+ Wassermann, be reported as a case of syphilis, to be put under the same supervision and precautionary instructions that the health department insists on in active syphilis? Please omit name.

M.D., New York.

Answer.—The history of this young woman is not covered in sufficient detail in the inquiry to permit an intelligent answer to the question. No examination of the family and no account of evidence bearing on the question of prenatal rather than postnatal infection is given. The skin manifestations appearing in infancy need have had no connection with the colored nurse girl. The mother of the patient in particular and the family at large, including siblings, should be studied to determine whether or not this young woman is the victim of a prenatal infection. If she is, the indications for treatment, the prognosis and decisions with reference to marriage, children and public health reporting and management differ entirely from those in what might be an early acquired case. Persistent and irreversible positive blood Wassermann reactions are known to occur both in early cases of acquired infection in which the patient has lived through to adult life practically without treatment and unaware of the presence of the disease as well as in prenatal infection unrecognized until the later years. If the infection is postnatal, an examination of the spinal fluid, which is not mentioned in the inquiry, is a necessary part of the determination of the status of the patient.

Granted that the infection was acquired in infancy or was prenatal, it is highly improbable that the patient is in the least infectious and there is therefore no reason for exercising the authority of the public health officials for the prevention of the infection of others. The question as given contains no account of previous treatment and therefore it is impossible to advise on further treatment. What is really required in the management of a case such as this is familiarity with the general principles of modern syphilology on the basis of which all the questions asked and a number of those which should be asked but on which the questioner provides no information could be easily answered.

APOPLEXY WITH FEVER AND LEUKOCYTOSIS

To the Editor:—A corpulent old lady had some rather vague abdominal symptoms and at the same time developed gradually, without loss of consciousness, a partial hemiplegia. During the three days that this was going on, she had a fever of 101 to 103.5 F. and a leukocytosis which reached 22,000 with 92 per cent polymorphonuclears. The question which arose, and which I wish to ask you, is this: Could this blood picture have been caused by a simple apoplexy? There was no reason to suspect encephalitis or septic emboli. It was more like thrombotic softening. I understand that such conditions can cause fever, but can they cause a leukocytosis of 22,000, or any leukocytosis? Please omit name.

M.D., Missouri.

Answer.—Cerebral hemorrhage frequently causes fever and leukocytosis and may have been the underlying factor in the patient mentioned. Obesity is often associated with atherosclerosis in elderly patients and could be a predisposing factor. Less likely is a cerebral embolus from a mural thrombus, which may have become separated from the auricular wall or auricular appendage. It is not necessary for such an embolus to be infected in order to produce fever and leukocytosis, as it is known that the sterile product of the resulting cerebral injury may cause similar manifestations.

ALOPECIA, EXFOLIATIVE DERMATITIS AND SYPHILIS

To the Editor:—I have a patient who came to me with a skin condition which I diagnosed as exfoliative dermatitis based on a history of treatment for syphilis. In addition to the dermatitis he has completely lost the hair of the scalp, face, eyebrows and lids. This condition is of about eight weeks' duration. I should like to be advised as to whether or not there is any chance of stimulating a new growth; also the procedure. When the patient first came to me, seven weeks ago, I gave him daily for fourteen days intravenous injections of sodium thiosulphate, and other treatment was symptomatic. What should the antisyphilitic treatment be in this case? Please omit name. M.D., Illinois.

Answer.—The alopecia accompanying exfoliative dermatitis as described in this patient may be an alopecia totalis, coincidental with, or associated with, the intoxication process that brought on the dermatitis. If such is the case, the outlook for at least a temporary recovery of hair spontaneously as the dermatitic process clears up and the patient regains normal health is fairly good. It is impossible, however, to offer any assurance that the hair will not be again completely lost without any nécessary association with the dermatitis. The correspondent does not give sufficient detail to judge whether the exfoliative dermatitis is actually a result of treatment for syphilis or whether the patient may not even present the exfoliative process with thinning or relative absence of the hair that is occasionally observed in the so-called ichthyosiform erythroderma. This matter, however, is a congenital affair and could hardly be confused with the picture described.

Stimulation of a new growth of hair may be to some extent aided by vigorous exposure of the scalp to the quartz mercury vapor lamp. It is inadvisable in view of the exfoliative dermatitis to use local irritants which constitute the next alternative. With reference to further antisyphilitic treatment, it is impossible to base any decision on the facts given by the correspondent as there are no particulars with reference to the stage and character of the syphilitic infection, or of the previous treatment. It may at least be said, however, that a careful patch testing of the patient for sensitivity to the arsphenamines should be conducted by some one familiar with this type of work, and that if such patch testing reveals a specific sensitivity to the arsphenamines these drugs at least should be permanently debarred from the therapeutic regimen.

CONSTIPATION IN A BREAST FED BABY

To the Editor:—Will you kindly inform me as to how to treat constipation in a breast fed baby? The child is 5 months old, weighs 13 pounds and 12 ounces (6 Kg.), and appears to be perfectly normal otherwise, except for a persistent and almost intractable constipation. Rectal examination gives negative results. The child apparently does not have any pains or cramps that would lead one to suspect a chronic obstruction. Some suggestion as to treatment would be greatly appreciated. Please omit name. M.D., South Dakota.

Answer.—Constipation in a breast fed baby is a different thing from constipation in a bottle fed baby. In the latter, the movements are often hard; in the breast fed baby they are never so. The treatment, therefore, is different. Commonly, constipation in the breast fed baby is due to the fact that the child is not getting enough food and, if an ample supply of milk, cereals, vegetable purées and orange juice is given, the condition will commonly remedy itself. If it does not, there is no objection to the use of a nonirritating suppository, such as one made of gluten or soap covered with oil or petrolatum. If the constipation still persists in spite of the additional food, there is no objection to giving liquid petrolatum or magnesia magma daily up to the necessary amount.

In the purely breast fed baby there is no objection to letting the baby go two, or sometimes even three, days before it has a movement. That there is no mechanical obstruction in this case is evident from the lack of pain or "cramps" and abdominal distention.

TYMPANITES

To the Editor:—Could you refer me to a source of information on tympanites? I have a patient, aged 50, with a history of chronic constipation for years, and pain in the lower left quadrant, with a spastic colitis. With rest, hot packs, diluted hydrochloric acid, atropine, bacillus acidophilus milk and lactose, and a bulky diet and oil enemas, the stools are fairly well formed and the spastic colon is improved. However, even after an adequate evacuation, he is troubled with gas. I am under the impression that the putrefaction of protein causes this tympanites, but a restricted protein intake has been of no benefit. Could you suggest a further means of therapy? Please omit name. M.D., Nebraska.

Answer.—Tympanites is ordinarily considered a chronic accumulation of gases in the intestinal canal. Briefly, the gases may originate from exogenous causes, such as aerophagy in nervous individuals or in rapid eaters, or from endogenous sources, principally the result of the action of bacteria on proteins, carbohydrate and fats. Impeded expulsion of gases, even though the quantity may be normal, can occur with any form of chronic constipation, and in every case a cause for intestinal stenosis must be sought. Cardiac decompensation and general arteriosclerosis are further causes.

In regard to treatment, the etiologic agent should be sought and treated if found. Changes in the constituents of the diet are recommended, such as low protein, low fat or low carbohydrate. Of the latter, rye bread, vegetables rich in cellulose, and potatoes are particularly harmful. Dietary changes depend on whether putrefaction or fermentation are the causes of the gas. Medicinal measures, aside from hydrochloric acid, atropine or atropine-like substances, physostigmine and pituitary solution, have been shown to be of little avail. Colon irrigations with various antiseptic substances have been successful.

DILATED VESSELS IN VAGINA FOLLOWING RADIUM TREATMENT

To the Editor:—I have a patient who had radium treatment for uterine fibroids and an amputation of the cervix five years ago. Since that time she has complained of tenderness and pain in the pelvis and extreme sensitiveness throughout the birth canal. She is unable to have intercourse on account of the pain. A vaginal examination is practically impossible. The vulva and the vagina are both covered with enlarged venules. There are no palpable enlargements in the pelvis and no discharge to speak of. Twenty years ago she had both breasts removed for suspicious malignancy. She is 49 years old. She has not menstruated for three years. Can you tell me whether the hypersensitiveness is the result of radium treatment? Can you suggest any treatment in this case? Kindly omit name. M.D., Michigan.

Answer.—The condition of dilated vessels of the vagina and vulva is not common following radiotherapy, though the close time relationship is suggestive in this case.

The sequelae that are due to irradiation are dependent largely on the dosage, filtration and the age of the patient and are the result of varying amounts of cell and tissue destruction with resultant scar formation if and when healing occurs. Any or all tissues within the radius of activity of the radium may be involved. The cicatricial contraction that may result could cause circulatory obstruction with dilatation of the terminal vessels. These tissue changes following the use of radium are not infrequently associated with pain and tenderness as well as narrowing of the vaginal lumen, especially in those cases in which the vagina has been exposed to the effect of the radium.

It is also possible that there may be some interference with uterine and vaginal drainage as the result of scar formation following the cervical operation or the radium treatment.

It would seem necessary to determine even under anesthesia whether or not there are any strictures of the vagina or cervix which are making difficulty. If there are they should be carefully dilated, or, if this cannot be accomplished, other necessary steps should be taken.

The condition might of course be something that is entirely unrelated to either the operation or the radium treatment.

POLIOMYELITIS AND PREGNANCY

To the Editor:—I should like to gain information regarding a case of poliomyelitis in a woman, aged 20, with a pregnancy of six months' duration. At the end of the third day the patient has no paralysis. She received 20 cc. of convalescent serum the first day and 15 cc. the second. Does the combination with pregnancy change the ordinary picture of the disease concerning the mother and what can be expected in the baby if the pregnancy terminates normally? Will there be any paralysis in the child, if the mother does or does not have paralysis? C. J. Lohmann, M.D., Burlington, Iowa.

Answer.—Although there are no statistics available on the occurrence of poliomyelitis during pregnancy, some observers have the impression that the disease occurs in the later months of pregnancy more often than would be expected if it were only a chance coincidence. If this proves to be the case, it would suggest that some physiologic alteration during pregnancy may affect susceptibility to infection with poliomyelitis.

Paralysis of certain muscle groups may necessitate instrumental aid in delivery. However, some of the observed cases, even with extensive paralysis, have terminated in normal delivery of a normal child. In one instance in which delivery took place while the mother was in the acute stage of poliomyelitis, the child is said to have developed the disease after birth; but it is not clear whether infection was contracted in utero or after birth.

The Harvard Infantile Paralysis Commission is studying this question and would be glad to have reports of any such cases.

TREATMENT OF FLATFOOT

To the Editor:—I have a patient, aged 2 years, who has an extreme degree of flatfoot or relaxed arch, depending on the different classifications. This child objects to going barefooted owing to the discomfort. The child is not overweight and has walked since the age of 16 months. Please advise as to the proper treatment and expected prognosis of the condition. Please omit name. M.D., Kansas.

Answer.—If the child has an extreme degree of flatfoot, the best treatment is a series of plaster-of-paris casts, maintaining varus position of the posterior half of the foot and valgus position of the anterior portion of the foot; i. e., the heel is tilted toward the outer border and the sole toward the inner border. These casts should be applied by one thoroughly trained in orthopedic work, or harm can be done. They should be changed once in three weeks, and the child should be encouraged to walk after the cast is 24 hours old.

After a number of casts, which varies from one pair to three or four pairs, the child should be fitted with the proper shoes: rigid shank, high-laced shoes, well fitted around the ankle, with a straight inner borderline and round toe. The heel of this shoe should be three-fourths inch longer on the inner border than on the outer. It should be three-sixteenths inch higher on the inner border. The outer border of the sole should be one-eighth inch higher than the inner. Felt pads should be put into the shoes to support the longitudinal arches.

If the child continues to walk with pronation, the uppers of the shoe should be reinforced by leather molded or cut over the malleoli. The child should walk on the outer borders of his feet. Any textbook of exercise provides suitable exercises for improving the longitudinal arch.

EPIDERMOLYSIS BULLOSA

To the Editor.—A man, aged 31, slightly overweight but otherwise in perfect health, for about fifteen years has been troubled with blisters on his feet after any unusual exertion, such as playing golf, excessive walking, or dancing. They appear the morning after one of these forms of exercise and have the appearance of ordinary bullae, sometimes filled with clear fluid and less often with blood. They do not itch, are as painful as the average bullae, and keep the patient off his feet about two days during the height of the attack. They take the usual length of time for a bulla to heal and then reappear after the next exertion. He has had treatment from dermatologists, chiropodists and internists, all without relief. He has worn every type of shoe on the market, from the softest to the hardest made, and also shoes made in a special form to prevent irritation. The lesions are confined to the feet and do not appear in any other part of the body. The urine is normal. Can you suggest a diagnosis, the proper procedures to follow, and treatments? Please omit name and address. M.D., New York.

Answer.—The most likely disorder in which bullae occur following slight trauma is epidermolysis bullosa. If the patient has this, it will be difficult to use treatment that will be of much service.

The cause of epidermolysis bullosa is unknown. A diminution in the amount of elastic tissue in the skin has been described by Engman and confirmed by others. Many suggestions have been made, but no conclusive observations have been recorded. The prevention of injury, together with treatment of the symptoms as they arise, is all that can be recommended. Arsenic compounds and other specific cutaneous agents have not had any effect on the progress of the disease.

REMOVAL OF FLOWERS FROM HOSPITAL ROOMS AT NIGHT

To the Editor:—It seems to be a universal practice in hospitals to remove vases of flowers from a sickroom for the night. Plants liberate oxygen, as we all know, when growing in soil. Why should flowers in a vase be removed? One hospital superintendent stated that she was taught that the process is reversed: that carbon dioxide is liberated.
R. J. Stein, M.D., Graceville, Minn.

Answer.—It is difficult to give any definite reason why the removal of flowers from the sickroom at night has become an institutional routine. The statement of one hospital superintendent that carbon dioxide is liberated is apparently not correct. Living plants absorb carbon dioxide and give off oxygen. It is doubtful whether cut flowers do this to an appreciable extent; and even if the cut flowers did decay, the amount of carbon dioxide liberated would have practically no effect on the ratio of carbon dioxide to oxygen in the air of the room. Generally the flowers are removed to a warmer room at night rather than to a cooler room, so that preservation of the flowers is not an argument. Furthermore, if the odor of flowers is bad for the patient at night, it would seem logical to assume that it would also be bad for the patient in the daytime.

The inquiry was also referred to an authority on hospitals, who replies: "There is a certain psychologic effect on the patient in seeing flowers wither and there is a beneficial psychological reaction in most instances when, after a night's rest, fresh flowers, or flowers that are apparently fresh, are brought into the room to lend a little color to the patient's surroundings. . . . The procedure of removing flowers from the patients' rooms at night and returning them in the morning is a rather beneficial one, from the patients' standpoint."

IDIOSYNCRASY TO GOLD SODIUM THIOSULPHATE

To the Editor:—Information is requested as to the treatment of severe enteritis, manifested by diarrhea and abdominal cramps, following a series of injections of gold sodium thiosulphate, given for lupus erythematosus. The patient showed marked idiosyncrasy to 25 mg. intravenous doses, manifested by swelling about the eyes and neck, by dizziness and other signs. The skin lesions have cleared nicely, but the patient now has an intractable and typical heavy metal enteritis. Is sodium thiosulphate useful in combating this? M.D., California.

Answer.—Most observers are not impressed with the efficacy of sodium thiosulphate as used in combating the toxic manifestations associated with injections of gold sodium thiosulphate. It would seem that enteritis ostensibly following the administration of a metal should be dealt with in this way plus the administration of calcium intramuscularly as the gluconate, for example, and by the use of appropriate measures, such as a non-residue containing diet, an insoluble bismuth compound such as the subcarbonate, and charcoal in 4 Gm. doses by mouth, rest in bed, and teaspoonful doses of camphorated tincture of opium at appropriate intervals. The complications of gold administration are more difficult to deal with than those of mercury or bismuth, and apparently involve a higher degree of idiosyncrasy on the part of the patient, and a slower or more difficult elimination of the injurious agent. It would be well to recall that not all enteritis which follows administration of a heavy metal is necessarily due to the drug as such, and careful stool examination would certainly be in order.

POISONING OR MENINGITIS

To the Editor:—Two children, aged 4 and 5 years, from the same family, showed the clincal picture of cerebrospinal meningitis. Spinal puncture was done on one of these children shortly before death, and the fluid showed a marked increase in pressure with slight cloudiness. Both children died within twelve hours after the first symptoms appeared. Is there a poison that would take effect with such suddenness and with the symptoms of meningitis? The laboratory report on the spinal fluid was unsatisfactory, except for the statement that there was contamination, with many bacilli and cocci. Please omit name. M.D., Montana.

Answer.—There is such a thing as a cerebrospinal type of arsenical poisoning which might produce symptoms suggestive of meningitis, followed by speedy death. The convulsant poisons, such as strychnine, brucine, santonine and aspidium, might also produce clinical pictures simulating meningitis. A well marked turbidity of the cerebrospinal fluid would be in favor of an infection rather than of poisoning, as would also the presence of many bacilli and cocci.

DIPHTHERIA IMMUNIZATION

To the Editor:—A child, aged 7 years, was given 10,000 units of diphtheria vaccine because of a membrane appearing on the tonsils. A swab was sent to the laboratory and a return reported negative for evidence of diphtheria. The parents now desire to have the child immunized against diphtheria. Is there any reason why this should not be done? Please omit name. M.D., Kansas.

Answer.—Presumably the child received 10,000 units of diphtheria antitoxin (not vaccine). If the Schick test is positive, indicating that the child is susceptible to diphtheria, there is no reason why it should not be immunized. For immunization, diphtheria toxoid should be used in preference to diphtheria toxin-antitoxin, not only because it is more efficacious but because this child has already had an injection of horse serum.

PATERNITY TESTS

To the Editor:—Will you please tell me the best method, if any, to determine whether a child, 1 month old, of a white mother has a Negro father? Is there any blood test that would assist in making this determination? Kindly omit name. M.D., Georgia.

Answer.—At the age of 1 month, the child of a white mother and a Negro father may not show any obvious, clear-cut Negro characteristics. There is no blood test that will reveal the race of either parent. The most that the available blood test can show is that a given man may have been the father of a given child or that he could not have been the father.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

Alabama: Montgomery, Jan. 11. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

American Board of Obstetrics and Gynecology: *Clinical.* Chicago, Dec. 29. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

American Board for Ophthalmic Examinations: Boston, Dec. 21. Sec., Dr. Wm. H. Wilder, 122 S. Michigan Blvd., Chicago.

Arizona: Phoenix, Jan. 5-6. Sec., Dr. B. M. Berger, 12 North Central Ave., Phoenix.

California: *Reciprocity.* Los Angeles and San Francisco, Dec. 16. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

Colorado: Denver, Jan. 5. Sec., Dr. Wm. Whitridge Williams, 422 State Office Bldg., Denver.

District of Columbia: *Basic Science.* Washington, Dec. 29-30. *Regular.* Washington, Jan. 11. Sec., Dr. W. C. Fowler, District Bldg., Washington.

Hawaii: Honolulu, Jan. 11-14. Sec., Dr. James A. Morgan, Room 48, Young Bldg., Honolulu.

Louisiana: New Orleans, Dec. 10-12. Sec., Dr. Roy B. Harrison, 1507 Hibernia Bank Bldg., New Orleans.

Maryland: *Homeopathic.* Dec. 17-18. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

Minnesota: *Basic Science.* Minneapolis, Jan. 5-6. Sec., Dr. J. C. McKinley, 126 Millard Hall, University of Minnesota, Minneapolis. *Regular.* Minneapolis, Jan. 19-21. Sec., Dr. E. J. Engberg, 524 Lowry Medical Arts Bldg., St. Paul.

Nebraska: *Basic Science.* Lincoln, Jan. 12-13. Act. Sec., Mr. P. H. Bartholomew, Lincoln.

North Dakota: Grand Forks, Jan. 5-8. Sec., Dr. G. M. Williamson, Grand Forks.

Oregon: Portland, Jan. 5-7. Sec., Dr. C. J. McCusker, 1014 Medical Dental Bldg., Portland.

Pennsylvania: Philadelphia, Jan. 5-9. Sec., Mr. Charles D. Koch, Harrisburg.

Rhode Island: Providence, Jan. 7-8. Dir., Dr. Lester A. Round, 319 State Office Bldg., Providence.

South Dakota: The St. Charles Hotel, Pierre, Jan. 19-20. Dir., Dr. H. R. Kenaston, Bonesteel.

Tennessee: Memphis, Dec. 18-19. Sec., Dr. Alfred B. DeLoach, Medical Arts Bldg., Memphis.

Washington: *Basic Science.* Seattle, Jan. 14-15. *Regular.* Seattle, Jan. 18-19. Dir., Mr. Charles Maybury, Olympia.

Wisconsin: *Basic Science.* Milwaukee, Dec. 19. Sec., Prof. Robert N. Bauer, 3414 West Wisconsin Ave., Milwaukee. *Regular.* Madison, Jan. 12-14. Sec., Dr. Robert E. Flynn, 315 State Bank Bldg., LaCrosse.

Oregon July Examination

Dr. C. J. McCusker, secretary, Oregon State Board of Medical Examiners, reports the written examination held at Portland, July 7-9, 1931. The examination covered 11 subjects. An average of 75 per cent was required to pass. Thirty-five candidates were examined, 34 of whom passed and one failed. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent
College of Medical Evangelists		(1931)	88.1, 88.4, 89.8
State University of Iowa College of Medicine		(1930)	81.2
University of Michigan Medical School		(1930)	90.4
Creighton University School of Medicine		(1930)	88.1
University of Nebraska College of Medicine		(1931)	83.5
University of Oregon Medical School		(1928)	86, (1930) 87.1, 88.3, 89.1, (1931) 81.2, 81.4, 81.8, 83.1, 83.6, 83.7, 84.4, 85.5, 86.2, 86.5, 86.6, 86.6, 86.7, 87.2, 87.6, 87.6, 88.4, 89.5, 91, 92.1, 93
Osteopaths			81.9, 83.6

FAILED

Osteopath *

Dr. McCusker also reports 8 physicians licensed by reciprocity with other states and 3 physicians licensed by endorsement from July 8 to Sept. 8, 1931. The following colleges were represented:

College	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Denver and Gross College of Medicine, Colorado		(1909)	Colorado
Atlanta School of Medicine, Georgia		(1908)	Georgia
State University of Iowa College of Medicine		(1929)	Iowa
University Medical College of Kansas City, Missouri		(1906)	Kansas
Washington University School of Medicine		(1928)	Missouri
University of Nebraska College of Medicine		(1923)	Nebraska
University of Oregon Medical School		(1929)	California, Indiana

College	LICENSED BY ENDORSEMENT	Year Grad.	Endorsement of
Harvard University Medical School		(1925)	N. B. M. Ex.
University of Oregon Medical School		(1930, 2)	N. B. M. Ex.

* Reexamined in four subjects. Failed in three.

Nevada Reciprocity Report

Dr. Edward E. Hamer, secretary, Nevada State Board of Medical Examiners, reports 7 physicians licensed by reciprocity with other states and 2 physicians licensed by the endorsement of credentials from June 13 to Aug. 3, 1931. The following colleges were represented:

College	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Cooper Medical College, San Francisco		(1907)	California
Hahnemann Med. Coll. of the Pacific, San Francisco		(1914)	Washington
University of Louisville Medical Department		(1915)	Montana
Baltimore Medical College		(1895)	Penna.
University of Nebraska College of Medicine		(1925)	Nebraska
Memphis Hospital Medical College		(1910)	Mississippi
Licentiate of the Royal College of Physicians and the Royal College of Surgeons of Ireland		(1908)	California

College	ENDORSEMENT OF CREDENTIALS	Year Grad.	Endorsement of
Columbia University College of Phys. and Surgs.		(1929)	N. B. M. Ex.
University of Toronto Faculty of Medicine		(1927)	N. B. M. Ex.

Book Notices

Motives and Mechanisms of the Mind: An Introduction to Psychopathology and Applied Psychology. By E. Graham Howe, M.B., B.S., D.P.M., Honorary Physician, Tavistock Square Clinic for Functional Nervous Disorders. Cloth. Price, 10s. 6d. Pp. 260. London: The Lancet, Ltd., 1931.

The twelve chapters of this book have appeared in serial form in the *Lancet.* The book is refreshing as a synthesis of the approach toward the patient of that venerable and vanishing figure in medicine, the family physician, and of the modern psychotherapeutist imbued with dynamic concepts of human motivation. Perhaps the key-note of the volume is struck, properly, in the quotation from Ecclesiasticus on the fly-leaf, "He that sinneth before his Maker, let him fall into the hands of the physician." Modestly disclaiming anything "more than a little originality save in certain details of exposition," Dr. Howe presents a clinician's digest of the material of modern psychopathology, gleaned primarily from the field of psychoanalysis. The language is rather pictorial, to borrow a term from the author, and diagrams are used freely in the exposition of his conception of emotional development and to portray such mechanisms as projection, ambivalence, and symptom formation as solution of conflict.

The author makes an earnest attempt to summarize and to classify his material as he proceeds. His method of exposition may be illustrated by a quotation from the summary of his chapter on "Love: The Rôle of the Mother":

> It is the unconscious attempt to find short cuts [for solution of the Oedipus situation] which provides the material of psychopathology, and the symptoms of the disordered mind.
>
> The first short cut, described as "fixation compromise," is an attempt to have the best of worlds, which very nearly succeeds, but it is at the expense of dissociation, conflict and phantasy. . . . The second short cut method is by emotional repression, which may give rise to sexual negativism (frigidity), a reversal of the feeling tone from love to hate (as occurs in the misogynist) or to the pseudo-intellectualism which is the psychopathology of the "high-brow." . . . The third short cut is found in the psychology of the prig. . . . This is an example of overcompensation and, as a reaction to the problems of the eternal triangle, may be described as "Messianic identification."

Brief synopses of case histories are used liberally by way of demonstration.

The arrangement of material is confusing. If the book is to be regarded as an introduction to psychopathology, it would appear that clearer definition of the terms and concepts utilized throughout the book should be achieved early. As a simple example, one finds "repression" first referred to on page 29, with the statement that suppression "is not to be confused with repression, which is an unconscious and automatic process." Next "repressed homosexuality" is discussed (page 87). On page 120, reference is made to "repression of the sex factor" in calf-love, and there is a short, incomplete section on repression (page 125). On page 188, repression is discussed in one paragraph as one of six listed defense mechanisms. Unfortunately, a typographic error in which the term suppression is used instead of repression confuses the meaning for the uninitiated. Finally, in a section on conflicting wishes (page 211), "conscious suppression" and "unconscious repression" are cited as the two methods of resolving conflict. An initial adequate discussion of repression (never actually achieved in the book) and of other mechanisms would add much to the clarity of the text, for the student.

The final chapter, "Psychopathology in Relation to Treatment," reveals a healthy skepticism as to efficacy of treatment procedures in vogue among medical men, together with an attempt at constructive criticism. "Perhaps it is inevitable that the practice of psychotherapy should always fall short of the preaching of psychopathology, but it is probable that the next few years may see a great advance in our present method of healing." The author recommends "modified analytic methods" of treatment for the "average patient." "The analytic approach to mental disorders is the aetiological pursuit of causative factors into the past, the childish and the primitive. Any such approach to the problems of the human mind must necessarily be analytic but it is nevertheless not to be confused with psychoanalysis. Psychoanalysis means 'Freud,' and assumes both a specific psychopathology and a definite therapeutic technique. The latter, though invaluable for research work, can never be suitable for ninety-nine per cent of patients who require treatment, because of the time and cost which such treatment involves." The "analytic method" of choice is not very clearly described, but it is suggested that "whatever analytic method we may adopt there are certain common factors which demand consideration, the most important of which are transference, resistance, and free association."

The book is a laudable attempt to present the material of psychopathology to medical men. Uninitiated medical students will doubtless find it confusing. The psychoanalyst will find it incomplete. The practitioner in medicine will find it informative and stimulating, but it would be unfortunate were he to attempt to base his technic of treatment exclusively on the expositions and suggestions offered.

Benzol (Benzene) Poisoning: A New Investigation of the Toxicity of Benzene and Benzene Impurities. By Carey P. McCord, M.D., in collaboration with Nora Cox and Charlotte O'Boyle of the Industrial Health Conservancy Laboratories, Cincinnati, Ohio. Paper. Pp. 78, with 10 illustrations. Cincinnati: Industrial Health Conservancy Laboratories, 1931.

Benzene poisoning has become one of the most serious hazards of modern industry. As pointed out in the preface to this report, conditions other than benzene poisoning simulate it so closely that the diagnosis is frequently confused. Indeed, recently the similarity of benzene poisoning to agranulocytosis has been a special problem. The part played in the production of pathologic conditions by impurities in benzene has not been adequately presented, and the range of symptoms has not been properly recorded. The review of the subject by Dr. McCord presents new evidence, provides a practical review of present knowledge, and affords orientation in this field. It includes much new experimental evidence and is exceedingly practical in its recommendations for treatment and particularly for prevention. Finally, it is supplemented by an excellent bibliography covering the literature on the subject.

Lehrbuch der inneren Medizin. Bände I und II. Von G. v. Bergmann (mit F. Stroebe), R. Doerr, H. Eppinger, usw. Paper. Price, 45 marks. per set of two volumes. Pp. 893, with 136 illustrations. Pp. 782, with 140 illustrations. Berlin: Julius Springer, 1931.

As evident from the list of authors, a galaxy of stars of first and second magnitude among the medical teachers and investigators of Germany, this is a cooperative enterprise yielding a thoroughgoing textbook. Siebeck's introduction alone on the "physician and his function" makes one wish either that this book were in the hands of American medical students or that a similar introduction were found in our textbooks on the practice of medicine. "Not erudition but real help is demanded by the patient." Almost every section of the book commences with a general introduction intended to connect the student's preliminary work in physiology, pathology and bacteriology with the special pathology and therapy of the disease group under discussion. For instance, instead of precipitating the student unceremoniously into the study of "typhoid fever," as is done in so many of our textbooks on medicine, a chapter on the general mechanism of infection (by Doerr) and on general therapy of infection (by Staehelin) precedes. Helpful views, schematic illustrations, photographs of typical patients, and reproductions of characteristic roentgenograms are liberally sprinkled throughout the book, all of which aid the forcefulness of the presentation. Particularly interesting is the chapter by Siebeck on neuroses. One gets the impression that therapy is dealt with in quite a practical manner and that psychotherapy especially is given more adequate consideration than is generally the case in books of this kind; and the final portion of fifty pages on general therapy by Lichtwitz gives the much to be desired finishing touch to the book, the emphasis on treatment at the beginning and the end of the course yielding the impression that therapy is the alpha and omega of medicine. One fault that may be found—if criticism there must be in a book review—is the almost pedantic characteristically German thoroughness displayed in most of the chapters, which would discourage many medical students not accustomed to such heavy mental pabulum. To medical teachers this book may be strongly recommended as an example of the aims of modern German medical instruction.

The Biology of the Amphibia. By G. Kingsley Noble, Ph.D., Curator of Herpetology and Experimental Biology, the American Museum of Natural History. Cloth. Price, $5. Pp. 577, with 175 illustrations. New York and London: McGraw-Hill Book Company, Inc., 1931.

This scholarly treatise is somewhat more than the title might indicate. It is a general discussion of modern biologic problems, Amphibia being used as illustrative material. In interesting and, so far as possible, nontechnical language, Dr. Noble deals with the following problems: the origin of the amphibia, in which one finds illustrated modern phylogenetic methods; development and heredity, including normal and experimental embryology and genetics; the mode of life history, largely a discussion of larval adaptations; speciation and adaptation, a discussion of modes of evolution; sex and secondary sex characters. Then follow a series of chapters on comparative anatomy and physiology, system by system; a chapter on instinct and intelligence; one on the ways of amphibia; one on ecology; one on geographic distribution and economic value; and, finally, one on relationships and classification. The book is so broadly conceived that it might readily be used as a textbook of vertebrate biology for senior college or graduate students. Few important problems of modern biology escape notice. Most interesting are the chapters on speciation and adaptation, sex and secondary characters, the endocrine glands, instinct and intelligence, and relationships and classification. The whole book, however, is of such even excellence that it is difficult to select its best features.

Clinique médicale des enfants: Affections des organes hemolymphopoïétiques et du sang. Par P. Nobécourt, professeur de clinique médicale des enfants à la Faculté de médecine de Paris. Paper. Price, 60 francs. Pp. 432, with 125 illustrations. Paris: Masson & Cie, 1931.

This is one of a series of monographs on various topics in pediatrics which Professor Nobécourt has published at various times since 1921. It consists of a series of lectures or clinics devoted to the blood and blood-forming organs in children. The author discusses clearly and in an interesting manner all the diseases of the blood, first presenting a case in detail and then following with an elaborate discussion of the pathology and differential diagnosis. The book is illustrated with graphs and pictures and comprises practically all the blood dyscrasias in infancy and childhood. Any one who has had the opportunity of attending some of Professor Nobécourt's clinics knows what a kind and able clinician he is.

The Harvey Lectures: Delivered under the Auspices of the Harvey Society of New York, 1929-1930, under the Patronage of the New York Academy of Medicine. By Dr. Ernst P. Pick, Dr. E. K. Marshall, Jr., Dr. E. W. Goodpasture, Dr. Alan M. Chesney, Dr. Philip E. Smith, Dr. Esmond R. Long, Dr. W. J. V. Osterhout, Dr. Rufus Cole and Dr. Graham Lusk. Series XXV. Cloth. Price, $4. Pp. 225, with illustrations. Baltimore: Williams & Wilkins Company, 1931.

The Harvey Lectures for 1929-1930 include the following: The Regulation of Water Metabolism, by Dr. Ernst P. Pick, professor of pharmacology, University of Vienna, Vienna, Austria; The Cardiac Output of Man, by Dr. E. K. Marshall, Jr., professor of physiology, Johns Hopkins School of Medicine, Baltimore; Etiological Problems in the Study of Filtrable Virus Diseases, by Dr. Ernest W. Goodpasture, professor of pathology, Vanderbilt University School of Medicine, Nashville, Tenn.;

Acquired Immunity in Syphilis, by Dr. Alan M. Chesney, associate professor of medicine, Johns Hopkins School of Medicine, Baltimore; Relations of the Activity of the Pituitary and Thyroid Glands, by Dr. Philip E. Smith, professor of anatomy, Columbia University College of Physicians and Surgeons, New York; A Chemical View of the Pathogenesis of Tuberculosis, by Dr. Esmond R. Long, professor of pathology, University of Chicago School of Medicine, Chicago; Electrical Phenomena in the Living Cell, by Dr. Winthrop J. V. Osterhout, member of the Rockefeller Institute for Medical Research, New York; Progress of Medicine During the Past Twenty-Five Years as Exemplified by the Harvey Society Lectures, by Dr. Rufus Cole, director of the Hospital of the Rockefeller Institute, New York, and the Harvey Society by Dr. Graham Lusk, professor of physiology, Cornell University Medical College, New York. The first twenty-five volumes of these lectures have constituted a record of scientific research. The history of the society, as told by Dr. Graham Lusk at the supper in celebration of its twenty-fifth anniversary, is a most interesting medical anecdote which needs to be read in its original form to be appreciated. The society seems to have arisen in the brains of Dr. Graham Lusk, Mrs. Anna Bowman Dodd and Dr. Samuel J. Meltzer. In its formation many distinguished men took part. The first lecture was given in German by Prof. Hans Horst Meyer of Vienna, and the society was introduced to the public by Dr. C. A. Dana. Because it contains an index to the first twenty-five volumes of the society, the present volume is especially valuable.

Die medikamentöse und allgemeine Behandlung der Ohrenkrankheiten. Von Dr. Conrad Stein, Privatdozent an der Universität Wien. Paper. Price, 6.90 marks. Pp. 103. Vienna: Julius Springer, 1931.

Any sound and rational program of therapeusis, even if it relates to special diseases such as those of the ear, as in Dr. Stein's monograph, must rest on a sound knowledge of the causes of those diseases. Furthermore, every physician prescribing treatment must through good judgment and experience (and this includes the experience of others in his own field) be aware of those conditions in which treatment cannot possibly cure but is only palliative. In general, the author has done well. He takes into consideration all forms of therapy and not only those relying on medicaments. There seems to be, as is so generally the case on the continent, a reliance on proprietary remedies without a careful checking up on the part of any official body of the claims of the various manufacturers.

Surgeon of the Seas: The Adventurous Life of Surgeon General Jonathan M. Foltz in the Days of Wooden Ships. Told from His Notes of the Moment by Charles S. Foltz. Cloth. Price, $3.75. Pp. 351, with illustrations. Indianapolis: Bobbs-Merrill Company, 1931.

Jonathan M. Foltz was commissioned assistant surgeon of the navy by President Jackson in 1831. He became surgeon general of the navy under President Grant. His work took him to the coast of Sumatra in pursuit of pirates, and to Mexico and other countries. In the Civil War he was fleet surgeon on the *Farragut* on the Mississippi River. After the war he accompanied Farragut on the cruise around the world. The present volume is constructed by the author from notes and letters. It is an engaging narrative with a special interest for physicians. The personal relationships of Dr. Foltz to Polk and Buchanan and to other notables afford a striking insight into conditions during the administrations of these presidents. The book is provided with interesting illustrations and an adequate index.

Proceedings of the Second International Congress for Sex Research, London, 1930. Edited by A. W. Greenwood. Cloth. Price, 21/-. Pp. 637, with illustrations. Edinburgh: Oliver & Boyd, 1931.

This volume is divided into five parts, dealing with biology, hormones, therapy, contraception and sociology. Practically all the studies here concerned are of scientific value. In the second section, particular attention is paid to the male and the female sex hormone and also to pituitary hormones. Contributions by Aschheim, Koch, Funk, Frank and Moore indicate the basic character of this material. As is usually the case, the least critical portions of the book are those dealing with therapy. Contributions on theelin and menformon are especially uncritical. The articles in this collection are in English, French, German and Italian.

The Black Death and Men of Learning. *By Anna Montgomery Campbell*, Assistant Professor of History, New Jersey College for Women. Cloth. Price, $3. Pp. 210. New York: Columbia University Press, 1931.

The great plague, known as black death, which swept across Europe in the fourteenth century influenced every phase of human life. Several volumes have been published concerning its manifestations. With the scientific knowledge of that day, the plague was believed to be due to some divine manifestation of wrath. The present volume deals with the effects of the plague on science. Chapter 4 concerns particularly its effects in the field of medicine, surgery and hygiene. There is a discussion of the members of the medical faculty who died of the disease and of attempts made through sanitation and hygiene to control the pestilence. Other chapters concern the effects of the plague on universities and schools and on other intellectual fields. A carefully compiled bibliography and index complete this excellent contribution to the history of science.

A System of Bacteriology in Relation to Medicine. Volume IX. By J. A. Arkwright, S. L. Baker, and others. Medical Research Council. Cloth. Price, £1 1s. 0d. Pp. 364, with 86 illustrations. London: His Majesty's Stationery Office, 1931.

This volume completes a system of bacteriology prepared under the auspices of the Bacteriological Committee of the Medical Research Council. It includes sections on the design of bacteriologic laboratories, the microscopic demonstration of bacteria, the preparation of culture mediums, such technical questions as the determination of p_H, the aerobic and anaerobic methods, isolation of single cells, filtration, bacteriophage, serology, anaphylaxis, breeding and care of laboratory animals, vitamin A deficiency, ultraviolet therapy, electricity, and the determination of the value of disinfectants. The book includes also the general index to the nine volumes. The material in this book is on a par with that in the preceding volumes and makes the study complete. No modern school or institution devoted primarily to bacteriologic studies can afford to be without this system.

Confessio Medici. By Stephen Paget, F.R.C.S. Reissued, 1931. Cloth. Price, $2. Pp. 158. New York: Macmillan Company, 1931.

This volume, first published in 1900, is now reprinted because of the demand for these excellent essays. To the physician, the nurse or any worker in the field of health the essays are inspirational. The essay for students establishes a point of view. The essay on Paré is a beautiful example of writing in medical history. The essays on medical practice, its rewards and its dissatisfactions will strike a sympathetic chord in every physician. The final essays on "Retirement" and "The Very End" lead gradually to the epilogue on the privileges of the physician:

"The natural dignity of our work, its unembarrassed kindness, its insight into life, its hold on science—for these privileges, and for all that they bring with them, up and up, high over the top of the tree, the very heavens open, preaching thankfulness. Circle above circle, the reasons for it are established, out of the reach of words."

Gewerbekrankheiten: Klinische Grundlagen der 22 meldepflichtigen Berufskrankheiten. Von Dr. med. Ernst W. Baader, Dozent für Berufskrankheiten an der Universität Berlin. Paper. Price, 9 marks. Pp. 144, with 29 illustrations. Berlin: Urban & Schwarzenberg, 1931.

Most books on occupational diseases are ponderous volumes, with far too many theoretical considerations to meet the needs of the general practitioner in industrial communities, who, however, is the one who sees the greatest number of cases of trade disease. Here is a small, well written booklet, embodying the essentials of medical requirements on the twenty-two occupational diseases compensable in the author's country. According to the preface, "The study of the relation between occupation and sickness is one of the most interesting and promising fields of future medicine, which, unfortunately, up to the present time, has only lightly been touched on by the general practitioner. The necessity for an increased knowledge of toxic work substances is, especially in industrial countries like Germany, most profound." The author ably discusses the practical aspects of the commoner trade diseases. He includes, among others, the clinical conditions arising after exposure to lead and its compounds; mercury and its compounds; arsenic and its compounds; phosphorus; manganese; benzene and its homologues; nitro and amido compounds of the aromatic series;

carbon bisulphide; hydrogen sulphide; carbon monoxide; compressed air; noise and other deafness-producing conditions; silicosis and other forms of pneumonoconiosis; parasitic conditions, such as hookworm infestation; harmful rays; skin diseases, and tropical diseases. This booklet should be translated into English for the use of practitioners in this country. It should serve as a stimulus to authors in this country to prepare simple textbooks covering occupational diseases of particular interest to specific areas, such as a textbook entitled "The Practical Medical Aspects of Occupational Diseases Compensable in New York." More books on occupational diseases are needed. This book is welcomed because of its merit. Others will be welcomed.

The Doctor Explains. By Ralph H. Major. Cloth. Price, $3.50. Pp. 277, with illustrations. New York: Alfred A. Knopf, 1931.

As a contribution to the growing literature for the public on subjects of health, Dr. Ralph Major contributes thirteen excellent essays on topics of major interest. These include:

1. The Physical Examination.
2. Seeing the Invisible.
3. The Rôle of the Blood.
4. Heart Disturbances.
5. The Mysteries of Blood Pressure.
6. The Dangers of Sugar.
7. Body Fuel and Its Consumption.
8. Vitamins and Deficiency Diseases.
9. The Malady of Venus.
10. Hypersensitive People.
11. X-Rays and Other Rays.
12. The Story of Antisepsis.
13. The Conquest of Pain.

Dr. Major writes directly and simply but without extraordinary literary skill. He uses the historical background for developing interest, but from the point of view of the reader who is looking for practical information there is somewhat too much of history in proportion to the amount of usable fact. Thus the chapter on "Body Fuel and Its Consumption" includes about three pages of fact and about fifteen pages of history. For those who want their medical information without too much romance, who want it directly and understandably, Dr. Major has provided a most satisfactory book.

Stereoskopischer Atlas der äusseren Erkrankungen des Auges nach farbigen Photographien: Für Studium und ärztliche Fortbildung. Mit begleitendem Text von Karl Wessely, Professor in München. Lieferung 3. Bild 21-30. Boards. Price, 12 marks. Munich: J. F. Bergmann, 1931.

This outfit includes ten of a series of thirty stereoscopic colored plates of diseases of the eye, with an explanatory text. The plates are beautifully made in colors and are therefore excellent for study by both the specialist and the student.

The Great Physician: A Short Life of Sir William Osler. By Edith Gittings Reid. Cloth. Price, $3.50. Pp. 299, with 10 illustrations. New York: Oxford University Press, 1931.

The author of this volume was a close friend of Dr. Osler and of his family. In preparing her book she has utilized material previously assembled by others and has had the help of other friends and biographers. This book does not substitute for and does not supplement the famous "Life of Osler" by Harvey Cushing. It is rather a simpler and condensed consideration, handsomely prepared and therefore especially suited to the reader who cannot devote the time and the thought that the more comprehensive work requires. The book is beautifully printed and has an excellent index.

Tables of Food Values. By Alice V. Bradley, B S., Supervisor and Instructor of Nutrition and Health Education, State Teachers College, Santa Barbara, California. Cloth. Price, $2. Pp. 128. Peoria, Ill.: Manual Arts Press, 1931.

These tables have been accumulated from computations published in other volumes as well as by the author herself. The physician and the dietitian who prescribe diets for patients with various disorders will find it of the utmost usefulness. The measures are given in quantities ordinarily used. For each food substance, information is given as to weight in grams of protein, fat and carbohydrates; total calories; the amounts of calcium, phosphorus and iron; vitamin content; value as a source of bulk, and the reaction, whether acid or basic.

Medicolegal

Trauma, Eczema and Workmen's Compensation

(Bernard v. City of Lafayette (La.), 132 So. 395)

The plaintiff, a common laborer, in the course of his work was struck on his leg about six inches below the knee by a heavy iron pipe. The only visible evidence of injury at the time seems to have been a scratch about 2½ inches long. He did not believe the injury serious, but on the Sunday night which followed the evening of the accident he was awakened by the effects of the injury and by Monday morning he could hardly stand on his leg. His foreman testified that a day or two after the accident the skin was scratched and red and the leg "kind of swollen," but not in a very bad condition. Three or four days later the plaintiff returned to work. He got wet while at work, by standing in mud and water during the entire day, the water being clear water from the city's water mains. According to his testimony, eight days after the accident pimples and little "heat eruptions" began to grow out around the sore or bruise on his leg. These pimples or sores spread in the course of a few months, covering the hands, legs, and in fact the whole body. The plaintiff brought suit under the workmen's compensation act, attributing the eruption to the accident from which he had suffered. In the trial court, judgment was given in his favor. The defendant, however, appealed, and the court of appeal of Louisiana, first circuit, annulled the judgment and refused the plaintiff's demand (*Bernard* v. *City of Lafayette*, 126 So. 585), saying: "It is not shown that the eczema with which the plaintiff is infected is the natural result of an accident received as alleged, nor that an existing condition in plaintiff's system was thereby activated into virulence." On a rehearing, however, the appellate court reversed that judgment and affirmed the judgment of the district court in favor of the workman.

The physicians who testified in the case had not examined the plaintiff until several months after the accident, when the eczema or rash had covered the body of the plaintiff, and not at a time when they might have made observations that would have enabled them to give expert testimony in reference to the origin of the disease. One of these physicians testified "that the affection of which plaintiff was suffering begins by an infection caused by a germ, and that a person with an abrasion on his leg would be subject to an eczema." Another testified "that he found plaintiff was suffering from an exudative eczema which was most probably caused by some broken or slight abrasion of the skin surface" and in such cases "the cause is not internal but is specific and external." The third medical witness, appointed by the court as an expert, testified "that it is possible for a person with a bruise or scar exposed to mud and water to develop the condition in which he found plaintiff when he made his examination." There was nothing in the testimony of this last witness, said the court, that contradicted the testimony of the other two physicians in reference to the probable origin of the trouble.

It was shown overwhelmingly by the evidence, the appellate court concluded after the rehearing, that prior to the accident the plaintiff was and had always been in fine health, strong, robust, and a reliable, efficient laborer, and, the court added:

> It is singular, and indeed passing strange, that, if the eczema of which he complains had had its origin from some invisible internal cause, arising from nervousness or such like, there had never been any indication that he carried in his system a trouble of that character. Usually, nature gives a warning by some symptom or other of an approaching disease. There should have been, it seems to us, some premonition of the coming trouble. If he really had such a dormant disease in his system, it is again very singular that it should have, immediately after the accident, started to grow from the point of injury and from there spreading over his whole body.
>
> It is known today by laymen, and which is not disputed by the physicians who testified in this case, that practically all diseases are caused by microbes, bacteria, or germs. It is also known that, when water, whether from city mains, clear or not, is mixed up with the dirt of ditches or streets, that mud, the result of it, may at any time be saturated with microbes or germs which may bring about different forms of diseases, and exceedingly virulent in character.
>
> If plaintiff was not affected with the trouble when he first received the injury, we think the proof shows with sufficient legal certainty that, after his exposure to the mud in laying the pipe, he was infected with microbes or germs which laid concealed there.

Insurance, Life; Presumption Against Suicide.—A policy on the life of the deceased provided that if within one year after its date the insured should die by his own hand or act, whether sane or insane, liability should be limited to the amount of the premiums paid. After the insured's death within the one year period, the insurer claimed that he had died by his own act. The insured had suffered from pellagra for a number of years, but his physician went no further than to say that he thought "at one time that 'he was possibly a little off,'" but that perhaps he would have overlooked that fact if he had not been hunting for it Neighbors and associates testified that they had never noticed anything wrong with his mentality. The insured and his wife were found dead in their home. His wife was on the bed, apparently having been killed by a blow on the head with some blunt instrument. She had died apparently at least eight hours before her husband, as determined by the relative degrees of decomposition of their bodies. The insured was lying on the floor, with his throat cut on both sides and incisions on both wrists and ankles. Lying near him was a large knife, and on the mantlepiece were a small knife and a razor blade, on all of which, as well as on an electric bulb, there was blood. Bloody prints were on the floor, apparently the tracks of some one who had stepped in the blood. There was testimony to the effect that the front door of the premises was unlatched, that it was the custom of the insured to leave the doors unlocked, thus enabling any one to enter the house without difficulty. There was further testimony that a few days before his death he had received $400 in a business transaction, which could not be found or accounted for. Neighbors had heard no disturbance in the house. The furniture in the room was not disarranged and there was no evidence of the ransacking of trunks, chests, bureau drawers, or other receptacles such as might have contained money. In quoting its own previous opinion (*McKendree* v. *Life Insurance Co.,* 112 S. C. 335, 99 S. E. 806, 807) the court said:

> The presumption of fact is that a man will not take his own life. Every action of a man, voluntary and involuntary, tends to preserve his life.

Under the testimony, said the court, it could not be said, as a matter of law, that the presumption against self-destruction had been overcome and the fact of suicide established. As more than one inference could be drawn from the evidence as to how the insured came to his death, the trial judge properly submitted the question to the jury.—*Swofford v. Life Ins. Co. of Virginia (S. C.), 157 S. E. 7.*

Dying Declarations: Mental State of Declarant.—The declarant died as the result of a gunshot wound, inflicted June 18, 1929. The bullet entered "the summit of the head," in a line drawn from the opening of one ear to the opening of the other, directly over the head. The bullet split, one half passing through the skull into the brain and the other passing along the top of the skull, under the scalp, emerging and finding lodgment in the wall near the ceiling. In the course of an operation an incision was made across the front of the head, an inch and a half above the eyebrows. The bone was found "shattered there, cracked loose." The surgeon removed such loose pieces of bone as he thought proper, along with parts of the brain, and extracted from the right lobe of the brain the fragment of the bullet that had lodged there. Dying declarations were taken on July 27 and August 9, and the patient died on August 14, 1929. An autopsy showed the path of the bullet through the right lobe of the brain, touching the left lobe also a little in one place. Posterior to it, there was necrosis. There was evidence of a devitalization of tissues along the course of the bullet.

The wife of the deceased was convicted of murder and appealed to the Supreme Court of Nevada, where her conviction was affirmed (*State v. Watts,* 290 P. 732). On a rehearing, it was urged, among other things, that because of the nature of the wound inflicted on the deceased, and his weakened condition, his brain had deteriorated very materially and his mentality was not sufficient to justify the introduction of the dying declaration made by him; also that there was a strong likelihood and possibility of his laboring under "a hallucination" by reason of the weakened condition of his brain when the dying declarations were made. The testimony of several witnesses showed, however, that at various times between the infliction of the wound and death, the mind of the deceased was clear. The attending physician testified that until about July 23 or July 24 the mentality of his patient was clear; that on or about July 27 and for four or five days prior thereto he was "slipping pretty fast," and between July 27 and August 9 his physical condition was progressively bad, but that his mentality on July 27 and August 9, the days when the dying declarations were made, was quite clear. After having examined the records "with the utmost care and the most minute scrutiny," the Supreme Court of Nevada concluded that the dying declarations were properly admitted in evidence.—*State v. Watts (Nev.), 296 P. 26.*

Optometry: Eyesight Testing Device Supplied for Use by Customer.—In Missouri, persons, firms and corporations who manufacture or deal in eye-glasses or spectacles in stores, shops or other permanently established places of business are not required to be licensed under the optometry act. The defendant sold eye-glasses in his jewelry store in Kansas City. In his store he kept a "self-fitting eye-testing machine," by the use of which customers were supposed to be able to determine, each for himself, the kind of eye-glasses he needed. The state instituted a prosecution for practicing optometry without a license, contending that the use by the defendant, or the furnishing by him for use, of the device described constituted something more than the sale of glasses and was the practice of optometry. The defendant was convicted. Thereupon he appealed to the Supreme Court of Missouri, contending that under the exempting provisions of the optometry practice act he was permitted to facilitate the sale of eye-glasses by the use of the device described. The Supreme Court upheld his contention, reversed the judgment of the trial court, and discharged the defendant. In exempting from the operations of the optometry practice act, persons who deal in eye-glasses or spectacles in stores, shops and other permanently established places of business, said the court, the legislature must be presumed to have intended that such dealers might do the things properly incident to such dealing. The sale of eye-glasses presupposes some test or trial by the customer to determine which glasses best suit him, just as in buying a suit of clothes or a pair of shoes there must be a "trying on" or test to determine the fit. If the dealer permits the customer to take from a tray, put on, and look through, pair after pair of glasses, or if the dealer hands the customer from a tray one pair of glasses after another until the customer finds the pair that suits him, it would hardly be contended that was more than is permissible under the exemption. The testing device furnished by the defendant, said the court, was in effect only the means by which a customer could try various eye-glasses without actually handling them.—*State v. Knapp (Mo.), 33 S. W. (2d) 891.*

Insanity: Prior Mental Condition as Evidence.—Evidence of prior and subsequent mental conditions is admissible to determine a person's mental condition at the precise time of the act in issue. A witness who has had opportunity and occasion to know and observe a person whose sanity is impeached may testify to facts and may express an opinion based on his knowledge and observation as to the mental condition of such person. While evidence of previous insanity of a temporary character may not raise a presumption of continued insanity, it may be considered by the jury in connection with other evidence in determining an issue as to a person's mental capacity.—*Mangum v. Brown (N. C.), 156 S. E. 535.*

Society Proceedings

COMING MEETINGS

Philippine Islands Medical Association, Manila. December 15-18. Dr. A. S. Fernando, 817 Taft Avenue, Manila, Secretary.

Society of American Bacteriologists, Baltimore, December 28-31. Dr. James M. Sherman, Cornell University, Ithaca, N. Y., Secretary.

Southern Surgical Association, White Sulphur Springs, W. Va., December 8-11. Dr. Robert L. Payne, 142 York Street, Norfolk, Va., Secretary.

Western Surgical Association, Denver, December 4-5. Dr. Frank R. Teachenor, 306 East Twelfth Street, Kansas City, Mo., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Cancer, New York

15: 2435-3117 (Oct.) 1931

*Occurrence of Malignancy in Radioactive Persons. H. S. Martland, Newark, N. J.—p. 2435.
*Prognosis of Gynecologic Cancer. H. C. Taylor, Jr., New York.—p. 2517.
Cancer of Thyroid Gland. H. M. Clute and S. Warren, Boston.—p. 2563.
Giant Intracanalicular Fibro-Adenomyxoma of Breast: So-Called Cystosarcoma Phyllodes Mammae of Johannes Müller. B. J. Lee and G T. Pack, New York.—p. 2583.
Comparison of Conditions Associated with Breast Cancer in Great Britain and America. J. M. Wainwright, Scranton, Pa.—p. 2610.
*Malignancy of Testis, with Especial Reference to Undescended Testis: Seventy-Six Cases (Seventeen Cases Previously Reported). C. E. Rea, Minneapolis.—p. 2646.
*Investigation of Physical Nature of Cancer Cells. G. W. Crile, Maria Telkes and Amy F. Rowland, Cleveland.—p. 2659.
*Interrelations Between Histologic Structure and Blood Chemical Findings in Cancer. W. C. Hueper, G. E. Woodward and E. G. Fry, Philadelphia.—p. 2666.
*Relation of Heredity to Cancer Occurrence as Shown in Strain 621: Studies in Incidence and Inheritability of Spontaneous Tumors in Mice. Maud Slye, Chicago.—p. 2675.
*Effect of Injection of Heated Tumor Tissues on Resistance to Tumor Implantation. K. Sugiura and S. R. Benedict, New York.—p. 2727.
Is There a Specific Bacterial Irritant to Four Sites of Carcinoma? E. W. Saunders and Mary A. Cooper, New York.—p. 2745.
*On Relation Between Parathyroid Hormone and Growth of Rat Carcinoma T. S. Paik, Seoul, Korea.—p. 2756.
Recent Biochemical Research in Cancer with Especial Reference to Metabolism of Normal and Malignant Cell. E. C. Dodds.—p. 2765.
Rôle of Heredity in Determining the Incidence and Growth of Cancer. C. C. Little, Bar Harbor, Maine.—p. 2780.
Action of Tumor Extracts on Spread of Experimental Vaccinia of Rabbit. F. Duran-Reynals and F. W. Stewart, New York.—p. 2790.

Occurrence of Malignant Conditions in Radioactive Persons.—Martland calls attention to certain data that he has accumulated in the study of radium dial painters which may have an important bearing on future research in the etiology of cancer and of certain obscure blood diseases. His studies indicate that it is important to have proper medical supervision over the use of radium and roentgen rays for therapeutic purposes, and governmental control over industries and occupations in which exposure to radioactive substances takes place. It would seem that the use of radiations for therapeutic purposes should be confined to hospitals and institutions specializing in and competent to handle such treatments, and that the indiscriminate use of radium and roentgen rays should be in some way controlled. All occupations in which the handling of radioactive substances occurs should be under strict governmental control and supervision. Rules and regulations covering the dangers of exposure should be outlined. Technical methods should be devised in specific industries so that exposure is reduced to a minimum. If in a certain industry the exposure cannot be reduced to a safety minimum, the procedure in use should be given up for some other method; if this is not possible, the industry should be discontinued. In this respect it is interesting to note that the U. S. Public Health Survey, which shows that the habit of licking brushes in the watch dial industry has been stopped and that various mechanical methods have been devised to apply luminous paint, states that, in spite of the utmost care and precautions against undue exposure, girls who work under the new methods still become radioactive and show an average of 0.5 microgram of radioactive substance in their bodies. It is a question whether under these conditions one should be satisfied to regard the industry as a safe one. The foregoing arguments apply also to the sale of radioactive waters, emanators, activators, and so on. The sale of all such commodities should be stopped until it is definitely established that they are harmless. The indiscriminate sale of these waters and apparatus by laymen and quacks is criminal. Their therapeutic effects are nil if one excludes the psychic effects produced on the patient. The human race would not suffer by eliminating them. These studies, aside from drawing attention to the occurrence of malignant tumors in radioactive persons and giving another cause for osteogenic sarcoma, may be of importance in the experimental study of cancer. It may be possible to show new methods by which malignant tumors may be produced in animals. Recently, in Germany, bone sarcoma has been produced in the rabbit by means of irradiation from implanted radium. The question arises, May not other forms of malignancy depend on the presence in the human body of increased amounts of radioactivity too small, perhaps, to be detected by the present methods? This question will be harder to answer than appears at first thought. While the amounts of radioactive substances in the dial painters are extremely small, being measured only with great difficulty, they must be much greater than one would ever expect the normal individual to acquire. Unfortunately, at the present time, it is impossible to estimate much smaller quantities. A great deal less might produce malignant changes over a longer period of time. Some have thought that 10 micrograms of radium deposited in the tissues of the body is probably just within the limits of tolerance of the average person. From the author's experience it is impossible to state what is the greatest amount of radioactivity the body can safely carry. He believes that less than 0.5 microgram is dangerous. Theoretically the exposure to or the use of any radioactive substance that will increase the normal radioactivity of the body is dangerous. At the present time he can only suggest that some other types of malignant tumors may be caused by minute amounts of radioactive substances to which the human body, in its normal environment, is exposed.

Prognosis of Gynecologic Cancer.—Taylor presents a clinical and pathologic study of 739 cases of gynecologic cancer observed at the Roosevelt Hospital from 1910 through 1930. Cancer of the cervix in the only two reportable years (1924-1925) in which radium was used practically exclusively was curable for at least five years in 18 per cent of all cases. The amount of irradiation in these years was inadequate. An increase in dosage, a better method of application, and the addition of high voltage roentgen therapy will, it is hoped, lead to improved results for the years after 1927. In the years 1921-1923, however, when the plan of treatment for favorable cases was preoperative radium and later radical hysterectomy, the absolute five-year cure rate was 29.7 per cent. Carcinoma of the corpus gave an absolute cure rate of 25.8 per cent, a disappointing figure, owing in part to a large number of lost cases. Among the traced cases in which operation was performed the results approached the average reported by other institutions. The high mortality, especially in women over 60, leads to the suggestion that irradiation should be substituted for surgery at least in this group. Carcinoma of the ovary yielded only 6.9 per cent of cures, a very low figure, owing perhaps entirely to a review of the sections and the exclusion of all cures in cases possibly classifiable as papillary cystadenoma. The successes were all due to factors uncontrollable by the surgeon; namely, the restriction of the growth at the time of operation to an unruptured cyst. Roentgen therapy has not produced cures in otherwise incurable cases in the Roosevelt clinic but will be continued in view of favorable outside reports. Carcinoma of the vulva yielded 21.1 per cent of cures, but it is probable that this figure might have been better had several of the patients in the early cases not been at first treated by a too conservative operation. Carcinoma of the vagina has recently been treated by radium, which has led to some preliminary encouraging results. Sarcomas of the uterus and ovary offer difficulties in histologic diagnosis which may largely affect the reported percentage of cures. From a more practical point of view a failure on the part of either surgeon or pathologist to differentiate myosarcoma from a benign fibromyoma may jeopardize the individual patient's chances. A few rarer tumors, carcinoma of the tube, chorionepithelioma, and sarcoma of the rectovaginal septum are reported. An apparent cure is noted in a case of the disease last cited. Advanced peritoneal malignant tumors of undetermined origin, usually regarded as ovarian, are separately considered. They form a fairly large and quite hopeless group. A careful review of the pathologic sections of cases of cancer of the cervix has led to little corroboration of the finding of several writers that histologic form bears a relation to prognosis as the result of variations in malignancy or in radiosensitivity. There was a very slight indication of such a relationship in carcinoma of the corpus. The correct separation of corpus adenocarcinoma from endometrial hyperplasia, of papillary cystadenocarcinoma of the ovary from papillary cystadenoma, of myosarcoma from fibromyoma, and of fibrosarcoma from fibroma of the ovary is, however, of vital importance in prognosis.

Malignant Tumors of Testis.—Rea states that while malignant tumors of the testis are uncommon, they occur relatively much more frequently in undescended than in descended testes, and the danger of malignant tumor in the abdominal is just as great as in the inguinal testis. The present forms of treatment are unsatisfactory. The proportion of four-year survivals after orchidectomy is but 13.2 per cent. When suitable irradiation is added to orchidectomy, this percentage is materially increased in patients without obvious metastases. Approximately 7 per cent of those with obvious metastases are saved, at least temporarily, by irradiation. The value of Coley's serum in conjunction with other methods requires further study. The best results from any single method in the operable cases follow the radical operation (block excision of the testis, spermatic cord, and regional lymph nodes). Judging by the literature, the author believes that results surpassing those yet attained should attend the combination of radical surgery and irradiation. Education of the public to seek competent medical advice early is the only practical solution of the problem of malignant tumors of the testis at present. Biopsy and frozen section diagnosis should be resorted to, with the patient prepared for immediate radical surgery, in early doubtful cases. The undescended testis should be placed in the scrotum, where it can be observed, in all cases. This proving impracticable, it should be excised, provided the opposite organ is normally placed or placeable.

Physical Nature of Cancer Cells.—In their investigation of the physical nature of cancer cells, Crile and his associates have sought evidence in support of the widely held theory that cancer owes its development to some alteration in the cells of the tissues as the result of some mechanical, physical or chemical factor. To this end they have been endeavoring to discover some physical principle which might account for the conversion of normal cells into cancer cells as the result of single or repeated injury; for cancer cells do not originate in uninjured, unchanged tissues, but in tissues which have been subjected to chronic irritation. It is clear that the cancer cell must owe its formation to the operation of existing laws of growth in the host, for cancer originates and lives only in the living. The problem, therefore, is concerned with the struggle for survival between the cancer cell and the normal cell; and the logical point of attack would seem to be the characteristics of the normal cell. The authors have therefore been trying to discover what physical differences might account for the conversion of differentiated into undifferentiated cells; of cells whose energy is used primarily for function into cells whose energy is used primarily for growth. They have found that as compared with neighboring cells cancer cells appear to have a greater conductivity and capacity. In rat cancer the injury current of a cancer is opposite to that of the neighboring tissues and organs. The electric potential may be an index controlling the treatment. By ionization the sign of charge of a cancer cell may be changed and the change maintained. It is suggested that after cancer tissue has been partly reduced by ionization it may be completely reduced by radiation at a lesser dosage than that used clinically.

Blood Chemical Examination in Cancer.—Hueper and his associates correlated the malignancy indexes and the blood p_H values in thirty-four cases of carcinoma. A preponderance of histologically highly malignant tumors was found in patients with an alkalosis, while the tumors of histologically low malignancy predominated in patients with a normal blood p_H. The alkalosis of the blood in cancer patients varies not only with the extent of the disease but also with the degree of malignancy and maturity of the tumor. The degree of cellular irregularity of cancerous tissue is increased in patients with an alkaline p_H of the blood as compared with patients with a blood p_H in the normal range. In about one third of the cancer patients with a hyperglycemia (which was present in 78.3 per cent of the cases) a high number of mitoses was found, while this phenomenon was absent in cancer patients with a normal blood sugar.

Relation of Heredity to Occurrence of Cancer.—Slye presents the record of an entire single strain of mice derived from the mating of a cancerous female and noncancerous male, and bred through three generations. The report includes all totals regarding the occurrence of malignant diseases and the ages of the mice. The entire strain, including the parents, consisted of 207 individuals, of which 115 were females and 92 were males. Of these, 23 were cancerous, or slightly over 11 per cent of the strain. The matings in this strain were practically typical of human matings, and the 11 per cent of neoplasms is a close approximation to the percentage of occurrence of neoplasms in man. The types of neoplasm occurring in this strain were carcinoma of the mammary gland, squamous-cell carcinoma of the skin, carcinoma of the lung, and leukemic diseases. In this strain two external factors were noted in connection with the two predominating types of cancer: (1) chronic dermatitis of the muzzle and eyelid skin, in both sexes; (2) a marked tendency to the formation of cysts in the inguinal mammary gland. Every case of skin cancer and every precancerous condition of the skin arose on a chronic dermatitis, frequently of long duration; and some of the mammary gland carcinomas seem to have arisen in mammary gland cysts. Other characteristics noted in the strain are the prevalence of pneumonia and nephritis, a tendency to emaciation in all of middle and late life, and a tendency to longevity. The average age at which cancer was noted in this strain was ten months and one day. The average age at death of the cancerous mice was 1 year, 1 month, 12 days. The average age at death of the noncancerous mice was 1 year, 3 months, 29 days. Thus, not only did the noncancerous mice of any given generation live well beyond the age at which cancer occurred in the cancerous mice, but their noncancerous offspring also lived long enough to confirm the classification of both themselves and their parents as noncancerous individuals. The twenty-three cancers were distributed as follows through the four generations studied: (1) In the parent generation, one, the parent female of the strain; (2) in the first generation, consisting of nine individuals, none were cancerous; (3) in the second generation of thirty-six individuals, nine were cancerous, and (4) in the third generation of 160 individuals, thirteen were cancerous. All the figures reported are a close approximation to the classic expectation for cancer as a mendelian recessive, and the classification of every mouse is confirmed by its progeny.

Effect of Injection of Heated Tumor Tissues.—Sugiura and Benedict placed fragments of fresh tumor tissues in a Locke-Ringer solution at p_H 7.0 and submitted them to various temperatures for varying periods in order to obtain the minimum lethal time for a given temperature. Inoculation of heat-inactivated Flexner-Jobling rat carcinoma cells previous to implantation of fresh, healthy homologous tumor cells did not prevent the growth of the latter. Injection of heat-inactivated Sugiura rat sarcoma cells produced slight but definite protection against the subsequent growth of new sarcoma cells in the treated animals. Injection of a fragment or emulsion of Rous chicken sarcoma in which the causative agent had been attenuated at a temperature between 45 and 60 C. with a minimum time of exposure conferred marked resistance to the subsequent implantation of the homologous tumor. The immunizing property of the attenuated chicken sarcoma was abolished by prolonged heating or heating the tumor tissue at a much higher temperature. Previous injection with the heat-inactivated Rous chicken sarcoma brought about prolongation of life in the tumor-bearing chickens, subsequently inoculated with viable tumor. Single or repeated subcutaneous or intramuscular inoculations of the heat-inactivated Flexner-Jobling rat carcinoma, Sugiura rat sarcoma, or Rous chicken sarcoma did not have any effect in checking the growth of firmly established tumors in animals.

Parathyroid Hormone and Rat Carcinoma.—Paik describes experiments on rats in which he demonstrated that there is a close relationship between the growth of transplantable rat carcinoma and the internal secretion of the parathyroid. The internal secretion of the parathyroid stimulates the development of rat carcinoma, but decrease of its internal secretion *interferes with development of such a carcinoma.*

Alzheimer's Disease.—Lowenberg and Rothschild report two cases of Alzheimer's disease. Although atypical in some respects, clinically and pathologically there were adequate grounds for classifying them with the Alzheimer group. In the first case the Alzheimer disease picture was superimposed on a chronic syphilitic meningitis in a feebleminded person. In addition, the brain showed cerebral hemiatrophy. This was thought to represent the anatomic substratum of the feeblemindedness. In the second case there were certain clinical features which seemed entirely inconsistent with a presenile disorder. The etiologic factor in this case was regarded as toxic in nature. These observations, taken in conjunction with others in the literature, lead to the conclusion that Alzheimer's disease is really a syndrome with a multiplicity of etiologic factors. The majority of the cases must still be brought into relation with atypical senile processes. However, there is a smaller group in which the causative agents appear to be toxic or organic diseases that are clearly independent of senility or allied conditions.

Sex-Linked Inheritance in Mental Deficiency.—A little over a year ago, Rosanoff undertook a study of mental disorders in twins. In the course of that study he sought out in state hospitals, institutions for the mentally deficient, prisons, reformatories and other such institutions patients or inmates who had a twin brother or sister living somewhere and accessible to investigation. In the group of mental deficiency cases he has thus far accumulated records of ninety-five pairs of twins. One or both in each pair had mental deficiency. The main purpose of the study was to compare the observations in monozygotic and dizygotic twins. Among the thirty-five pairs of monozygotic twins, both twins were found to be affected in thirty-three instances; and only one was affected, the other having normal intelligence, in two instances. Among the sixty pairs of dizygotic twins, both twins were affected in thirty-two instances and only one was affected in twenty-eight instances. In the entire group there was a greater number of cases of mental deficiency in the male sex than in the female sex: normal subjects were, on the contrary, fewer in the male sex than in the female sex. The greater frequency of mental deficiency in the male than in the female sex was most strikingly shown in opposite-sex twins. Among twenty-seven pairs of opposite-sex twins, both had mental deficiency in eleven instances, the male alone in eleven instances, and the female alone in five instances. It appears in a consistent way that girls make a slightly better showing than boys in intelligence tests and in scholastic record. These facts suggest that gene factors of intelligence may in some cases be carried in the X-chromosomes and not only in the autosomes; or, in other words, that there may be a sex-linked factor in some cases in the genetic history of mental deficiency and of general intelligence. In order to make the simplest provision in biologic symbols and formulas for a sex-linked factor, it is necessary to assume the existence of six possible types of males, nine types of females, and fifty-four types of mating. Theoretically, from thirty-eight of these types of mating only normal offspring can result. The mentally deficient offspring that may result from eight other types of mating may be expected to be equally distributed in the two sexes, as far as the possible influence of any sex-linked factor is concerned. Only male mentally deficient offspring can result from the remaining eight types of mating. When both parents are mentally deficient or when the father alone is mentally deficient, an equal distribution of mental deficiency in the two sexes of offspring may be expected. When both parents are normal or when the mother alone is mentally deficient, mentally deficient offspring of both sexes may result; but their distribution will not be equal in the two sexes, for the cases in which a sex-linked factor may be operative will be included in this part of the material. Here, according to theory, any relative excess of mental deficiency in the male sex must be, at least in part, attributed to a sex-linked factor. A reinvestigation of a part of Goddard's published material, selected by reason of relevance to the questions raised by the author's study, bears out the assumption of a sex-linked factor in the genetic history of mental deficiency. The general relative excess of mental deficiency in the male sex is, however, greater than can be accounted for by this factor; to some extent it must be attributed to some other factor or factors.

Skin and Radiation.—Bachem and Reed describe experiments from which they draw the following conclusions: Visible (and near infra-red) rays are strongly absorbed by the blood of the corium and subcutaneous layers, with direct effects on the blood to be expected. The heating effect must be rather mild on account of the small absorption in the epidermis and the strong convection by the blood stream. The far infra-red has little penetrating power. Most of it is absorbed in the epidermis. The produced heat is slowly conducted down to the deeper layers and up to the surface and convected away by the blood stream and air circulation. Overexposure of the germinal layer may lead directly to blistering. The ultraviolet exhibits greater variations than the other parts of the spectrum. At 280 micromicrons the absorption in the corneum (and granulosum) is pronounced. The great antirachitic effect of this wavelength must occur in or above these layers. At both sides, 300 and 250 micromicrons, the penetration is greater, more radiation reaching the malpighian layer and the corium. These observations, together with those of Hausser and Vahle, indicate that erythema production occurs in the germinal layer (or the corium) in the shadow of the upper layers. The stratum corneum (plus granulosum) must play an important part in the protection of these sensitive layers against too strong irradiation. From 250 micromicrons on, the absorption of the horny layers increases rapidly. Near 200 micromicrons the absorption is so complete as to prevent any radiation from reaching the living layers of the skin. These observations prompt some speculation as to the rôle of the skin in the systemic effects of irradiation. The fact that certain effects of a local application are systemic can be explained either by assuming that rays penetrate into the blood stream and produce changes that are reflected in systemic reactions, or that nerve endings in the skin are stimulated, producing reflex changes, or that some substance is liberated in the skin and taken up by the blood and lymph, to be distributed to other organs or tissues.

Diathermy in Postoperative Lung Conditions.—In the diathermic treatment of postoperative lung conditions, Seybold uses large electrodes that cover the whole chest. The electrodes are made of mesh and sewed on white felt 1 inch thick. This mesh is 1 inch smaller on all sides than the piece of felt. Different sizes are kept so as to fit large or small chests. They are placed anteriorly and posteriorly, or occasionally they may be placed laterally in some pleurisy cases. No lubricant is used, just ordinary warm tap water. Treatments are given for thirty-minute periods or longer. They are given every twelve hours, or oftener as indicated. The milliamperage averages from 1,500 to 3,000 with a frequency of 1,000,000. The high voltage tap is always used in the author's cases. Any medication that is requested can always be given, as the diathermy does not interfere.

Late Effects of Toxemias of Pregnancy.—Of a series of 545 consecutive deliveries of toxemic patients, excluding eclampsia and vomiting, 66⅔ per cent of the patients were reexamined by Peckham and Stout from four months to four years after delivery, and at that time 40 per cent of them were found to have a definite chronic nephritis. The differential diagnosis between nephritic and nonnephritic toxemia frequently cannot be made during pregnancy or the puerperium, and even at six weeks after delivery the diagnosis is sometimes incorrect. Nephritis is seen more frequently in the older age groups and among multiparas. Two thirds of the nonnephritic toxemias occur in women under 25, and a similar proportion are primiparas. A marked hypertension (systolic 200 mm. or more and diastolic 150 mm. or over) is more frequently associated with nephritis, although an occasional case of preeclampsia is seen with this reading. Albuminuria and its amount is not of prognostic import. The presence or absence of casts in the urine likewise does not give differential information. The phenolsulphonphthalein and Mosenthal renal function tests give almost identical results in the two types of cases. Edema occurs in the same proportion of cases in the two groups. Toxemia patients in general seem to have shorter and easier labors than normal; however, the fetal mortality is high, particularly in nephritis. The blood pressure is higher on discharge in the nephritic type. However, many women who have nephritis leave the hospital with a normal blood pressure, while about a fifth of the women later returning normal still have hypertension. Albuminuria on discharge is noted in relatively the same proportion of cases, nephritic or nonnephritic. Even six weeks after delivery many normal women still have hypertension and albuminuria, while a small number of nephritic patients appear normal in these respects. Only 7 per cent of nonnephritic patients show hypertension or albuminuria prior to the seventh month of pregnancy, whereas over half the nephritic patients were known to be abnormal at that time. However, almost a fifth of the women who ultimately were diagnosed as nephritic were known to be normal until after the seventh month. This would seem to indicate that chronic renal damage may be a result of the toxemic process. If vomiting and eclampsia are excluded, one of every three women seen with a toxemia of pregnancy will ultimately be found to have nephritis. Except in perfectly obvious cases it seems better to defer the final diagnosis until four months after delivery, although a diagnosis intelligently made at the time of discharge from the hospital is incorrect in only one case in nine.

Treatment of Anemia of Infancy. — Josephs treated a series of anemic infants with iron, and iron with copper supplement. The results were considered statistically through the construction of a curve corresponding to the average rise in hemoglobin after iron alone. It was found that copper accelerated the rise in hemoglobin when given in addition to iron. This acceleration was most evident when the hemoglobin was above about 50 per cent, for above this point the hemoglobin curves from patients on iron alone tended somewhat to flatten out, whereas those from patients on iron and copper continued to rise steeply up to about 70 per cent. In this series it made no difference in the speed of recovery whether the child was on a diet of milk alone or whether vegetables or eggs were included, and medicinal iron was found to be far superior to food iron in causing a rapid recovery. The effect of the iron is first on the reticulocytes, then on the hemoglobin, and there usually exists a latent period before the effect on the hemoglobin is manifested by a rise. The end of the latent period appears to coincide with a sufficient rise in reticulocytes. Copper appears to accelerate hemoglobin formation and does not have an effect on the reticulocytes.

Arthroscopy.—According to Burman, the most important indication for arthroscopy is for diagnosis in place of the exploratory operation. But, until arthroscopic pictures of disease are standardized, arthroscopy should first be done, and the observations verified, when necessary, by operation. If the observations arthroscopically are considered definite and decisive enough, it may not be necessary to operate. It is to be expected that, with time and the help of many workers in this interesting field, arthroscopic pictures of disease will become as well known as those of cystoscopy. There should be no hesitation in doing an arthroscopic examination, since it is simple, being a mere puncture in its ultimate essentials, and since it may avoid the more serious opening of the joint. The hole made by the trocar is heart-shaped, and less than 4 mm. in diameter. Whether it is advisable to incise the skin to puncture the joint is a matter of preference. Arthroscopy is indicated also in cases of joint disease the diagnosis of which may be in question and in which exploratory operation is not contemplated. It may be advisable to do an arthroscopic examination to make certain of the diagnosis and therefore to determine the treatment. Arthroscopy should also be done before reoperating on a joint for a possible relapse of an original condition. In this way may be determined, for instance, the posterior remaining fragment of a supposedly completely removed meniscus of a knee joint. When biospy is contemplated to secure synovial specimens, these specimens should be secured by an operative attachment to the arthroscope. Here one is enabled to inspect the joint and to remove the specimen without doing an open operation, especially in doubtful tuberculosis or tumor of a joint. Large bands of adhesion may also be cut by the operating arthroscope. Arthroscopy should be found invaluable in a whole host of diseases—arthritis of joints, diseases of synovia or of the fat pads, intra-articular fractures, foreign bodies or free bodies, injuries to the meniscuses or crucial ligaments of the knee intra-articular tumors, tuberculosis and other granulomas. Therapeutically, ultraviolet rays for internal irradiation of the joint cavity may be produced intra-articularly, and used in the treatment of joint diseases. Arthroscopy is contraindicated when there is no definite indication for it. It should be used discriminatingly in collaboration with a good history and physical examination, and well taken roentgenograms. It is not intended that arthroscopy take the place of joint roentgenograms, nor should the latter be neglected.

Separate Neural Arch.—In a series of 1,520 human skeletons, Willis found a separate neural arch in seventy-nine, or more than 5 per cent. In vertebral columns with twenty-five presacrals, the incidence is almost twice as great as in columns with the regular twenty-four, but the actual percentage in both series is an accident of the sampling rather than a criterion of the population at large. Study of the defect, whether unilateral or bilateral, substantiates its essential origin in a skeletal anomaly and assigns a very minor rôle to trauma. Embryologically the defect falls into the category of anomalous ossifications, of which there are many other examples scattered over the skeleton. It is an anomaly peculiar to the lumbar region and may be found in any lumbar vertebra and on either or both sides, but it is usually confined to the last presacral. Thus spondylolisthesis may be a sign of the anomaly. Trauma plays a secondary part in this condition, the fibrous tissue constituting a point of less resistance to strain than bone structure. The separate neural arch in its origin resembles spina bifida, defective articular processes, and separate bony centers for transverse, mammillary and accessory processes which are peculiarly associated with the lumbar column; it is found more frequently when some other anomaly—such as a twenty-fifth persacral—is present. It is the ultimate result of imperfect ossification, whether this be caused by failure in the ossific process itself or by a defect of the preexisting cartilage.

Progressive Pseudohypertrophic Muscular Dystrophy.—Hough presents data from which he concludes that progressive pseudohypertrophic muscular dystrophy is a more common syndrome than is commonly appreciated, having an incidence of approximately six per hundred thousand of total population in the New England states. The disease is widespread, occurring throughout the civilized world. The recently acquired knowledge of the double enervation of skeletal muscles has opened up a new conception of the pathology and pathogenesis of the disease. Contrary to the original conception that the disease is primarily of the muscle substance, there is evidence to justify the belief that there is a primary lesion of the midbrain, affecting the autonomic nervous system. The endocrine disturbances frequently reported are not an essential part of the disease but are due to derangement of the autonomic enervation of these glands. The endocrine dysfunctionings are seen most commonly in the less typical cases. The complicating central nervous system disorders are due to a more extensive involvement in the primary lesion. In some cases there is suggestive evidence that the primary lesion may be caused by an acute infection. In the majority of cases, however, there is no direct evidence of this. The natural course of the disease is fairly constant—with onset of symptoms appearing between the ages of 2 and 4 and progressing to inability to walk at between 8 and 12. In from four to six years more the use of the arms is lost, and death from an intercurrent infection occurs after another two to three years, at an age of from 15 to 20. Previous therapeutic measures have been almost uniformly without effect. Hypodermic injections of epinephrine and pilocarpine have been of symptomatic temporary benefit in every case. In the extremely advanced cases this improvement has been of more scientific interest than of practical value. In hopelessly bedridden patients, definite increase of independence by the improved use of the arms has been obtained. In a comparatively early case, a symptomatic and functional recovery has been obtained. No claim can be made for the permanence of the improvement. It is the author's purpose to keep the cases under observation and report subsequently on their ultimate outcome.

Fusion of Knee in Charcot's Disease.—Cleveland and Smith report four cases of Charcot's disease of the knee in which operation was performed and in which solid bony fusion resulted in three and the results were highly satisfactory; i. e., the patients were able to walk without a brace or other support and had no instability in the knee. It is interesting also to note that firm union was present in one at four months, in another at five and one-half months and in the third at six months. This compares favorably with cases in which the fusion operation was done for other conditions, such as tuberculosis or stabilization of the knee in poliomyelitis. Not a little doubt was felt as to the possibility of obtaining bony fusion in a Charcot joint. Although this series is too small to justify any general conclusions, the results are sufficiently encouraging to warrant trying the operation in other selected cases. The fourth case, in which fusion did not take place and in which the wound broke down with the formation of sinuses, undoubtedly was too far advanced and the patient should not have been operated on. The patient's general condition was poor and, in addition to involvement of both knees, there was partial destruction of the metatarsal bones of one foot and a trophic ulcer. The technic used in these operations was that described by Hibbs for stabilization of the knee in poliomyelitis, and afterward employed for any condition in which arthrodesis of the knee is indicated, modified somewhat to meet the peculiar circumstances of each case. Weight-bearing in plaster was allowed at the end of from six to eight weeks.

Differences in Racial Susceptibility to Measles.—In a statistical study of case incidence and deaths among several race groups of tenement dwellers in Manhattan, borough of New York (1921-1925), Emerson found significant differences in the death and case incidence rates and in the case mortality percentages for diphtheria and scarlet fever, and in the death rates for measles, which do not appear to be explained by other factors than those of variations of susceptibility and resistance among the children of these races, under the approximately uniform conditions of contact exposure described. While unequivocal proof of specific race resistance cannot be offered by the statistical methods used in his study alone, the author believes that the factor of race is the only one of importance that can be recognized clearly as a variant of significance among the population groups studied.

Food Poisoning Due to Staphylococcus.—Jordan and Hall report an instance of food poisoning in a man and his wife who were suddenly taken ill with violent vomiting and purging accompanied by great prostration. The family consisted of three—the father and mother and a child about 9 years of age. The two adults, who had eaten gravy with the evening meal, developed severe symptoms in about three hours; the child, who did not eat gravy, showed no signs of illness. The gravy had been prepared on Tuesday from the leftover portions of canned chicken that had been served for Sunday dinner. The can bore the brand of a reliable, well known and nationally advertised firm. The chicken eaten on Sunday had caused no symptoms of any sort. In making the gravy, the bits of chicken meat and the broth or stock from the can were used. After preparation, the gravy had been kept in the icebox until Wednesday evening, when it was warmed and eaten at about 6 p. m. The gravy which was brought to the laboratory in the bowl in which it had been served the evening before, was normal in appearance and odor. Platings were made on plain agar, Endo medium and eosin-methylthionine chloride medium. No colonies suggesting those of the Salmonella group were found, but staphylococcus colonies were abundant on the plain agar. The general cultural characters of this staphylococcus were those of the common Staphylococcus aureus type. In pure culture the staphylococcus formed substances that, when swallowed by human volunteers, reproduced the typical picture of the original outbreak.

Contamination of Cakes with Staphylococci.—Dack and his associates report that staphylococci, introduced through inoculated egg whites or yolks into various cake batters of either the sponge or butter variety, were killed during the baking process. This was true in cakes of hydrogen ion concentrations ranging from 5.0 to 8.2. Staphylococci similarly introduced into a cream filler for cakes were destroyed during the cooking of the filler. Staphylococci inoculated into the filler after its preparation invaded the cake substance. Human feeding experiments showed that both the organisms and the toxic substance were present in the filler and in the cake itself. It therefore seems likely that, in some of the food poisoning outbreaks due to staphylococci in cake, the filler is contaminated after its preparation, the microbes from the filler later invading the cake substance.

Typhus Fever.—Dyer and his associates present experimental data showing that the rat flea (Xenopsylla cheopis) as a vector of endemic typhus meets the requirements of the epidemiologic evidence. The virus of endemic typhus has been recovered repeatedly from rat fleas taken at typhus foci, and, finally, experimental transmission of the virus from rat to rat by means of the rat flea has been carried out in the laboratory. The foregoing evidence points to the rat flea as a common vector of endemic typhus fever from rat to rat and from rat to man.

Centripetal Paralysis Arising Out of Arrested Bloodflow to Limb.—Lewis and his associates state that if the circulation to an arm is arrested, the limb after a time ceases to function owing to paralysis of its nerves. It is the nerve itself and not the nerve ending that is affected. Loss of tactile sense and of sense of position is early; it begins distally and spreads centripetally. Appreciation of pain, heat and cold is maintained much longer than is the tactile sense. The motor apparatus is affected in an order that is described and that is in general centripetal. Extensors become involved before flexors. The pilomotor nerves long retain their function. The sequence of loss of function is discussed in relation to the size of fiber involved. Recovery from ischemia is rapid and the order of recovery is the reverse of the order of involvement. The mechanism of centripetal paralysis is fully discussed on the basis of experimental work and evidence is brought to show that the nerves (sensory and motor) become more sensitive to ischemia as they are traced back from their endings toward the central nervous system. Evidence has not been obtained that ischemia produces conduction with decrement. The rate at which given nerve fibers cease to function is affected by their temperature. If nerve and muscle have been exposed equally to a toxic influence, and it is found that the muscle responds to direct stimulation but not to nerve stimulation, a conclusion that the neuromuscular junction is at fault is not justified. The fault may lie in the nerve trunk itself, as ischemic paralysis illustrates. A type of uniformly developing anesthesia resulting from pressure rendering short stretches of nerve trunks ischemic is described and contrasted with centripetal anesthesia. Subjective tingling occurring after the bloodflow to an arm has been arrested and released is due to a certain state of recovery of the fibers of the nerve trunks and is referred to the periphery. There is evidence tending to suggest that it is an affair of the tactile nerves; it is referred to the territories of the fibers that are most affected by circulatory arrest, namely, those supplying the fingers. The observations and experiments described are applicable to clinical cases from several points of view. First, they lay stress on a special form of sensory and motor palsy here termed "centripetal." It is well known of peripheral neuritis, arising out of various forms of poisoning, that the disturbances of sensation and the loss of power appear first in the distal parts of the limbs, that on the motor side the tendency is for the extensors to become affected before the flexors, and that the symptoms in progressing invade more proximal parts of the limb and that the trunk remains relatively immune. In these forms of neuritis, all parts of the body are exposed to a toxic agent but there is discrimination. The form of paralysis resembles in type the one studied, and it is difficult to believe that they are brought about in ways that differ fundamentally. It is suggested that the common factor is increased susceptibility of the nerve fiber to certain forms of damage as it is traced away from its peripheral ending. It is further suggested that it may be proper to regard numbness developing in the finger tip and weakness or paralysis of distal muscles in the limb, more rigidly than these symptoms have been regarded hitherto, as evidences of a disorder of the peripheral nerves. In the same connection it may be profitable to consider whether tingling of the precise form described is or is not a symptom characteristic of a specific type of change in the peripheral sensory (and especially tactile) nerve paths. Secondly, the observations establish the time relations of numbness and other symptoms of nerve damage arising out of vascular obstruction on a reasonable basis. If a clot lodges in the main artery of a limb, obstructing it, or if the main arteries of a finger or of a larger part of the limb enter into a spasm sufficiently intense to arrest the bloodflow, sensory and sometimes motor disturbances occur in the corresponding territory. They are of centripetal type and from the standpoint of forming an exact parallel to the paralysis observed do not require further comment. It is important to understand that such disturbances do not develop at once, but after intervals of time that depend on the length and temperature of the nerve that has lost its blood supply. To illustrate, it is often stated by patients, and seemingly believed by many who report such cases, that, in Raynaud's disease, fingers become white and numb at the time the circulation to them is lost; and this numbness has even been regarded as an evidence of a primary disturbance in the nervous system. Such views are proved erroneous by the authors' observations; the numbness is due to arrested bloodflow, and occurring in cold fingers appears only after a long delay. When a patient states that fingers that have been warm previously become dead, meaning numb, in cold weather, the numbness is evidence that the blood has ceased to flow to the fingers for a time period of the order of one hour. Similarly, if a patient complains of pain in the leg and within five minutes the leg is found to be numb and to have lost the pulsation of its vessels, it is certain that the obstruction preceded the pain by many minutes. Statements that limbs suddenly become white (or pale) and numb should be regarded critically until such incidents are more fully and accurately recorded.

Vasodilatation in Limbs in Response to Warming the Body.—According to Lewis and Pickering, a simple method of testing the capacity of arteries of the extremities to dilate is to note the reaction in the cool extremity when the body is exposed to a warm atmosphere. In the hand, vasodilatation so induced manifests itself first by a rise of temperature and by brightening in the color of the finger tips. The time at which the response begins is influenced by the initial temperature of the extremities, being delayed by coldness. The response is effected entirely through the sympathetic nerves. By studying the reaction in Raynaud's disease and comparing the effects of ulnar anesthesia, the authors obtained evidence that the human sympathetic nerves contain vasodilator as well as vasoconstrictor fibers. The warm chamber is valuable clinically in differentiating obstruction arising from spasm and from structural disease of the arteries. In the former the response is rapid and proceeds to a high level. In the latter the response is slow and less pronounced. The chamber can also be used in determining that the sympathetic innervation of vessels of the limb has been lost.

*Occurrence of Scarlatinal Types of Streptococci in Nonscarlatinal Infections. V. D. Allison.—p. 844.
Case of Multiple Personality. R. M. Riggall.—p. 846.

Surgery of Pharynx.—Trotter calls attention to the fact that the mortality of operations for malignant disease of the pharynx is considerable, whether the actual treatment of the growth is by excision or by radium. The chief factor in this mortality is infection either of the lungs or of the extrapharyngeal tissues but in any case due to access of the pharyngeal contents to the infected part. The actual conduct of the operation can undoubtedly reduce the risk of such infections, but it cannot ever exclude it with certainty. While therefore every step of the operation will be oriented toward the limitation of infection, other means must be found of a more general usefulness if the mortality is to be kept below a level prohibitively high. The infection that follows contamination of a wound by pharyngeal mucus has clinical features and a clinical course that are characteristic. It is a progressive sloughing cellulitis, nonsuppurative for several days, accompanied by moderate fever for eight to ten days, when suppuration and the separation of sloughs begin. It is intolerant of the least restraint of drainage and always involves a risk of serious secondary hemorrhage. Clinical experience proves that the cause of this characteristic infection is always present in those who have teeth whether the teeth are many or few, or with or without obvious disease; it also proves that in the edentulous the cause of this infection tends to disappear or to be greatly attenuated. Thus, in the aggregate the risks of major operations on the pharynx are greatly reduced in the edentulous, and there is no general precaution in the preparation of a patient for such an operation that can compare in value with a clearance of the mouth and a delay until the gums are soundly healed. There are few facts of clinical surgery more firmly established than this relation between the presence of teeth and the liability to sloughing infections of wounds to which the oral or pharyngeal mucus has access; there is certainly none so unquestionably true that is so little valued and acted on. So much is this the case that it is necessary to speak of the subject with emphasis and without ambiguity. It is doubtful whether a major operation on the pharynx is ever justifiable in any but an edentulous patient. This question is quite different from that of clearing the mouth to produce an effect on some general or distant disease. One is not concerned with anything so problematic but with the attempt to get the pharynx into a condition as near surgical cleanliness as one can, and no other precaution for such a purpose has any claim to compare with this one. It is necessary to lay stress on the fact that if the relative sterility of the mouth is a most important preliminary to any major pharyngeal operation, it is doubly important if radium is to be used. It is perhaps because radium is sometimes regarded as having simplified the treatment of malignant disease of the pharynx that there is a tendency to disregard the stringent necessity for every precaution against infection when it is used. If it is questionable whether any major operation on the pharynx should be done except in the edentulous there can be no doubt that if radium is to be used this precaution is essential to reasonable safety.

Size of Healthy Heart and Its Measurement.—Bedford and Treadgold believe that location of the apex beat by palpation is the most reliable clinical method of measuring the heart, and orthodiagraphy is the simplest and most accurate roentgenologic method. The total transverse diameter is the most reliable index of heart size for practical purposes. The transverse diameter varies directly with body weight but not with height. At any given weight, the transverse diameter varies inversely with height. Short, broad subjects have wider hearts in proportion to body weight than tall, slender subjects. The normal transverse diameter may be predicted with reasonable accuracy from body weight in those whose height is ideal for their weight. In others both height and weight must be taken into account in predicting heart size. The observed transverse diameter expressed as a plus or minus percentage of that predicted from weight and height is the best way of indicating heart size. If one takes into account both weight and height, about 85 per cent of normal hearts fall within a range of plus or minus 10 per cent of the predicted normal, and less than 10 per cent of hearts exceed the upper limit of plus or minus 10 per cent. Measurements cannot be applied as a rule of thumb method in separating healthy from diseased hearts, but must be considered in relation to the clinical data. In borderline cases changes in the shape of the heart silhouette, viewed from different angles, are likely to be of more value than measurements.

Cerebral Tumor as Cause of Generalized Epileptic Attacks.—Pritchard reports five cases which show that it is possible for a cerebral tumor to give rise to generalized convulsions and to status epilepticus for many years (in one case for eighteen years) before any other signs indicating a local cerebral lesion are detected. In general it may be stated that such tumors are slow-growing and do not originate in, but beneath, the cerebral convolutions. The seizures cannot be rightly regarded as resulting from a rise in intracranial pressure, since they may be present for many years before other signs of such a rise are present, and also because they do not increase either in frequency or in severity when a rise in intracranial pressure later supervenes. The inference drawn from these considerations is that when convulsions commence and occur repeatedly in persons of middle age—even though the convulsions are generalized in character and do not leave behind them local impairment of function—they should be regarded as possibly resulting from an intracranial tumor and the patient should be kept under repeated observation, which may only after several years discover definite signs indicating the nature of the lesion.

Scarlatinal Types of Streptococci in Nonscarlatinal Infections.—Out of a total of 396 strains of hemolytic streptococci, isolated from nonscarlatinal infections, Allison found that only eight (2 per cent) belonged to one or other of the four main serologic types of scarlatinal streptococci. The results indicate the high degree of specificity of the scarlatinal streptococci, as 63 per cent of hemolytic streptococci from scarlatinal patients can be typed serologically. Among the eight typed strains, a type I strain and type III strain were isolated from uterine cervical swabs in cases of puerperal infection, while a type I strain and a type III strain were isolated from throat swabs of midwives in attendance on the respective patients. These results corroborate those recently shown by Smith and support the view of many clinicians that puerperal infection may arise by infection from the air passages of persons in attendance on the patients. From 100 consecutive cases of diphtheria and 100 consecutive cases of measles, 62 strains and 32 strains, respectively, of hemolytic streptococci were isolated, but none were placed in any of the main serologic types of scarlatinal streptococci.

*Strictly Cell-Free Transmission of Rous Chicken Sarcoma. W. Nakahara and H. Nakajima.—p. 131.
Heteroplastic Transplantation of Artificially Produced Skin Cancer of Mice. S. Itô.—p. 141.
An Interesting Case of Melanoma. M. Hirai.—p. 191.

Transmission of Rous Chicken Sarcoma.—By means of the capillary method and of the application of the micro-isolation technic, Nakahara and Nakajima were able to test the tumor-producing action of that portion of the Rous sarcoma filtrate which had been directly examined and found to be free from cells. With the capillary method, the proved cell-free filtrates produced sarcoma in two out of nine chickens, or two out of eighteen inoculations, while with the micro-isolation method as many as thirteen out of thirty-two inoculations (seven out of sixteen chickens) resulted in tumor production. The larger percentage of tumors in the latter experiment is traceable to the larger amount of filtrate injected. Positive tumor production by inoculation of minute amounts of chicken sarcoma filtrate directly examined and proved cell-free vindicates the long and generally held supposition that this class of tumors can be transmitted without the intervention of intact cells. Thus the last cloud of doubt as to the cell-free transmissibility of the Rous sarcoma, and consequently as to the existence of a causative agent distinct from sarcoma cells recognizable as such, has been removed.

Hepatic Manifestations in Course of Encephalomeningeal Diseases. C. Richet, Jr., A. Jacquelin and F. Joly.—p. 1528.

Atrophy of Mammary Gland and Artificial Pneumothorax.—Rist and Véran describe their experiences in which six women, out of a total of ninety patients with pulmonary tuberculosis treated by artificial pneumothorax, developed an atrophy of the mammary gland on the side of the pneumothorax. There was present not only a displacement of the gland, which is common to contraction of the chest, but in addition actual atrophy of the glandular lobules. The atrophy was evident from the first, but when more or less masked by the neighboring tissue its extent was determined by palpation. The patients themselves noticed this complication during the first months of collapse therapy or several years after the beginning of the insufflations. The condition was slowly but regularly accentuated and the glandular mass was reduced to more than half of the original size. The condition was independent of the type of the primary pulmonary lesion or the side of the chest affected. In most instances, the pneumothorax had been complicated by febrile, prolonged, recurrent, tenacious effusions. In every case there was contraction of the chest, with intense thoracic retraction, pleuricostal depressions and dextrocardia or sinistrocardia. The atrophy of the mammary gland was independent of ovarian function and all other endocrine disturbances. The authors did not doubt the relationship of cause and effect between the pleuropulmonary and thoracic retraction on the one hand and the glandular atrophy on the other hand. They were not able to determine the actual anatomy and physicopathology of the complications but believed that the condition was due to elective lesions of the sympathetic or cerebrospinal fibers, separately or together; the neuritis of the intercostal nerves, by reason of a probable pleurogenic irritation, may have been responsible for the homolateral atrophy of the mammary gland. This trophic disturbance is unlooked for in the course of pneumothorax therapy.

*Importance of Sympathetic System in Metabolism. E. Leschke.—p. 1517.

Importance of Sympathetic System in Metabolism.—Leschke discusses the various hypotheses on the etiology of diabetes insipidus, sugar diabetes, and disorders in fat metabolism. His observations are contrary to the theory that the hypophysis is the etiologic factor in diabetes insipidus. Hypophyseal alterations when present are secondary factors to the rôle of the thalamencephalon, which acts through the central sympathetic nervous system in the regulation of water-mineral metabolism. The endocrine factor in pancreatic diabetes is given second place to the sympathetic nervous system, since the production of insulin itself is regulated by the sympathetic system. His observations prove that pancreatic diabetes does not depend on the amount of insulin secreted or parallel the changes in the islands of Langerhans. The assertion is made that polyuria is almost always a sign of disorder in the plurisympathetic regulation of water and mineral metabolism. Constant chloride retention in diabetes is an indication of aggravation of the conditions in metabolism; and a sudden diminution of chlorides is a forewarning of coma. There is also a relationship between arterial pressure and diabetes. Idiopathic hypertony may cause the appearance of sugar in the blood and alimentary glycosuria. The author breaks down the old theories that named the hypophysis as chief cause and substitutes the diencephalon as a factor in adiposogenital dystrophies as well as obesity in general. Endogenous obesity is designated in this classification as a symptom of vagotonia. The author designates as plurisympathetic many regulatory disorders of the diencephalon in which diabetes insipidus may be combined with disorders in sugar metabolism, regulation of temperature, obesity, hypertony and polyuria, as well as regulation of the basic instincts.

*Association of Vagotonic Pancreatic Extract (Vagotonic Hormone) with Insulin in Diabetes. D. Santenoise, T. Brieu, G. Fuchs, P. Louyot and M. Vidacovitch.—p. 259.

Vagotonic Pancreatic Extract and Insulin in Diabetes.—Santenoise and his co-workers have shown that the pancreas plays an important part in the regulation of reflex excitability and pneumogastric tonus. The pancreas introduces into the circulation a substance that regulates the activity of the vagus nerve. Purified insulin is not vagotonic as is usually believed; that property is a function of another hormone. They have extracted from the pancreas a substance presenting all the characteristics of true hormones and endowed with considerable pneumogastric activity. The substance differs from insulin in biologic, chemical and physicochemical characteristics and has been designated by Santenoise in 1922 as a pancreatic vagotonic hormone. Insulin demonstrated vagotonic properties when it was not pure and contained the accessory hormone. This vagotonic hormone seems to be a regulator of glycogen through its influence on the vagus nerve. There is a dual action in the glycoregulatory hormones of the pancreas; the vagotonic hormone regulates the anabolism and insulin the catabolism of carbohydrates. The addition of the hormone increases the action of insulin. Their glycoregulatory action is synergistic and complementary. The results obtained when the two hormones were associated in the treatment of diabetes were conclusive. In summary, the addition of the vagotonic hormone to insulin in the treatment of some diabetic persons increased the glycoregulatory function of the pancreatic extract, the quantity of insulin necessary was diminished and the number of daily injections sometimes cut to one; increased carbohydrate tolerance made possible an increased intake of sugar; the glycosuria and acetone bodies disappeared; the lipoid and protein metabolism was improved; there was an increase in weight and an improvement in the general body condition. More than thirty patients with diabetes were treated in this way. The authors believe that their results recommend the association of the vagotonic pancreatic extract with insulin in the treatment of diabetes.

Thrombopenic Hemorrhagic Diathesis with Severe Secondary Anemia. J. V. Grott and L. Galınowski.—p. 547.

Leukemias with Tumors.—Emile-Weil and Isch-Wall believe that (1) leukemias with tumors are acute leukemias; (2) the appearance of osseous, cutaneous or lymph node tumors in the course of a chronic leukemia announces the transformation into acute leukemia with a rapidly fatal prognosis. When the acute stage has appeared, all treatment that might lead to destruction of leukocytes, roentgen rays, or benzene should be discontinued, and purely palliative and symptomatic therapeutics retained. Continuation of active therapy only helps to precipitate the evolution with consequent acute hemorrhagic accidents. The authors review five cases including an acute leukemia with a primary tumor of the mediastinum, a chloroma diagnosed as acute leukemia, two cases of acute leukemia with tumors of the lymph nodes subsequent to myeloid leukemia, and one case of acute leukemia with cutaneous tumors subsequent to myeloid leukemia.

*Fat Necrosis of Subcutaneous Tissues. D. Mosto.—p. 452.
Therapeutic Action of Drainage of Bile Ducts. H. A. Zunino.—p. 472.

Fat Necrosis of Subcutaneous Tissues.—Mosto reviews the literature on fat necrosis of the subcutaneous tissues and reports ten cases in new-born infants, children and adults. The lesions do not show an elective localization since they may develop in the subcutaneous tissues of the mammary gland, abdomen and muscles, particularly in the muscle regions in which oil injections are given. From his observations the author concludes that fat necrosis of the subcutaneous tissues is similar in adults, children and infants. The following are its principal types: (1) primary (aseptic) necrosis of spontaneous development (which is caused by disturbances of the fat metabolism) and (2) necrosis secondary to trauma or to inflammatory processes. The form of diffuse nodular fat necrosis of the subcutaneous tissues of the new-born infant and of children may be either of the first or of the second type. From the anatomic and pathologic points of view, the lesion is similar to lipoid granulomas caused by injections of oil or some other liquid or by the presence of collections of cholesterol. In the anatomicopathologic observations the saponification of the fat and the formation of granulation tissue are evident. In the genesis of the tumors, both predisposing and determining factors are involved. The outstanding predisposing factor is a condition of special tendency, governed by the endocrine and the sympathetic nervous systems, which certain organisms have to develop the disease. Trauma, hemorrhage, ischemia, vascular lesions, inflammatory processes and the presence of toxins in the organism are the most frequent determining causes of the development of the disease.

Lowering of Hyperchlorhydria After Gastric Resection According to First Method of Billroth. F. Basch.—p. 505.
Therapeutic Action of Medical Drainage of Bile Ducts. A. Zunino.—p. 521.

Syndrome of Anterior Condyloid Foramen and of Foramen Lacerum Posterius.—Pinedo states that the syndrome of the anterior condyloid foramen and of the foramen lacerum posterius (paralysis of the last four cerebral nerves) is uncommon. He could not find any reference to the syndrome previously published in Argentina. Vernet in 1916 compiled fourteen cases from the literature. In the author's case, clinical and anatomopathologic observations were made. In the case under his observation the syndrome proved to be caused by compression of the glossopharyngeal, the vagus, the accessory and the hypoglossal nerves of the right side, produced by a myelosarcoma arising from the transverse processes of the first and second cervical vertebrae, with extension to and destruction of nearby structures. The author describes the mechanism of the syndrome in detail, thus explaining the whole picture given by the syndrome: anesthesia of the velum palatinum, anesthesia and paralysis of the pharynx, the larynx and the tongue, dysphagia, disturbances of the voice and of the taste, and respiratory disturbances with grave asphyxia, all the symptoms undergoing a progressive evolution to a fatal outcome.

*Multiple Perforations of Small Intestine by Bullet. J. A. Luco and J. Passerini.—p. 921.

Milk in Infant Feeding.—Foster believes that breast feeding is the best alimentation for nurslings. He made a chemical analysis and a comparison of effects of breast milk, cow's milk and ass's milk. The content of lactalbumins in breast milk and in cow's milk is similar (5.2 and 5.5 Gm. per thousand cubic centimeters, respectively), while in ass's milk it is higher (8 Gm. per thousand cubic centimeters). The number of calories produced by breast milk and by cow's milk is 761 and 676, respectively, while that given by ass's milk is 500. The author (basing his observations on the results of his studies on problems of anabolism and catabolism of the elements of the three kinds of milk, in relation to digestive ferments and enzymes, as permitting a better assimilation of the nutritious elements of milk by the infant's digestive apparatus) regards cow's milk as the most satisfactory substitute for breast milk whenever the latter is not available. Raw cow's milk may contain pathogenic bacteria (including tubercle bacilli); it is difficult to digest and therefore causes intestinal disturbances. To make it more easily assimilable and safer for infants, one should properly modify it, trying, however, to keep the concentration of its elements in the most approximate proportion to that in breast milk. When used in artificial feeding, it should be boiled, mixed with an equal amount of water and then enriched by the addition of cream or carbohydrates (saccharose or common sugar), to compensate for the loss of its nutritious value which it undergoes through dilution and boiling. The addition of cream (as representative of fatty substances) may be higher in winter than in summer. Evaporated milk and dried milk, because of their avitaminic properties, if used in artificial feeding should be given either temporarily or as a supplementary food to breast milk or to cow's milk.

Multiple Perforation of Small Intestine by Bullet.—Luco and Passerini advise the performance of an abdominal operation immediately on admission of patients who have received a bullet wound, when there are good reasons to suppose that the bullet has penetrated the abdominal cavity, even though peritoneal or abdominal symptoms may be absent. Their patient, aged 28, received a shot in the right inguinal region. There was not any opening showing the exit of the bullet. (Besides the abdominal wound, the patient had also received other wounds in his head, with a knife, and on admission he was in a grave condition of anemia and shock due to the hemorrhages from the wounds. This grave condition, however, was controlled.) Roentgen examination showed the presence of the bullet in the symphysis pubis. Five hours after the patient was wounded, operation was performed. A large hematoma in the suprapubic and retropubic regions and in the perivesical space, behind the symphysis, was found after the performance of an infra-umbilical laparotomy. The hematoma was eliminated, and the bullet was removed from the symphysis pubis. The authors thought that the patient had received an extraperitoneal wound, but on opening the abdominal cavity they found that the small intestine had four perforations in a segment about 30 cm. long. The perforations were sutured, and the ,operation was finished after two drainage tubes had been inserted. The patient did well and was discharged twenty-nine days later in good condition.

Experimental Hydronephrosis and Pyelovenous Backflow. V. Ghiron and C. Giacobbe.—p. 91.

Pyelography.—Zanetti admits that his experience has not been so extensive that his conclusions have the character of finality. The method that up to the present has been found entirely harmless appears to the author satisfactory. It is certainly rare to see in pyelograms such excellent and distinct images as are secured with ascending pyelography. But irrespective of the value of the method there remains always a field that belongs to intravenous pyelography. In this field are included all the cases (and they are many) in which ascending pyelography is impossible. The two methods, then, do not exclude but supplement each other. Descending pyelography cannot pretend to replace the old methods of research; it merely supplements them and collaborates with them in establishing a diagnosis. The author recommends whenever possible an examination by means of endovenous pyelography, as a preliminary inquiry. Later, if it is impossible to reach a definite conclusion otherwise, he supplements the information furnished by the first method by the use of the ordinary method of pyelography. The author recalls the words of the French physician Papin uttered at the congress of the French Urologic Society, May 13, 1929: "It is not with impunity that we inject into the urinary organs massive solutions of bromide and iodide, for, when one operates immediately afterward, one finds that the damage is sometimes considerable."

Desensitization of Organism Toward Disturbances Following Spinal Anesthesia in Urinary Surgery.—Vitale explains a new prophylactic treatment with reference to the mild and the grave disturbances resulting from spinal anesthesia, as presented by patients subjected to various operations on the urinary passages. Comparing his observations following the use of his method in 100 persons subjected to spinal anesthesia for various surgical interventions on the urinary passages with the results secured in the same number of patients subjected to various surgical interventions on the urinary tract, in which the method was not applied, he demonstrates the great value of the method, which consists in the intravenous injection, just prior to the beginning of the operation, of 10 cc. of cerebrospinal fluid, which is withdrawn before the injection of the anesthetic. The mechanism of the action consists doubtless in the fact that the fluid, introduced into the blood stream, produces a desensitization of the organism, whereby the appearance of the disturbances (often grave and sometimes fatal) that may follow spinal anesthesia is prevented.

*Collateral Cerebral Circulation After Ligation of Large Veins of Neck. M. Romeo.—p. 881.

Changes in Sugar Content of Blood and Cerebrospinal Fluid in Persons Suffering Cranio-Encephalic Injuries.—Cazzamali studied in twenty-seven patients the influence that cranio-encephalic traumas may exert on carbohydrate exchange. In fifteen patients he determined the behavior of the sugar content of the cerebrospinal fluid. From the results secured he concludes that all such traumas, if fairly severe, provoke transient hyperglycemia, the degree and significance of which are in relation to the mechanism of the traumatic action, the violence of the impact and, particularly, the depth and duration of the loss of consciousness and the degree of cranial hyperpressure. A constant relation cannot, however, be deduced from the site and nature of the bone lesions. As regards the sugar content of the cerebrospinal fluid, he found, in the main, normal values, although in some cases there was a diminution, and only in one case an increase. The diminution may possibly be attributed to the sugar-burning action of the blood elements thrown into the cerebrospinal fluid, and to the fact that the determination was made soon after the trauma. The study of the sugar content of the cerebrospinal fluid at later intervals makes it appear probable that in course of time the glycorrhachia increases under the direct influence of the posttraumatic hyperglycemia.

Collateral Cerebral Circulation After Ligation of Large Veins of Neck.—Romeo, in a series of experimental researches on dogs, studied the behavior of the peripheral arterial pressure and of the blood flow per minute, measured on the internal carotid artery, following the ligation of the left common carotid, and then also of the vertebral artery—isolated or associated with the ligation of the jugularis externa and the jugularis interna on the same side. He observed that the ligation of these veins leads in every case to a sensible increase not only of the arterial pressure but also of the blood flow. The increase is, however, a transient manifestation, since, after a time, the hydrodynamic equilibrium of the brain tends to become reestablished, and also the peripheral arterial pressure and the blood flow tend to return to primary values. The experiments performed by the author to show the formation of the collateral cerebral circulation, by injecting a radiopaque mixture into the carotid artery of the side opposite to that of the ligation, demonstrated that in the cases of the simultaneous ligation of the arteries and of the veins the disposition and the development of the arterial network were almost uniform in the two cerebral hemispheres; whereas in the three experiments of isolated ligation of the left carotid artery the corresponding cerebral hemisphere always appeared less injected than the right hemisphere, as was substantiated also in the two animal controls in which the injection of the radiopaque mixture into the right carotid was made without ligation of the left-side vessels.

*Action of Iodine in Experimental Arteriosclerosis. H. Liebig.—p. 1400.
Traumatic Chylothorax. R. Spaccialbello.—p. 1402.

Action of Iodine in Experimental Arteriosclerosis.—Liebig's researches were on cholesterinic arteriosclerosis in the rabbit, which was induced by a linseed oil-cholesterol mixture. The vascular lesions developed in all the experimental animals, with predominant localization in the aorta. With the weak doses of the special iodine preparation, as at first administered, no modifications in the changed vascular system were brought about. However, with doses of from 50 to 100 mg. of iodine a day, per kilogram of body weight, it was possible to influence the vascular lesions, so that in 75 per cent of the animals either no lesions or no lesions of importance were found. It cannot be stated with certainty as yet whether, and if at all, to what extent, the experimental results are applicable to man.

Polypus on Rim of Choana in Small Child. K. Rupilius.—p. 209.

Electrocardiography for Prognosis of Diphtheria.—Von Kiss maintains that for a correct prognosis in malignant diphtheria and for determining the condition of the heart it is necessary to resort to electrocardiography. However, a single test is rarely sufficient, for only when the examination is repeated is it possible to detect progressive deterioration of the cardiac condition. In patients with diphtheria a dysfunctioning of the heart is indicated by lowered ventricular complexes, by depression of the T and P deflections in at least two leads, by extension of the T deflection, and especially by eventual omission of the T and P deflections; also by disturbances of the Q-R-S complex in at least two leads. If these abnormalities become more marked in the later tests, or if the curve presents the aspects of complete muscular dysfunctioning, the prognosis is usually unfavorable, even when the clinical signs do not indicate a dysfunctioning of the heart. The author gives several case histories and illustrates them with electrocardiographic charts.

Tonsillectomy and Schick Reaction.—In studies on 161 tonsillectomized children, aged between 1 and 6 years, Orosz and Kugler found that contrary to the theory of a relationship between tonsillectomy and the Schick reaction, which was advanced by Tomlin and later corroborated by Schick and Topper as well as by several others, they did not observe any relationship whatever between the two. On the contrary, they observed an increased susceptibility to diphtheria rather than a reduced susceptibility. Neither did the authors find a relationship between the aftergrowth of the tonsils and the behavior of the reaction. They think that the fluctuations in the negativity of the Schick reaction are largely due to the epidemiologic conditions existing at different times, and they think that the results which Schick and Topper ascribe to tonsillectomy may be due to some of these incalculable external factors. The practical conclusions which Schick and Topper arrived at from their theory, namely, to resort to tonsillectomy instead of to immunization, and to test tonsillectomized children before immunization in order not to give superfluous treatment, are likewise rejected by the authors.

Traumatic Nephritis.—Schörcher reports the clinical history of a man in whom bilateral glomerular nephritis developed after a trauma, which the man sustained by a fall over a pole, while ski-running. The nephritis resulted in a contracted kidney. The author further discusses the various conditions that may cause nephritis and also the relations between trauma and nephritis, and he thinks it possible that a trauma may be the only cause of a nephritis. He considers three possibilities in which a traumatic nephritis may develop: by a prolonged spasm of the renal vessels, by formation of nephrotoxins and by a local reduction of the resistance power. It is also possible that all these factors combined lead to nephritis.

Physiology and Disorders of the New-Born and of Female Breast. H. Rossenbeck.—p. 78.

Fetal Birth Traumas and Their Treatment.—Liebmann shows that although skull depressions are usually caused by a narrow pelvis, fractures and paralysis are generally the result of extraction by the breach. It is of great significance that the injuries be recognized immediately for, if the proper therapeutic measures are taken, neither the functioning nor the further development becomes noticeably impaired.

Significance of Retroplacental Blood for Detection of Syphilis.—Hilden states that examination of the retroplacental blood always gave the same reaction as the venous blood gave on the seventh day of the puerperium. The result of Wassermann tests made during confinement was found just as reliable as the result of those made at other times. Nonspecific reactions were not observed, and the author thinks that the positive reactions during confinement and puerperium, which later disappear again, are reactions produced by a latent syphilitic infection. The diagnosis of syphilis should never be based on a single positive reaction. Every unexpected positive reaction during birth and the puerperium requires careful after-examination.

Sure Sign of Hypermaturity in the New-Born.—Roentgenologic examination of the wrist joints of the new-born convinced Szellö that those in whom signs of the os capitatum and of the os hamatum are detectable on the first day after birth are hypermature, for ordinarily these bones do not become visible until the second half of the first month of extra-uterine existence. This sign is valuable for forensic medicine, but since it is not detectable in utero it is not of value for determining the advisability of the artificial induction of labor.

Pathogenesis of Chronic Inflammation of Gums and Cause of Odontoptosia. B. Gottlieb.—p. 1200.

Subungual Tumors.—Eisenklam points out that subungual tumors of the fingers and toes are often incorrectly diagnosed. Thus many patients have to endure severe pain for prolonged periods, and in other cases the life endangering significance of the tumor is recognized too late. After reporting several case histories he discusses the three types of subungual tumors; namely, the benign, the intermediate and the malignant forms. The benign forms are the exostoses that usually develop in young patients, the subungual fibromas that generally grow slowly and cause little pain, and rare forms such as osteochondromas, papillomas, leiomyomas and myxochondromas. The intermediate forms of tumors usually develop following a trauma. First there is a small blue spot underneath the nail, which causes severe pain. Then a ledge-like protrusion develops in the nail, which by its livid color differs from the rest of the nail. Extirpation reveals a tumor about the size of a pea, which, although situated in a groove of the bone, involves neither the periosteum nor the bone. The surrounding tissues frequently show inflammatory changes, but this form of tumor does not metastasize. Among the subungual tumors of malignant character many resemble fibromas and angiosarcomas, and even the primary malignant melanoblastomas may, in their beginning stages, be mistaken for benign tumors. These growths usually originate in the pigment cells of the skin. Their pathologico-anatomic structure indicates that they are melanocarcinomas. They metastasize rapidly. Of especial interest is the fact that although the primary tumor is not pigmented it causes melanotic metastases. There are also subungual melanoblastomas that develop from a nevus. In the conclusion the author points out that most patients with subungual tumors suffer from intermittent pains. For this reason even the benign tumors should be removed as soon as possible. Especially deplorable are the cases of melanoblastomas that, because the nail, like a foreign body, causes suppuration, are diagnosed and treated as paronychia.

Postclimacteric Hemorrhages of Benign Origin. K. Adler.—p. 343.

Roentgenologic Aspects of Sterility.—Schultze discusses contrast visualization of the female genitalia in its significance for the diagnosis, prognosis and treatment of sterility. First he discusses the roentgenologic aspects of the various obstructions and of other pathologic changes on the uterine tubes, and then the abnormalities of the uterus and of the cervix. In the conclusion he emphasizes that by limiting his treatise to the roentgenologic aspects of sterility he does not wish to overemphasize its significance or advocate its one-sided employment to the exclusion of other diagnostic methods. On the contrary, it should complement the other diagnostic methods, but it is not intended to replace them. In cases in which the cause of the sterility is clear, contrast visualization is not necessary and in other instances it is to be employed only after certain other examinations have been completed. However, in some cases roentgenoscopy reveals conditions that are not detectable by any other method and thus it permits individualization in the treatment.

Number of Uterine Contractions During Confinement of Multiparas.—Observations on 200 multiparas with normal pelvis, and in whom the bag of waters did not rupture prematurely, convinced Frey and Meier that the largest number of uterine contractions during the period of dilatation following rupture of the bag of waters is between 51 and 100. During the period of expulsion, provided the bag is ruptured, the number of contractions varies between 26 and 35. The total number of contractions during both periods following rupture of the bag of waters is between 101 and 150. If therefore in a multipara, following rupture of the bag of waters, the highest number of contractions for each respective phase has been reached without that period of the process of labor being completed, the condition is pathologic, the spontaneous delivery of a living child by the natural process cannot be expected, and an intervention becomes necessary. The authors think that if the labor pains are not counted the indications for the cesarean operation, for instance, are too indefinite.

Number of Labor Pains with Premature Rupture of Bag of Waters.—On 200 multiparas with prematurely ruptured bag of waters and with pelvis of normal width, Frey and Dressler investigated whether for the entire process of confinement and for its phases a maximum number of contractions can be determined within the limits of which spontaneous delivery may be expected without injury of either mother or child. They observed from 151 to 175 contractions for the period of dilatation, from 26 to 35 contractions for the period of expulsion, and for the entire process of delivery from 151 to 175 contractions. The authors think that the management of confinement should be expectant until the highest numbers of contractions have been reached, but after that intervention is necessary.

Sterility and Prevention of Conception.—Knaus maintains that in women, just as in most mammals, fertilization occurs at the time of the termination of the ovulation process. In a sexual cycle of several weeks' duration there is therefore a comparatively long period of physiologic sterility. In a healthy woman who menstruates regularly every twenty-eight to thirty days, ovulation takes place between the fourteenth and sixteenth days of the mensual cycle. On the basis of observations the author maintains that in such women the conception capacity is limited to the time between the eleventh and the seventeenth day. During the first ten days, and from the eighteenth day of the menstrual cycle, a physiologic sterility exists. The author thinks that abstinence during the time of the conception capacity is the only natural and also the most hygienic, ethical and esthetic method for the prevention of conception. In women with longer or shorter menstrual cycles the periods of conception capacity and also of physiologic sterility vary somewhat.

Cohabitation in Etiology of Puerperal Fever.—Batisweiler discusses the detrimental results that may be caused by cohabitation during pregnancy. He reaches the following conclusions: 1. During the first half of the period of gestation, cohabitation may cause hemorrhage and even abortion. It is therefore advisable, especially for primigravidas, to abstain from sexual intercourse at least during the first three months. 2. During the second half of pregnancy a too intensive sex life may cause either abortion or premature birth, especially if there is a predisposition for habitual abortion; however, under normal conditions cohabitation is without danger. 3. Toward the end of pregnancy, that is, from six to three weeks before confinement, cohabitation may cause premature rupture of the bag of waters, infection and puerperal fever. For this reason strict abstinence is necessary. 4. A cohabitation after labor pains have already set in may lead to fatal sepsis. 5. Coitus during the puerperium involves likewise the danger of fatal sepsis. Cohabitation should therefore not be resumed until the fourth or fifth week after confinement.

Small Doses of Quinine in Treatment of Malaria. A. A. Solomin.—p. 1349.

Insulin in Treatment of Pernicious Anemia.—Lebedov describes his observations in the treatment of seven persons with pernicious anemia. Insulin was used to increase the appetite; this treatment was followed by a decided improvement in the patient's condition. In instances in which arsenic and iron were ineffective, insulin produced an increase in the percentage of hemoglobin as well as an increase in the number of red blood cells and an improvement subjectively and objectively in the patient's condition. There was no influence on gastric secretion. In the cases in which the spleen was enlarged, the treatment led to a decrease in its size. The effects of insulin lasted not only during but after the conclusion of treatment. Secondary anemia conditions were markedly improved; but in pernicious anemia and in anemia without regeneration of erythrocytes there was a relapse within six months after treatment.

Prophylactic Roentgen Irradiation After Operative Removal of Cancer of Breast. A. E. Nordholt.—p. 4892.

Auto-Agglutination in Human Blood.—Van der Hoeden and Verbeek state that in the serum and plasma of the blood of four patients with hypertrophic biliary cirrhosis, which blood was collected at body temperature (37 C., or 98.6 F.) they demonstrated the presence of a substance that at temperatures below about 25 C. (77 F.) caused auto-agglutination of the erythrocytes. The agglutination at these temperatures is reversible. In the microscopic preparation one observes that the erythrocytes first collect in short chains, which then, as the temperature falls further, are brought together to form larger conglomerates. Through saturation of the serum with suitable erythrocytes at temperatures above 25 C., the iso-agglutinins can be withdrawn, whereas the substance mentioned, which former researchers have termed "auto-agglutinin," remains present unchanged. Not only in the serum but also in the plasma, the auto-agglutinin remains stable in physiologic solution of sodium chloride for at least six months. It stands heating up to a temperature of 60 C. (140 F.) but at 65 C. (149 F.) it is lost. It is not soluble in ether and cannot be passed through a collodion membrane. With saturated ammonium sulphate it is precipitated out of the solution, but not with calcium chloride. It is thus fixed to the globulin fraction of the serum and not to the fibrinogen. The auto-agglutinin is filtrable through a Chamberland-Pasteur candle and a Seitz filter.

*Splenectomy in Essential Thrombopenia. Å. Grevilluis.—p. 657.
*Pneumothorax for Diagnosis of Cavern. R. Borelius.—p. 661.

Splenectomy in Essential Thrombopenia.—In Grevilluis's case of essential thrombopenia with rather acute course, with massive nosebleed as the main symptom, and with internal therapy ineffective, splenectomy, done at a stage when the patient was greatly exhausted, resulted in an immediate recession of all symptoms and after a couple of months the number of blood platelets was normal.

Pneumothorax for Diagnosis of Cavern.—Borelius presents two cases in which artificial pneumothorax, induced for diagnostic purposes, showed that a roentgenologically indistinct circular shadow was a cavern, and four cases in which pneumothorax, induced for therapeutic purposes, revealed the presence of caverns previously suspected or not visible. The result is due, he says, to the greater prominence after pneumothorax of the formerly indistinct circular shadows and to the shifting of the shadows, usually toward the hilus. This change of position constitutes the strongest evidence for an intrapulmonary (and not pleural) process. Since the pneumothorax is not wholly without danger, it is advised only when other methods fail, and it should not be applied in ambulant cases.

Bronchial Asthmas, Illustrated by Invalidity Insurance Commission's 625 Cases. I. H. C. Gram.—p. 616.

Studies on Gastric Ulcer: Nervous Symptoms.—Boye's material comprises 937 cases of ulcer, partly established cases, partly cases with probable diagnosis of ulcer (about one third). He finds that the proportionate frequency of the condition in men and women is as 3 to 2. In both sexes the subjective symptoms, including nervous symptoms, show a tendency to increase as the objective ones decrease. In the group with numerous objective symptoms, men dominate; in the group with few objective symptoms, women. Nervous symptoms are common, especially in women.

*Septic Pleural Empyemas with Especial Regard to Late Results. E. Schildt.—p. 2.
*Case of Endometrioma with Localization in Round Ligament of Uterus. H. Marcus.—p. 207.

Septic Pleural Empyemas: Late Results.—Schildt reports 289 cases, without complications in the form of tuberculosis, actinomycosis or tumor, in which the patients were treated from 1916 to 1929. There was marked increase in the number of cases of empyema during the influenza years. About 50 per cent of the cases occurred in the first twenty years of life and about 70 per cent in the first thirty. Over 61 per cent were in the male sex. Etiologically about 85 per cent of the cases are ascribed to certain or probable pulmonary diseases. Streptococcus infection was the most frequent infection. Typical complications of empyema appeared in fifty-nine cases, with fatal outcome in about 60 per cent. Subperiosteal resection of the ribs or intercostal incision with open drainage was the chief method of treatment. After-examination was done in over 95 per cent of the cases. Permanent recovery for from more than one to over fourteen years was seen in 178 cases, or about 61.5 per cent of the total number. There was recurrence in 32 cases, or about 11 per cent, appearing within four years in 97 per cent of the cases; no recurrence was noted after five years. There were fifteen chronic cases, or about 5 per cent. Restored full ability to work after six months was seen in 80 per cent of the 178 cases. The total mortality was 18.6 per cent.

Endometrioma with Localization in Round Ligament.—Marcus's patient had had for two years a slowly increasing swelling in the right groin, without symptoms except a sense of weight and tension on menstruation. Examination showed a tumor-like formation of firm consistency about 3 or 4 cm. long and of the thickness of the little finger, situated corresponding to the course of the round ligament and attached to the pubic bone. The microscopic diagnosis following extirpation was adenomyofibrosis.

NEUROPSYCHIATRIC COUNTERFEITS OF ORGANIC VISCERAL DISEASE *

T. H. WEISENBURG, M.D.
J. C. YASKIN, M.D.
PHILADELPHIA
AND
HENRY PLEASANTS, Jr., M.D.
WEST CHESTER, PA.

Visceral disease may be masked by a variety of neuropsychiatric manifestations. Patients may present themselves with pains referred to the extremities and the trunk, especially with sciaticas and backaches, bearing the earmarks of nerve or cord involvement, but which are due to underlying visceral disease. More frequently there are patients referred as "psychoneurotic" in whom the outstanding symptoms are emotional and whose numerous bizarre and variable complaints cannot be explained by objective organic phenomena. Even more commonly a combination of peripheral pains and psychoneurotic manifestations are encountered forming a bewildering clinical picture difficult to disentangle. Psychotic states may conceal underlying visceral disease and may be the earliest manifestation of visceral disease, as in the four cases of pancreatic tumors reported by one of us.[1]

The following are illustrative cases in which patients with unrecognized somatic disease were referred to the neuropsychiatric service as presenting neurologic conditions. These cases were divided for descriptive purposes into cardiac, pulmonary, gastro-intestinal, genito-urinary and sciatic groups.

THE CARDIAC GROUP

That psychic factors, especially emotional, should influence cardiac action is not surprising when it is borne in mind that, like the gastro-intestinal tract, this organ has a rich sympathetic and parasympathetic innervation and that the vegetative system is under the control of the nervous system. In addition, Cannon[2] has shown that under the influence of emotions there is a chemical alteration in the epinephrine content which is particularly prone to influence the accelerators of the heart. Cardiac disturbances of emotional origin are therefore of great frequency, and neurocirculatory asthenia, a disordered heart action of the soldier, is a common symptom. Parenthetically, cardiac neuroses are often a result of careless, sometimes casual, remarks on the part of the examining physician, a fact worth while remembering, for it is much easier to create than to cure these "cardiac" cases.

On the other hand, cardiac diseases often have psychic components which should be borne in mind. The occurrence of transient and more or less lasting psychotic episodes (mood changes, suspicions, hallucinations) in the course of heart disease was studied by Head,[3] who attributes these symptoms to pain reflected from the diseased viscus. Cardiogenic psychoses with a variety of psychotic pictures have been described by Riesman,[4] who attributes the psychoses to a variety of causes including the psychopathic make-up of the patient, toxemia of the kidney, acidosis, drugs especially digitalis, and disturbances of cerebral circulation.

Behavior disorders attributable to restricted activity, imposed by cardiac disease in adults and especially in children, are of interest and are discussed by Foster.[5] Psychoneurotic complaints may be readily conceded to a frank cardiac case as being at least distantly related to cardiac dysfunction. By frank cardiac cases we mean patients with valvular lesions, disturbances of rate and rhythm, blood pressure changes, mild evidences of decompensation and the like. The situation is entirely different with the so-called myocarditides. Here the evidences of cardiac disease, even in the hand of experienced internists, are slim and often doubtful. The vague "anginoid" pains over the anterior chest wall and in the arms are much more conspicuous than the objective signs. Often these pains are only a small portion of the pains, aches and mood disturbances which dominate the picture. Thus these patients, with the condition formerly called "pseudo-angina pectoris," become psychoneurotic and are referred to the neuropsychiatrists for psychotherapy.

Case 1.—J. F., a man, aged 56, a merchant, seen, Oct. 14, 1924, complained of severe cramplike pain in both arms, forearms and hands. These pains commenced several hours previously, following a quarrel with a son. The family history and past medical history were negative; the patient had typhoid in his youth, smoked cigars and a pipe in moderation, and indulged mildly in alcohol. He was "highly strung" but there was no history of a "nervous breakdown."

The patient was somewhat short and slim, and presented no evidences of somatic or neurologic disease. His pulse rate was 76, the blood pressure was 140 systolic and 105 diastolic, the heart was not enlarged, no murmurs were audible, and the heart sounds were good. Neurologic examination revealed no disturbances in motor, reflex, synergic or sensory control.

There was no tenderness over the nerve trunks. He was restless, unable to remain in bed and screamed and cried. Bromides and barbital were administered, and the following morning he returned to work.

Within a few days there was a recurrence of pain in both extremities which also yielded to sedative agents. Within a couple of weeks, however, the patient complained of dyspnea and precordial oppression. About November 1 he developed a bilateral hydrothorax, which was tapped, affording the patient considerable relief. November 4, when the nurse returned after the absence of a few minutes, the patient was dead.

The character of the subjective manifestations as well as the marked neurotic phenomena certainly justified regarding this patient as psychoneurotic. In retrospect, the pains and emotional disturbances masked a pronounced case of myocardial degeneration.

Case 2.—A. S., a woman, aged 52, referred in June, 1929, complained of general weakness and nervousness and inability to walk because of weakness and pain in the back. The family history and past medical history were irrelevent. Although "highly strung," she had never had a nervous breakdown. Her present illness began several months previously with generalized pain and nervousness, especially pain in the eyes. In February, 1929, she was studied for two weeks in a teaching hospital, where the investigations failed to reveal organic disease. In the past few weeks her condition became much worse. She was unable to walk about because of weakness in the back. When seen at her home, the patient looked thin, pale, anxious and unwilling to move out of bed. The internist who referred the patient gave the assurance that his studies and those made in the hospital excluded somatic disease. Neurologic examination revealed a pseudoptosis of the left upper eyelid and inability to raise the right arm because of pain in the shoulder. She refused to leave the bed or even to sit up. A psychologic examination revealed that she was distressed over two unmarried daughters who were rather promiscuous in their mode of living. She cried and was anxious and depressed. The patient was hypnotized without difficulty, and in ten minutes walked out of bed much relieved. She returned several times for treatment, showing improvement, with the exception of "fainting spells" with partial loss of consciousness, which were attributed to emotional upsets.

July 2, the patient suffered a fainting spell. She was motionless, with an ashen gray face and blue lips and finger nails. Her extremities were cold, she perspired profusely, the pulse rate was rapid and feeble, and the heart sounds were poor. There was no pulmonary edema. She rallied with digitalis and caffeine and was admitted to the Graduate Hospital. She had several similar attacks while in the hospital. During one of them the blood sugar rose to 260 mg. per hundred cubic centimeters, while between attacks the blood sugar was under 100. She died, July 5, during one of these attacks. The cause of death was assigned to coronary occlusion.

The psychogenic background, the bizarreness of the symptoms, the absence of objective signs after intensive study and the favorable reaction to hypnosis all favored a diagnosis of psychoneurosis. However, the basic manifestations were undoubtedly attributable to myocarditis.

PULMONARY GROUP

Pulmonary disturbances of psychogenic origin are not nearly as common as those of the gastro-intestinal or cardiac systems. Nevertheless, cough, disturbance of rate and rhythm of respiration, and even asthma may be of functional origin. The fear of tuberculosis in some cases is one of the commonest manifestations of psychoneurosis. Nevertheless, psychogenic causes of pulmonary manifestations are relatively rare. Whether they may be due to relatively poorer innervation by the vegetative system and relatively richer somatic innervation (abdominal walls, intercostal muscles, parietal pleura) in comparison to other viscera is difficult to state and requires further investigation.

That pulmonary disease, especially tuberculosis, may cause mental symptoms is well known. Head[3] ascribes it in part to reflex pain referred from the diseased viscus and partly to the fever, loss of weight and anemia. The general clinical conception is that the mental symptoms in these cases are toxic in origin. Head points out that lesions in the upper part of the chest are not as likely to cause mental changes as lesions in the basal lobe. We feel that this is not due so much to the reflected pain from the lower lobe, as claimed by Head, as to the fact that when tuberculosis invades the lower lobe the case is usually more advanced and the patient more toxic.

There are cases in which neuropsychiatric manifestations mask underlying pulmonary pathologic changes. Among these may be mentioned early pulmonary tuberculosis especially in late adolescence, and carcinomatosis.

Case 3.—A woman, aged 39, seen, Feb. 1, 1928, had developed, eight years previous to admission to the Orthopedic Hospital, a pelvic peritonitis two months after the birth of a second child, following which there was a removal of her uterus, tubes and ovaries with the establishment of a complete surgical menopause. *Following this she began to have attacks of nervous* exhaustion, which were ascribed to the consequences of the operation and to certain domestic difficulties. Three months prior to her admission, the patient was in an automobile accident in which she suffered a concussion following a blow on the head. At the time of the accident, she remembered taking a deep breath, and following her recovery from the concussion for a period of three months she complained of difficulty in getting her breath and of pains across her shoulders. This was followed by severe crying spells, considerable mental depression and general exhaustion, in which the patient felt unable to do her usual housework. Her respiratory difficulties were much worse whenever she became emotionally upset. In addition, she complained of a gripping feeling in her throat and she had a tendency to cough to get rid of it. She had to use two pillows instead of one when lying in bed.

On admission she had a constant dull aching pain over the scapula. At times this became more severe and would shoot and radiate down the left flank and around the chest to the left breast. On admission to the hospital this was her chief complaint, and it was thought that all her symptoms were of a psychoneurotic character and had been present a long time but had been aggravated by the automobile accident. After her admission the pains increased and in addition she began to complain of nausea and vomiting. While under observation she developed a weakness and numbness in the right upper limb, but physical examination did not denote anything. Later on, a roentgen examination showed that she had a primary carcinoma of the lung. Following this she developed an increasing weakness in the right side, which developed into a right hemiplegia. This was followed by generalized convulsions, limited mostly to the right side, and the patient finally died of multiple carcinomas of the brain.

The diagnosis in this case was particularly difficult in the beginning because of the history of the old neurosis with the more recent one of trauma following an automobile accident in which the question of compensation entered. The medical man who referred her was undoubtedly swayed by this history and on her admission to the hospital we also felt that the case might be one of traumatic neurosis. It was, however, the character of the pains, which were of a rootlike variety, that first directed our attention to the possibility of the presence of a spinal cord involvement. Roentgen examination disclosed the presence of the carcinoma and the later symptoms were so outstanding that there was no doubt left as to the proper diagnosis.

CASE 4.—E. B., a woman, aged 24, a trained nurse, who had graduated two years prior to observation, complained of general nervousness, inability to sleep, depression and slight loss of weight. She was easily exhausted. She had been nursing a psychasthenic patient and these symptoms developed after she had been on duty for about six months. She gave up the case because she felt that it was too much for her and ascribed all her symptoms to a neurosis brought about by the mental and physical fatigue attendant on the nursing of this difficult patient. General examination was entirely negative. No examination was made of the chest. It was obvious that the patient was psychoneurotic and we agreed with the idea that all she needed was rest; she was sent home to recuperate. The patient came back in about three months feeling much worse. She had lost considerable weight. She began to complain of night sweats, and examination showed the general symptoms of an early tuberculosis. This was confirmed by a roentgenogram and an examination of the chest.

This is a typical example of how a neurologist can slip up in a diagnosis of an early tuberculosis by assuming that the neurotic symptoms are of a generalized character. The later history of this patient, who was put on a suitable treatment, showed the complete disappearance of the symptomatology as the condition of the chest improved.

GASTRO-INTESTINAL GROUP

That gastro-intestinal disturbances may be purely psychogenic in origin is a common experience, and "nervous dyspepsia" has been handed down from ancient times. The gastro-intestinal tract, by reason of its innervation by the vegetative nervous system, remains out of the sphere of consciousness as long as there is no disturbance in this long tract or in the various pathways connected with the involuntary nervous system. But the functions of this system are readily influenced by the psychic processes as shown by the experimental work of Cannon[2] and by the clinical observations of Alvarez,[6] Ziegler,[7] McLester,[8] and many others. The digestive disturbances in relation to disease of the spinal cord, as in tabes and transverse myelitis, are well recognized and the close connection with the diencephalon, as in epidemic encephalitis, is at least debatable.[9] Diseases of the autonomic system itself (autonomic unbalance) are regarded as a predisposing factor in organic gastro-intestinal disease such as peptic ulcer and cardiospasm. On the other hand, the improved methods and more intensive studies in gastro-enterology in recent years have demonstrated that many cases of "nervous dyspepsia" are organic in nature. It is found that many mild lesions or slight secretory and motor disturbances give rise to a variety of neuropsychiatric symptoms which mask the underlying pathologic changes. That marked gastro-intestinal disturbances give rise to reflected pain and other disturbances was shown by Head,[10] who demonstrated that the pain reflected to the cutaneous surface from diseased viscera was to a large extent responsible for the mental symptoms observed in some cases, and that pain reflected to the abdomen was more closely associated with psychic disturbances, especially depression, than pain reflected to the upper part of the trunk. Head found this to be the case in individuals with a negative family and past medical history. He ascribed the psychic disturbances to involvement of the vegetative nervous system—the abdomen being, in the words of James,[11] "the sounding board of the emotions." One can readily conceive how relatively mild gastro-intestinal lesions may, in an individual with a neurotic make-up, produce a variety of emotional disturbances in keeping with Head's conception, which would mask the original abdominal complaints. That the superimposed neuropsychiatric manifestations may disguise the underlying organic condition is shown by the following cases:

CASE 5.—M. F., a man, aged 44, a merchant, seen in March, 1924, complained of insomnia, dizziness, nausea and vomiting, general weakness, and loss of weight. He was under observation in two general hospitals, at which times no organic disease was found. His family history and past medical history were irrelevant. He was a widower and had a great deal of trouble with his children. He was treated as a psychoneurotic patient at the Orthopedic Hospital, where, in a few months, he completely recovered. He remained in good health until September, 1927, when he returned, complaining of attacks of headache, dizziness, general weakness and insomnia, attributing these difficulties to business reverses and unpleasant differences with his son-in-law. Although he had been ill for only a few weeks, he appeared pale and, when questioned closely, showed a slight difficulty in swallowing. The roentgen examination was inconclusive but esophagoscopy by Dr. Gabriel Tucker established the diagnosis of carcinoma of the esophagus. Despite the suffering incident to the lesion and the treatment, his neuropsychiatric symptoms during the remaining fifteen months of life were not so pronounced as during the attack of three years previously.

In this case the organic lesion occurring in an individual with a psychoneurotic make-up and with a previous psychoneurotic episode would have been easily overlooked were it not for the close questioning in the case and the existence of a slight secondary anemia.

CASE 6.—J. L., a woman, aged 37, married, with an irrelevent family and past medical history, was referred to the neurologic clinic of the Orthopedic Hospital in October, 1927, as a case of gastric neurosis. She complained of nervousness, loss of weight, and palpitation of the heart, with considerable epigastric pain, which was somewhat relieved by food. She was studied at the hospital with the following observations:

The gastric analysis showed only a moderate degree of hyperchlorhydria. The roentgenogram of the gastro-intestinal tract was entirely negative. There was extreme tenderness in the epigastrium, with marked rigidity of the upper part of the right rectus muscle. Despite the extreme nervousness and relatively negative roentgen observations, an exploratory operation was advised. This was done by Dr. George Muller at the university hospital, and a large ulcer was found on the posterior wall of the stomach, not involving the pyloric region, and therefore producing no demonstrable filling defect. Following a gastro-enterostomy, she gained 20 pounds (9 Kg.) and was entirely relieved of the symptoms.

This woman had been referred as a psychoneurotic patient; superficially, she might easily have been regarded as such. Despite the negative laboratory observations, however, a careful history and the constant abdominal pain with rigidity in the upper part of the abdomen led to the unmasking of the true condition.

CASE 7.—P. S., a man, aged 45, a clothing operator, had been treated by one of us from 1919 to 1924. His family history was negative. The patient had the usual complaints of general weakness, fatigability, abdominal pain and repeated attacks of dizziness. He had frequent attacks of indigestion, which apparently had no reference to meals and were unaccompanied by nausea and vomiting, but there was marked constipation. The entire attitude of the patient was that of pronounced psychoneurosis. He showed improvement with a bromide treatment, suggestion and persuasion, gaining and losing weight depending on his emotional state. He had occasional fainting spells, frequently caused by emotional stress. In April, 1924, he had one of these attacks and his physician was summoned. There was also a history of an argument with the foreman in the shop in which he was employed, after which he fainted. His wife casually remarked that the patient had had a bowel movement which was black. Examination revealed that it was melena, and the patient was admitted to the university hospital without delay. A roentgen examination within a few days revealed a duodenal ulcer, and, at an operation by Dr. I. S. Ravdin, he was found to have a hard mass in the region of the duodenum. He died a few weeks later of metastases of carcinoma of the duodenum.

This man undoubtedly had an organic lesion that had not been carefully investigated. The symptoms yielded to psychologic treatment until malignant degeneration set in and the organic manifestations became evident.

Case 8.—J. B., a man, aged 38, a fireman, with a marked psychopathic family history, when first seen in May, 1928, complained of attacks of precordial distress, dyspnea, anxiety and pronounced nervousness. He had been examined by police surgeons at the fire-house on two or three occasions, and the case was diagnosed as "hysteria." Between attacks, he seemed to have been in fairly good health excepting for somewhat increased fatigability. The patient was rather undersized though fairly well nourished and weighed 135 pounds (61 Kg.). The size of the heart was within normal limits, the pulse rate 96, the blood pressure 166 systolic and 70 diastolic. There was no exophthalmos and no von Graefe sign. The thyroid was slightly enlarged. The abdomen was soft and somewhat tender around the umbilicus and just to the median line of the right lower quadrant. The patient was admitted to the Policeman's and Fireman's Ward at the Philadelphia General Hospital, where all examinations, including a complete gastro-intestinal study, were entirely negative. However, from observation over a period of months, it was felt that his attacks were due to a mechanical cause, probably abdominal in location. A laparotomy was performed (Dr. Hubley Owen) and an extremely long appendix, extending from the retrocecal region to the retrohepatic region, was found and removed. The patient made an uneventful recovery, returning to duty within eight weeks.

He remained in good health until the spring of 1926, when he developed pronounced anxiety, restlessness, insomnia, loss of appetite and weight, and feared such things as going out into the street. At this time there had been a great amount of worry due to illness and domestic discord within the family. At the Orthopedic Hospital careful studies failed to reveal organic etiology and within a few months he recovered from an anxiety neurosis, returning to active duty in the fire bureau, where he has been ever since.

At the time of the attack in 1923, the patient was regarded as definitely psychoneurotic. However, he appeared to be in fairly good health between attacks. There was no psychogenic background, and on examination it was felt that there was visceral difficulty to account for his trouble. This was verified both by the operative observations and the subsequent recovery. The second episode, in 1926, was associated with definite psychogenic factors, and in addition the character of the symptoms was such that they bespoke very clearly their psychologic nature.

Case 9.—H. R., a man, aged 42, a broker, came to Philadelphia in September, 1927, complaining of nervousness, insomnia, restlessness, loss of appetite and vague abdominal discomfort, not related to the intake of food. The condition was gradual in onset and of about four months' duration. Family and past medical histories were irrelevant. The family ascribed the trouble to financial reverses, and his wife insisted on Christian science treatment. Physical examinations and laboratory investigations made in Boston and repeated in Philadelphia disclosed no positive finding excepting a mild secondary anemia; roentgen examination revealed no abnormalities. A psychiatric examination disclosed a mild anxiety state without definite depression and a persistent, gradually increasing complaint of abdominal discomfort with very little emotional coloring. An exploratory laparotomy was advised, and an operation in October, 1927, by Dr. Michael Warmuth revealed carcinomatosis of the peritoneal cavity with the primary lesion in the small intestine.

A careful analysis of the case, negative family and past medical histories, the gradual onset of the abdominal discomfort, the secondary character of the nervous symptoms, and especially the character of emotional reaction, aroused the suspicion of primary visceral disease. Despite negative physical and laboratory examinations an operation was advocated.

Case 10.—J. L., a man, aged 37, a knitter, was referred by the genito-urinary clinic because of sharp shooting pain in the perineum, of several months' duration. Complete genito-urinary studies, including catheterization of both kidneys, revealed no abnormalities or disease of the spinal cord, and a neurosis was suspected. Neuropsychiatric studies revealed no evidence of organic neurologic disease, nor was there evidence of neurosis. A rectal examination revealed cryptitis and internal hemorrhoids. An operation gave complete relief within a few days.

In this case, the very absence of neuropsychiatric symptoms bespoke the existence of visceral disease.

Case 11.—F. H., a boy, aged 12 years, in September, 1922, suddenly developed epileptiform convulsions. He was studied most carefully from every angle, having been under close medical observation since childhood, owing to the fact that his was a case of asymmetrical development of the limbs without paralysis or evidence of asymmetrical cranial development. A few months after the first convulsions acute appendicitis developed and he was operated on, but the removal of the appendix failed to prevent the recurrence of the convulsions. A complete study of the cranium and accessory sinuses by Dr. G. E. Pfahler was entirely negative. A comprehensive gastro-intestinal study showed some evidence of cecal stasis, thought to be due to postoperative adhesions. Operation revealed only a few minor filmy bands, which were not considered sufficient to produce symptoms of obstruction but were removed. The convulsions returned with moderate severity but this time the patient's mother made the observation that they were always coincident with drinking milk. Exclusion of milk from the boy's diet was followed by a complete recovery, and there has been no recurrence of the convulsions since June, 1924.

This appears to be a true case of protein anaphylaxis with epileptiform convulsions. Such cases have been reported by Ward and Patterson.[12] While anaphylaxis cannot be regarded as a visceral disease, it was deemed advisable to bring it into relation with neuropsychiatric counterfeits.

GENITO-URINARY GROUP

Pain over the bladder region, painful and frequent urination, impotence, premature ejaculation and failure of erectile power are frequently of psychogenic origin. This is not difficult to understand when it is borne in mind that the pelvic organs are innervated to a great extent by the involuntary nervous system—the lumbar sympathetic and sacral autonomic—and that these are subject to segmental and suprasegmental—cortical and subcortical innervation [9]—and therefore by psychic and especially emotional states. The pudendal nerve—the somatic component—innervates largely the external sphincter and the pelvic floor. There is still another reason why these organs are a favored seat of neurotic expression: the sex development, in a broad sense, intimately conditions the development of the entire personality, and many disturbances in the latter show a tendency to "fixation" at the genital level. Feelings of inferiority, self accusation and depreciation have a tendency to manifest themselves by pelvic symptoms. Therefore, pelvic symptoms, common not only in the psychoneuroses but also in the psychoses, are evidences of regression.[13]

---

[12] Ward, J. F., and Patterson, H. A.: Protein Sensitization in Epilepsy, Arch. Neurol. & Psychiat. 17: 427 (April) 1927.

But pelvic symptoms due to structural changes in the bladder and genitalia may be accompanied by a great many complaints not related to these organs, and by their bizarreness and variability may be of definitely psychoneurotic or psychotic nature. In these cases, the underlying pathologic condition may be easily overlooked, as in the following case:

CASE 12.—J. H., a man, aged 43, a laborer, was referred by Dr. Jacob Makler to the Neurologic Clinic of the Graduate Hospital in May, 1930, complaining of insomnia, nervousness, a feeling of despondency, inability to concentrate or to work, loss of weight, pain in the hypogastrium, frequency of urination, and impotence. The condition commenced about six months previously with distress in the bladder and frequency in urination, following some emotional disturbance incidental to marital difficulties. The patient had never observed blood in the urine, and several physicians had told him that he was nervous. His father committed suicide at the age of 52; otherwise his family and past medical histories were unimportant. Objectively, the patient was moderately well developed and nourished. General physical and neurologic examinations were normal. He appeared much older than his actual age, was very depressed, talked in an undertone, and ascribed his difficulties to a venereal disease which he thought must have been contracted in his youthful days. The somatic complaints and the depression led us to suspect an involution psychosis. The blood Wassermann reaction was negative. He was referred to the genito-urinary department but discontinued attending the clinic. The following subsequent report was obtained from his family physician, Dr. Makler. He went to the genito-urinary department of another hospital, where carcinoma in the urinary bladder was found. He was operated on at the Philadelphia General Hospital and succumbed shortly thereafter.

From a psychiatric standpoint, this case was clearly one of involution psychosis. A careful chronological study, however, directed attention to the genito-urinary tract as the immediate causative factor in his condition.

THE SCIATIC SYNDROME

The "sciaticas" require at all times an etiologic diagnosis. This was recently reemphasized by Grossman and Keschner,[14] who call attention to the fact that sciaticas often mask bony changes in the pelvis or neoplastic conditions around the spinal cord. It may be well to call attention to the fact that sciatic pain may be the only evidence of intrapelvic disease, as illustrated in the following case:

CASE 13.—M. S., a woman, aged 43, with irrelevant family and past medical histories, complained in 1920 of recurrent attacks of pain in the left foot for two years. The pain was sharp and shooting in character. It often appeared after retiring at night and became progressively greater in frequency. A number of doubtful teeth were removed without relief. Neurologic examination was negative. A pelvic examination by Dr. J. C. Hirst revealed a hitherto unrecognized small fibroid tumor attached in the neighborhood of the left cornu uteri. A hysterectomy (St. Agnes Hospital) resulted in permanent relief.

No diagnosis of sciatica is justifiable without a complete and often repeated pelvic study. The following case illustrates this point from another angle:

CASE 14.—G. K., a man, aged 35, a broker, in August, 1929, complained of pain in the back and in the right thigh and leg. When he was a child he had had occasional pains in the back, causing incapacitation for several weeks at a time. At times he was free from pain for a period of months and even years and actively engaged in outdoor sports. About one and one-half years before observation the pain became much worse, following a strenuous game of handball. Since then he had had great discomfort. The pain was located chiefly over the region of the right sacro-iliac joint, radiating into the hip and leg. It was dull in character but not influenced by weather, coughing or sneezing. The pain improved with rest and the application of heat. There was no history of any important illness or injury. He stated that he had not had venereal disease. A tonsillectomy had been performed three years before. He did not indulge in alcohol.

The patient was well built and well developed muscularly. His back was symmetrical, other than a slight drooping of the left shoulder. His spine was in the midline and there was no deviation or rotation. There was, however, a moderate increase in the lumbar curve, which was explained by the moderately protruding abdomen. There was no definite muscle spasm. The motions of the spine were free and unrestricted, causing no discomfort. There was no pain on pressure throughout the spinous processes, lumbosacral region, sacro-iliac joints or along the course of the sciatic nerve. Anteriorly, the chest was symmetrical and the abdomen protruding. All signs for sacro-iliac derangement were negative.

A neurologic examination revealed no evidence of organic disease. The Lasègue sign was negative. The Achilles jerks and knee jerks were equal and prompt on both sides. A roentgenogram of the teeth was entirely negative. Prostatic examination, by two genito-urinary specialists, revealed no evidence of pus. The orthopedic examination confirmed the observations, and baking and massage were advised. This, however, did not relieve the patient.

About six months ago he came in with the following story: Without any apparent cause, he developed a purulent urethral discharge which on examination was found to be a mixed staphylococcus infection. A few days after discharge, the patient was entirely free from pain in the sacro-iliac region and along the sciatic nerve. The urethral discharge continued for several weeks, during which time the patient was symptom-free. It ceased, and there was a return of the pain in the back and leg. With subsequent massage and use of autogenous vaccine, his symptoms subsided entirely.

In neuritides, a search should always be made for focal infections. Often it is not sufficiently persistent or is incomplete.

COMMENT

This presentation would be of little use if it could not answer, or attempt to answer, two questions: (1) Why were these errors made and (2) What general principles should be followed to avoid similar mistakes?

1. Regarding the first question, several factors come into consideration. The first of these includes faulty and incomplete examinations. Some cases are referred with the assurance that no organic disease exists and the correctness of such observations is assumed without adequate check-up (cases 2, 3, 6, 9 and 10). Many organic conditions, such as the "myocarditides" and carcinomas of abdominal organs, fail to reveal, in the early stages, trustworthy organic manifestations (cases 1, 2, 6, 9 and 13). In some cases the underlying causes, such as some focal infections, are illusive and difficult of demonstration. In others, unwillingness and

[14] Grossman, Morris; and Keschner, Moses: The Sciatic Syndrome, Arch. Neurol. & Psychiat. **21**: 398 (Feb.) 1929.

incooperativeness preclude suggested investigation. A second factor is the assumption of the presence of a psychoneurosis because of the richness, bizarreness and variability of "functional" symptoms, which make further investigations seem unnecessary (cases 1, 2, 3, 4, 5, 7 and 12). A third factor is the assumption that the present symptoms are merely a variation of a former reaction to a psychogenic situation (cases 1, 5, 7 and 8). In the second and third factors not only a great deal of care but also much judgment must be exercised.

2. To avoid such errors as those just quoted, the following formulation seems justifiable in the practice of neuropsychiatry:

(*a*) Every case should be considered from the standpoint of personality make-up with reference to heredity, early development, school and vocational records, sexual and marital factors, social and economic adaptability, and the individual's reaction, at various periods, to environmental conditions. The latter includes disease, injury, and mental and physical storms.

(*b*) A careful history, especially the chronological development of the symptoms, should be obtained from the patient. The assistance of relatives and friends may be needed. Additional valuable information is frequently obtained in reexamination.

(*c*) Every case should receive a complete somatic as well as neurologic examination. Every neuropsychiatrist should be sufficiently well trained to do this and in every case urinalysis, complete blood count, blood chemistry and blood Wassermann tests should be made.

(*d*) No special examination should be made until the neuropsychiatrist has obtained a view of the total situation—of the formulation as to what possible physical and psychic changes are present in the patient with the particular make-up. This requires a psychologic evaluation of the case—a difficult and often time consuming method.

(*e*) Every one seems to agree that no case should be diagnosed as psychoneurosis until all indicated investigations are completed. Some insist that a diagnosis of psychoneurosis should always be one of exclusion. This, like blind faith in laboratory procedures, has its disadvantages: in some cases certain avoidable surgical procedures, especially in the nasopharynx and abdomen, only tend to accentuate the already existing vicious circle; and, lastly, it is felt that, in competent hands, neuropsychiatric manifestations can be evaluated on their own merits. This requires time consuming, repeated interviews. Special examinations, therefore, are best directed when the neuropsychiatric investigation justifies them. When doubt exists, however, the patient is justifiably subjected to investigations.

(*f*) From the standpoint of neuropsychiatry, every disease must be considered as having both a somatic and a psychic component. These two components are indivisible and should be evaluated in their relation to etiology and to the total situation. With this broad psychologic point of view, errors in diagnosis may frequently be avoided.

SUMMARY

1. A variety of neuropsychiatric manifestations often mask visceral disease of etiologic significance.

2. Visceral disease may give rise to neurologic manifestations by reason of the fact that the viscera are innervated by the vegetative nervous system. They are not only influenced by the segmental and suprasegmental portions of the central nervous system and of the emotions but in turn are capable, when disturbed, of giving rise to a disturbance in the emotions and by reason of reflected pain to all sorts of peripheral phenomena. Psychic and emotional states influence the vegetative nervous system and visceral functions and vice versa.

3. Illustrative cases are given wherein neuropsychiatric symptoms have masked cardiac, pulmonary, gastro-intestial, pelvic and genito-urinary diseases.

4. The causes of errors in diagnoses are traceable to faulty and incomplete examinations, to the failure of judgment and proper evaluation of neuropsychiatric manifestations, and to the fact that in predisposed individuals the earliest manifestations of visceral disease may be purely psychiatric in type.

5. From the neuropsychiatric standpoint, disease cannot be regarded as purely psychic or purely somatic. Every disease has a somatic as well as a psychic component and should be viewed from that standpoint for both diagnostic and therapeutic purposes. Moreover, every case should be studied in the light of a total situation.

ABSTRACT OF DISCUSSION

Dr. Julian M. Wolfsohn, San Francisco: Sometimes a neurosis is due to a physical cause and sometimes it has its starting from a mental cause. About a month ago I read a paper before the State Medical Society of California on "Traumatic Disease as a Cause of Mental Disorder," and I brought forward cases very similar to the cases cited by Drs. Weisenburg, Pleasants and Yaskin. The conclusions in that paper were just about the same. As an illustration, one of the individuals who had manifestations of psychosis for about a year, in which he went through a severe neurotic phase, was agitated and uncontrollable; but was finally in a position in which a physical examination could be made, a year and a half after the onset. At that time, tenderness was found in the right iliac fossa. At operation an abscess was found, containing about 2 ounces of thick, green pus, which had evidently been there thirty-two or thirty-three years. The patient was operated on and in two weeks went home, and has been free from any complaints whatever for ten years.

Dr. David C. Wilson, University, Va.: It is highly important to stress that the carcinoma or the ulcer, or whatever the patient has, is not the psychoneurosis; that is, because a person has a gallbladder, it doesn't mean that he cannot have a psychoneurosis. A psychoneurosis is a reduction of that person's personality, a part reaction, as it were; and just because the diagnosis was made in these cases of some organic lesion this does not mean that the patients did not have a psychoneurosis also. The authors made another point which I should like to have them discuss further. They seemed to imply that certain visceral diseases, organic diseases, had some certain rather definite personality reaction; that is, tuberculosis had some kind of definite nervous reaction; carcinoma, another. I don't think they meant that, but I should like them to bring out that point. Certainly in handling people in tuberculosis sanatoriums one sees a great many different psychoneurotic reactions, depending, as one would expect, on the different personalities of the patients.

Dr. Henry Pleasants, Jr., West Chester, Pa.: One of the cases to which, because of lack of time, attention was not called was that of an individual who showed marked neuropsychiatric disturbance, which was extremely difficult to fathom; in fact, the patient at one time presented the picture of an early pernicious anemia before blood changes are demonstrable. This individual was carefully studied and, during this period, a depressive type of psychosis developed. We could not find anything as a cause of the factor until finally we discovered a streptococcus infection of the colon, which under appropriate vaccine, cleared up, its disappearance being accompanied by the appearance of hydrochloric acid in the gastric contents which had been absent before. This was an absolute instance of a masking of the somatic symptoms by neuropsychiatric manifestations.

Dr. Joseph C. Yaskin, Philadelphia: I am afraid that Dr. Wilson misunderstood us. We did not mean to convey the idea that diseases in special organs produce special neuropsychiatric symptoms. These symptoms depend on a number of factors, such as the mental make-up of the individual, the duration and intensity of the disease, and the site of the process. Thus, in tuberculosis of the upper lobes there is a tendency to euphoria whereas with the invasion of the basal lobes or in diseases of the abdomen there is a tendency to depressive types of reaction.

ROENTGEN TREATMENT OF AGRANULOCYTOSIS *

ALBERT E. TAUSSIG, M.D.
AND
PAUL C. SCHNOEBELEN, M.D.
ST. LOUIS

Although it has been nine years since Werner Schultz first described the new symptom complex which he termed agranulocytosis, and although several hundred cases have been reported in more or less detail, there is as yet no generally accepted definition by means of which the concept of the disease can be accurately circumscribed. Schultz's own definition of the disease is sharp enough: an acute febrile disease with angina, prostration and jaundice, a normal red blood picture, extreme leukopenia with nearly or quite complete absence of granulocytes, a normal number of blood platelets with absence of any tendency to hemorrhage, and an invariably fatal ending. Almost at once, however, cases were reported that lacked one or more of these cardinal symptoms. Jaundice was found more frequently absent than present; a considerable degree of secondary anemia is not rare in otherwise quite typical cases; instead of angina one may find ulcerative processes elsewhere, or even absent; an occasional case runs a chronic rather than an acute course and, finally, cases of recovery, often with repeated recurrence, occur. Accordingly it seems necessary to define agranulocytosis as characterized by fever, usually but not always by ulcerative processes, leukopenia with great diminution of the granulocytes, and nearly normal blood platelets. At autopsy a very characteristic change is found in the bone marrow, consisting in a great paucity of the myelogenous white cells, which are also absent or nearly so in any inflammatory foci that may occur.

But even this description is not quite precise. While a typical case is unmistakable, the disease shades off into a variety of other conditions that can definitely not be included in the concept of pure agranulocytosis. The most important of these is the myelopathy that sometimes occurs in the course of antisyphilitic treatment, most frequently after the use of one of the arsphenamines, but occasionally also after compounds of bismuth or mercury. Ordinarily such cases present a fairly typical clinical picture of their own. The metallic poison depresses all the functions of the bone marrow, so that one encounters, in addition to the symptom complex of agranulocytosis, an anemia, often extreme, and a sharp reduction in the blood platelets with a resulting tendency to hemorrhage. Large numbers of such cases have been reported,[1] and the condition seems to have been known for some years before Schultz's agranulocytosis was recognized as a clinical entity.

In typical cases the blood alteration in the panmyelopathy following antisyphilitic treatment is much more extensive than in agranulocytosis, so that the two can properly be distinguished. But individual cases of each approach one another so that it is possible, from the literature, to construct a series of cases shading almost imperceptibly from the typical agranulocytosis of Schultz to the equally typical panmyelopathy after arsphenamine. It would thus appear that the delimitation of the clinical picture of agranulocytosis is a somewhat artificial one. Nevertheless, most of the cases of agranulocytosis so definitely belong together that convenience justifies setting up this group of cases as a clinical entity.

Oddly enough, the myelopathy following antisyphilitic treatment seems to offer a much more favorable prognosis than true agranulocytosis, and a considerable proportion of the patients recover merely as the result of discontinuing the treatment. The explanation may lie in the fact that with the cessation of antisyphilitic treatment the causative factor of the myelopathy is withdrawn, whereas in true agranulocytosis the unknown agent continues to operate.

A similar condition is sometimes seen in diphtheria. A number of cases have been reported with the typical blood picture of agranulocytosis, differing only in the appearance after the first few days of a moderate percentage of eosinophils. Most of the cases hitherto observed occurred in the course of a single year in Alexandria, so that they are apparently more common in some epidemics than in others. Here, too, the mortality has been essentially better than in idiopathic agranulocytosis. Thus, of the eight cases reported by Farmakidis[2] and by Janz,[3] six recovered after the injection of large amounts of diphtheria antitoxin, making a mortality of only 25 per cent. The explanation of this low mortality is probably the same as that of the myelopathy following antisyphilitic treatment.

Cases of agranulocytosis have been repeatedly observed apparently to pass over into acute lymphatic leukemia. Whether this is really what occurs or whether the resemblance between agranulocytosis, properly so called, and the aleukemic stage of lymphatic leukemia is merely so close that they are readily confused . cannot be determined until something more definite is known about the etiology of agranulocytosis.

The etiology is still fundamentally a mystery. Agranulocytosis has been observed repeatedly in the course of phlegmonous tonsillitis and of septicemia, during influenza,[4] in the course of Hodgkin's disease[5] and malaria,[6] in kidney tumor in an infant,[7] and even after the prophylactic injection of typhoid vaccine.[8] But these are obviously only secondary causes and presuppose a weakness of the bone marrow due to some other factor. The weakness can hardly be congenital, in spite of the fact that a familial occurrence of agranulocytosis has been observed,[9] since it would then occur more frequently in early life and not be, as it is, essentially a disease of late maturity. Everything indicates that the necrotic processes in the throat, mouth and elsewhere are the results, not the cause, of agranulocytosis. The fundamental etiologic factor may not be found until we have succeeded in producing agranu-

locytosis, as distinguished from a nearly complete prostration of the bone marrow, experimentally. A possible hint in this direction may be found in the relative frequency with which an allergic tendency has been observed in the victims of the disease. At present, however, our information on this subject is too scanty to justify conclusions.

In no aspect of the disease do opinions differ so widely as in the matter of treatment. Most of the cases in the literature have been treated symptomatically with stimulants and local antiseptics; many have been treated with foreign proteins but without perceptible effect. The production of a sterile turpentine abscess has been followed by a turn for the better,[10] and the latter has repeatedly been the case after injections of small doses of neoarsphenamine. Reznikoff[11] has reported three recoveries out of four cases of agranulocytosis treated with intravenous injections of guanine or adenine; but these results require confirmation by others, and in one case so treated at the Jewish Hospital of St. Louis no beneficial effect of any kind could be observed. Transfusions[12] have been followed by a sharp rise in the granulocyte count followed by recovery, and the same has been true of small stimulating doses of x-rays[13] applied to the long bones. Other observers, however, have failed to obtain any benefit either from transfusions[14] or from x-rays.[15]

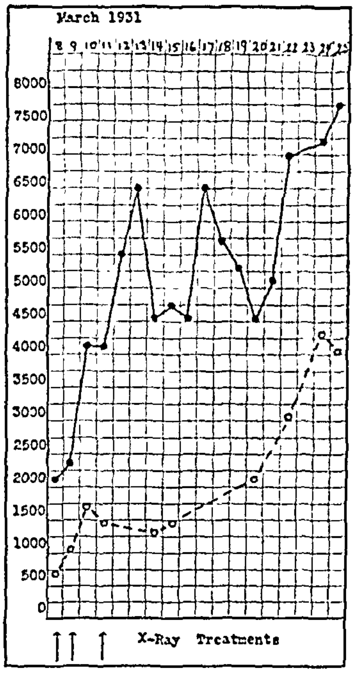

Chart 1.—Leukocytes (solid line) and granulocytes (broken line) in case 1.

The difficulty of estimating the value of therapeutic measures in agranulocytosis is twofold: no one observer, possibly excepting Friedmann with his forty-three cases treated by means of irradiation, has seen enough cases of agranulocytosis to be justified in drawing conclusions from his own experience; and the not infrequent spontaneous recovery from agranulocytosis makes it difficult, in any concrete case, to be certain of the rôle played by treatment in the patient's recovery.

Until recently, the total number of cases reported has not sufficed for the employment of statistical methods. At present, however, this is no longer the case. A review of the literature accessible to us, which unfortunately does not include the Slavic nor all of the Scandinavian, affords 334 well authenticated cases of agranulocytosis, care having been taken to exclude the other forms of bone marrow injury previously mentioned. An analysis of these cases reveals some interesting facts, which may be summarized as follows:[16]

1. Of the 330 cases in which the sex was noted, 104 were in males and 226 in females, a proportion of a little over 2:1; among the males the total mortality was 75 per cent; among the females 77 per cent.

2. The inflammatory lesions were distributed as follows: angina, 241, or 74 per cent; stomatitis, 36, or 11 per cent; no lesion of any kind, 17, or 5 per cent; anal ulcers, 13, or 4 per cent; other lesions, 18, or 5 per cent.

3. The age incidence was as follows: under 20 years, 26, or 9 per cent; from 20 to 40 years, 117, or 38 per cent; from 40 to 60 years, 127, or 40 per cent; over 60 years, 43, or 13 per cent.

4. In analyzing the results of therapeutic measures, it has seemed necessary to exclude from consideration those cases which terminate fatally within forty-eight hours of the time treatment was instituted. These were either fulminant cases in which no treatment could have been of avail, or cases which had been neglected until the end was near. It would obviously be unfair to estimate the value of any therapeutic measure when applied to a moribund patient. With this proviso, the results of therapy as recorded in the literature are shown in the accompanying table.

Results of Therapeutic Measures

	Cases	Deaths	Mortality, per Cent
Cases treated by means of irradiation	64	34	53
Cases treated by means of transfusion	53	34	64
Cases treated with arsphenamine	33	24	73
Cases treated with other therapeutic measures	178	133	75

Since Friedemann has reported such a large portion of all the cases of agranulocytosis treated by means of x-rays, it might be thought that the statistics may have been loaded by his favorable results and that the latter should be looked on somewhat skeptically. This is not the case. Friedemann and Elkeles[13] reported, in all, forty-three cases so treated. Of these patients, eighteen were moribund when first seen. Of the remaining twenty-five, twelve died, making a mortality of 48 per cent. Other observers have reported, in all, thirty-nine cases, in four of which the patients were moribund. Of the thirty-five remaining patients, twenty died, making a mortality of 57 per cent. Our own four cases showed a mortality of 50 per cent, figures which harmonize sufficiently well for so small a group.

In any event, the figures indicate definitely that transfusions and roentgen therapy are useful in the treatment of agranulocytosis and that, of the two, irradiation of the long bones gives the better results. It will probably be wise to use both methods in the treatment of a severe case, and doubtless the results will be the better, the earlier these methods are applied.

During the past year, seven patients with agranulocytosis entered the Jewish Hospital of St. Louis. Of these, two were moribund when admitted and died the same day; a third received only symptomatic treatment. The other four illustrate very well some of the features of roentgen therapy. We use 200 kilovolts corrected by sphere gap; 30 milliamperes, checked on two meters; a target skin distance of 50 cm.; a port of 30 cm.; a filter consisting of 0.5 mm. of copper plus 1 mm. of aluminum. With this set-up, an exposure of forty-five seconds corresponds to about one-twentieth erythema dose, the dose advised by Friedemann. This exposure was given at each sitting in cases 1, 3 and 4; in case 2 the time of each exposure was two and a half minutes.

[16] It will be noted that the totals in the different classifications do not tally. The reason for this is twofold: First, a number of the case reports fail to state the sex of the patient, others the age; some do not even note the site of the inflammatory lesion. Second, in analyzing the therapeutic results, cases of complete and long continued recovery, with subsequent relapse, were counted once for each attack. Only the extraordinary case of Rutledge, Hansen-Pruess and Thayer, with its innumerable recurrences recovering without therapy, was counted but once.

REPORT OF CASES

Case 1.[17]—N. W., a woman, aged 30, was admitted to the Jewish Hospital, March 9, 1931, with a history of fever and general malaise for five days. The temperature was 100.6, pulse 88, respiration 44. Physical examination gave negative results except for a dirty gray exudate on both tonsils. The blood contained 4,400,000 red cells, 75 per cent hemoglobin, 2,000 white cells; the differential count showed stabs, 19 per cent; segmented cells, 4 per cent; lymphocytes, 50 per cent; mononuclears, 24 per cent; degenerated cells, 3 per cent. The subsequent changes in the blood are shown on the chart. The patient received three roentgen treatments over the long bones of 0.05 skin unit dose each. Almost at once the blood and the clinical picture showed a marked improvement, and she was discharged in good condition, March 25. During her entire stay in hospital the patient received fairly large doses of desiccated hog stomach.

Case 2.—Mrs. B. S., aged 51, was observed in consultation with Dr. D. L. Sexton, who had been treating her at home for pityriasis rosea. Aug. 1, 1930, she felt slightly ill and had a temperature of 101, which rose next day to 102, with great prostration and crackles over the bases of both lungs. Pneumonia being feared, she was transferred to the Jewish Hospital. Physical examination gave negative results, except as already described and except for a thrombosed pile; the mouth and the pharynx, in particular, were quite clear. A blood count showed 3,880,000 red cells, 73 per cent hemoglobin and 825 white cells; there were no granulocytes, only lymphocytes being found in the stained spread. The subsequent changes in the blood are recorded on the chart. On August 2 and again on August 3, she received an irradiation of 0.25 skin unit dose over the long bones. An immediate clinical and hematologic improvement resulted; within a few days the blood picture was normal and the patient clinically well. Two weeks later the white blood cell count and the percentage of granulocytes dropped sharply, though the patient continued to feel well. August 25, however, the white blood cell count having fallen to 2,400 and the granulocytes to 11 per cent, she again received an irradiation of 0.25 skin unit dose over the long bones. Again there was a prompt rise in the white and granulocyte count but not to normal. August 30, she began to receive daily large doses of liver extract. This was followed by a rapid return of the blood picture to normal, and the patient was discharged, clinically well, September 5. She has remained well ever since.

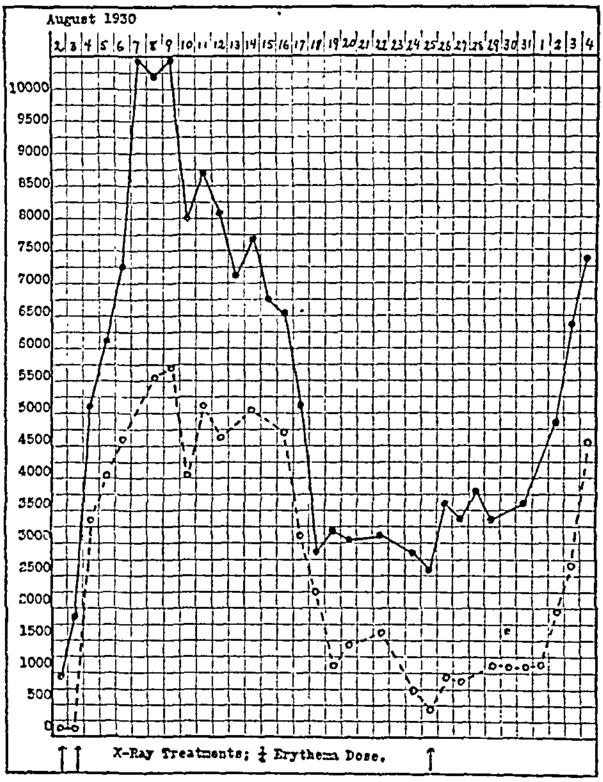

Chart 2.—Leukocytes (solid line) and granulocytes (broken line) in case 2.

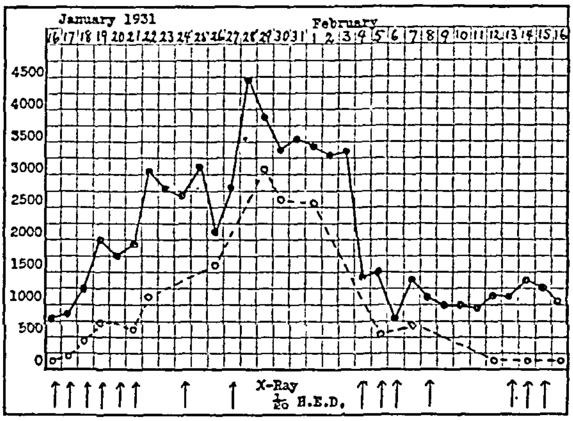

Chart 3.—Leukocytes (solid line) and granulocytes (broken line) in case 3.

Case 3.—Miss E. C., aged 80, had received a radium treatment for cervical polyp in the spring of 1930. A small but irritable rectal burn resulted that made her an invalid all summer. In the fall she grew much better and was supposed to be on the way to recovery. January 15, however, weakness and vague malaise set in and the next day, on attempting to get out of bed, she collapsed on the floor. She was brought to the Jewish Hospital, where she was found to have a temperature of 103, pulse 110, respiration 26. Physical examination gave negative results except for the usual senile changes and a small rectal ulcer. The diagnosis was not made until the next day, when a blood count was done which showed 4,420,000 red cells, 80 per cent hemoglobin and 950 white cells, with 5 per cent granulocytes. A slight angina then made its appearance, rapidly grew worse and culminated in phlegmonous tonsillitis; there was also some gingivitis. For the first six days of her stay in the hospital, she received a daily irradiation of 0.05 skin unit dose over the long bones and during the second week two similar doses. The white blood cell count and the granulocyte count slowly rose to a fairly satisfactory figure (chart 3); the angina cleared up completely; the fever ceased, and the patient gained strength and felt quite well. February 3, the white blood cell count and the granulocyte count again dropped sharply and again presented the picture of an extreme agranulocytosis. This time, roentgen therapy was of no avail, nor was there any response to the injection of large doses of leukocyte extract and the feeding of liver extract. In spite of the marked agranulocytosis, the patient remained euphoric and free from symptoms for ten days. February 13, the temperature rose; the patient became drowsy and finally comatose, and died, February 17. Autopsy showed only the typical bone marrow changes and the rectal ulcer previously referred to.

Case 4.—Mrs. M. G., aged 41, was observed in consultation with Dr. Elmer Richman. Her previous history was not important. For a week she had had a coryza with an unusual degree of prostration. The white blood cell count at that time was 7,000, with a normal differential picture. On the appearance of a suppuration in the middle ear, she was transferred to the Jewish Hospital, with a temperature of 102, pulse 100 and respiration 20. Physical examination gave negative results except for a purulent discharge from the left ear and an injected pharynx. A blood count showed 4,400,000 red cells, 80 per cent hemoglobin, and 3,300 white cells, all of which were large and small lymphocytes. A blood culture was negative. In spite of adequate local treatment, the temperature remained high; the pharynx rapidly became phlegmonous, with necrotic areas; the prostration grew extreme, and the white blood cell count fell to 650 without any granulocytes. The patient appeared moribund. Beginning March 4, she received six daily irradiations over the long bones, 0.1 the first day and 0.05 skin unit dose thereafter. The white blood cell count and the granulocyte count rose sharply to far above the normal (chart 4); the fever ceased; the angina cleared up, and the patient became clinically well. Her condition remained satisfactory until March 20. Two days later, concomitantly with a drop in the white blood cell count and the granulocyte count, the pharynx again became injected. Four daily irradiations of 0.05 skin unit dose over the long bones failed to halt the drop in the white blood cell count and the granulocyte count; the fever reappeared, and the angina became phlegmonous. Liver feeding, the injection of leukocyte extract and of "nucleotids," according to the method of Reznikoff, were equally without effect. The patient became increasingly prostrated, finally grew comatose, and died, April 1. Autopsy was essentially negative except for the usual bone marrow changes characteristic of agranulocytosis.

COMMENT

An inspection of the blood charts in these four cases can hardly fail to justify the conclusion that stimulating doses of x-rays are an effective therapeutic measure in agranulocytosis, provided the injury to the bone marrow is not too extreme. In two of the cases recovery was permanent, at least for the time being. In the other two the first response was also satisfactory. Apparently, however, the unknown toxic agent, obviously independent of the angina, continued to act, and finally depressed the bone marrow function to such an extent that neither roentgen therapy nor any of the other measures used were of avail. It is of interest to note that in the second case roentgen therapy was only moderately effective during the patient's relapse but that the blood returned to normal concomitantly with the feeding of liver extract. Unfortunately, this is not the usual experience in these cases.

The use of roentgen therapy in agranulocytosis dates from Friedemann's first communication in 1927 and has been kept alive by repeated papers on this subject ever since. The effect of the usual massive dose on the bone marrow is well known. There is a simultaneous depression of the production of erythrocytes, leukocytes and thrombocytes, producing the picture of an aplastic anemia, often with a tendency to hemorrhage. Apparently, minimal doses have the opposite effect, especially as regards the granulocytes. Burgheim[18] exposed the long bones of a number of healthy individuals to single exposures of one-twentieth erythema dose; in each case he observed a slight but definite rise in the granulocyte count, often within two hours. Thoma gave roentgen treatments to a number of typhoid patients with marked leukopenia and observed a rise in the leukocyte count of from 1,000 to 3,000. In diseased bone marrow the effect of roentgen therapy appears to be still more marked. In three of our cases the rapidity with which the granulocytes regenerated after the first few irradiations speaks strongly for the value of the treatment.

What is the optimum dose of x-rays in the treatment of agranulocytosis? Friedemann uses one-twentieth erythema dose daily, and nearly all the clinicians who have used the method have followed in his footsteps. His fundamental notion is to have a quantity of rays which will assuredly not exert a depressing action on the bone marrow. But there is reason to believe that the dose was chosen a little too low. In our third and fourth cases a number of exposures with this dose were necessary to bring about a satisfactory effect on the blood picture, whereas in the second case a prompt and satisfactory effect was produced by one or two exposures with a dose five times as great. Whether the larger dose is safe as well as efficient remains to be determined by further experience.

CONCLUSIONS

1. Cases of agranulocytosis are being observed with increasing frequency, so that it may be said to have ceased to be a rare disease.
2. The symptom complex of agranulocytosis has been circumscribed somewhat arbitrarily. While it is convenient to distinguish it from the bone marrow depression observed in benzene poisoning, in the course of antisyphilitic treatment and in the aleukemic stage of lymphatic leukemia, borderline cases are not infrequent, in which proper classification is difficult.
3. Cases 2 and 3 show clearly that the fall in the granulocytic blood count may precede the appearance of a sore throat. A study of the literature reveals numerous similar observations and justifies the conclusion that the agranulocytic blood picture is the cause and not the result of the angina.
4. Agranulocytosis occurs about twice as frequently in women as in men; the mortality in the two sexes is about the same.

[18] Burgheim, F.: Strahlentherapie 38: 152-156, 1930.

5. Of the methods of treatment at present in use, the most promising appears to be the irradiation of the long bones by means of minimal doses of x-rays. Transfusions are also apparently useful.

ABERRANT THYROID[*]

RICHARD B. CATTELL, M.D.
BOSTON

In its broadest sense the term "aberrant thyroid" includes all portions of thyroid tissue in other than the normal position of the thyroid gland and unconnected with it. This includes (1) lingual thyroid and thyroid tissue found along the thyroglossal tract, (2) lateral aberrant thyroids or those in a cervical position lateral to the jugular vein, (3) the extremely rare intrathoracic goiter with no connection with the main thyroid body and, finally, (4) those portions of thyroid tissue found in teratoid tumors and in sites far removed from the thyroid. The fact that certain portions of the thyroid extend into intrathoracic, substernal, subclavicular, retrotracheal and retrolaryngeal positions does not make them aberrant in any sense. True intrathoracic goiters with no connection with the inferior pole of the thyroid are rarely found and it is quite likely that these have previously been a part of the gland but have become separated during their growth and descent during adult life through the upper thoracic strait. Davis[1] found normal appearing thyroid tissues in the aortic fat bodies of twenty-two out of fifty dogs examined but did not find them in any other animal and they are not present in man, so are of only academic interest. In this paper only lateral aberrant thyroids will be considered since the two cases of lingual aberrant thyroid that we have observed in the clinic have already been reported[2] and because the thyroid tissue in tumors is not of clinical interest.

Thirteen patients with lateral aberrant thyroids have been operated on in the Lahey Clinic in the past six years. From a review of the literature one is impressed with the relatively rare occurrence of this condition. Billings and Paul[3] were able to find only thirty-four proved cases in the literature from 1857 to 1923, and they added one case. All their reviewed reports were individual case reports with the exception of two, each describing three instances. In 1928 Leech, Smith and Clute[4] reported four cases from this clinic. Twelve additional cases have been reported since this publication, including a possible bilateral one by Lewisohn.[5] Nine additional cases have been seen since the first report from the clinic and all thirteen cases are considered together since a follow-up examination has been obtained in all of them.

A consideration of the embryology is of practical importance to understand this condition. The origin of the thyroid gland from a median ventral position in the pharynx is well established. This readily explains the origin and presence of thyroglossal cysts, sinuses and fistulas as well as lingual thyroid and the aberrant portions of the thyroid tissue in the midline. On the other hand, it does not explain the lateral cervical portions of thyroid tissue. From a review of comparative and human embryologic studies, it seems clear that groups of cells arise from a lateral position in the pharynx which would correspond to a fifth pharyngeal pouch or ultimobranchial body.[6] These pass downward and come into relation to the main thyroid body. Norris,[7] in a study of seventy-two human embryos, has shown that these cell groups fuse with the lateral lobes of the thyroid in the 15 mm. human embryos but atrophy and form no part of the normal thyroid gland. An arrest in this lateral descent and atrophy will account for lateral aberrant thyroids and seems a logical explanation of their origin. An arrest in development is further indicated since all our thirteen cases have shown a tumor structure in the aberrant thyroid, and this agrees with our understanding of fetal rests.

A consideration of our thirteen cases offers a clear clinical picture of this disease and is perhaps more accurate than a review of individual case reports. The age of these patients seems of little value in diagnosis. The youngest was 11 years of age, and this case showed adenocarcinoma in the aberrant thyroid. Five patients were under 30 and eight were above this age, two of them being 67 and 70, respectively. There were ten females and three males, a ratio which corresponds with the incidence of patients having thyroid disease in our clinic. The duration of the tumor seems of more importance. Only four had been noticed under one year. Of the nine present longer than a year, five had been noted over five years and one for twenty years. It would seem that a tumor of long standing that had shown little variation in size would be more likely to be of this type than one with a history of rapid growth or increase and decrease in size. There are no characteristic symptoms associated with this condition. Ten of our patients sought advice because of the discovery of a mass in their neck. One had symptoms of hyperthyroidism, while another had symptoms related to pressure of the tumor on the trachea. Hyperthyroidism, which was noted in one case, was due not to the aberrant thyroid but to a hyperplastic main thyroid gland. There was no corresponding hyperplasia in the aberrant thyroid tissue. We have no evidence in any of our cases to indicate an increased physiologic activity of the lateral aberrant thyroids. There has been no elevation of the basal metabolic rate; there has been nothing in their histories to suggest changes in size of the tumors similar to those commonly observed in the thyroid gland. This absence of symptoms related to these tumors is of definite diagnostic value and is helpful in differentiating them from lymphosarcoma and tuberculous cervical glands.

With regard to position, six patients presented tumors on the right side and six on the left side with one being found in the midline. A single discrete mass was found in eight patients. These varied in size from an English walnut to a small orange. In four patients there were extensive tumor nodules scattered from the mastoid process and angle of the jaw to the clavicle. In one, only a few nodules were present. None of our cases were proved to have bilateral involvement. The diagnosis of lateral aberrant thyroid is rarely made before operation. A preoperative diagnosis was made in two of our patients without biopsy, but these were in recent cases after several had been observed. In any consideration of cervical tumors this condition should be thought of, although no positive diagnosis can be made without a biopsy. Three of our patients had had a biopsy before coming to us. In our series a diagnosis of tuberculous glands was made three times; Hodgkin's disease, branchial cyst, dermoid cyst, adenoma of the thyroid and carcinoma or sentinel gland were made each once. Other conditions which must be considered are tumors of nerve origin, carotid body tumors, lipomas, fibromas and carcinomas of nasal or pharyngeal origin.

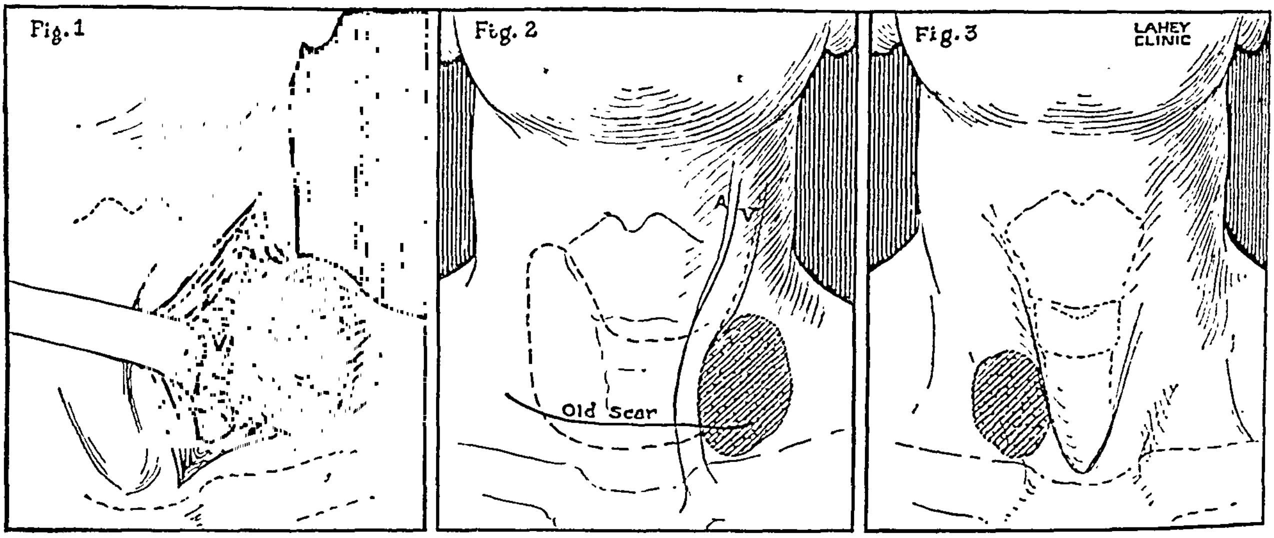
The operative treatment in our cases was determined by the extent of the tumor. In five, local excisions were done. Four had local excisions together with a biopsy of the main thyroid or hemithyroidectomy. Four had radical block dissections of the neck with removal of the internal jugular vein. The main thyroid gland was examined by palpation and direct inspection, and any portion appearing abnormal was removed.



Figs. 1, 2 and 3 (cases 1, 2 and 3).—Wide variation in size, number and position of lateral aberrant thyroid nodules.

Even with an incorrect preoperative diagnosis the condition can usually be recognized at operation. In the discrete type that we have seen the surface of the tumor appears coarsely lobulated and divided by vessels much as in the case of the normal thyroid lobe. Smaller ones are usually solid tumors and are quite granular on their surface. Colloid is not usually abundant. In the larger discrete tumors, central areas of necrosis are present. When multiple tumor nodules are found, the same characteristics may be in evidence; but all our cases of this type have shown a distinctive coloring. On exposure of the nodules, bluish black areas are seen alternated with the gray or brownish red contrasting thyroid tissue. This could readily be confused with the metastatic glands of melanotic sarcoma. The dark coloring, however, is due to small areas of hemorrhage. Hyperplastic lymph glands are occasionally seen in association with them. The nodules were found adherent to the internal jugular vein four times, and in one instance a thin portion was left where it was attached to the common carotid artery.

The microscopic examination of these glands has shown a characteristic picture. All have shown the same papillary type of structure which is recognized as papillary cystadenoma. Six showed this type of structure without invasive characteristics and without marked epithelial proliferation. Five showed malignant characteristics consisting of invasion of muscles and involvement of the regional lymph nodes. Two showed definite adenocarcinoma. One patient with multiple aberrant nodules showed hyperplasia and moderate colloid storage in the nodules. The metabolism test was normal and there was no change in the main body of the thyroid gland. Only four showed any appreciable amount of colloid, so that if this finding was considered as the most important in their recognition as of thyroid origin it would be difficult to recognize some of them. In six, a portion of the lobe on the side of the aberrant thyroid was removed. One showed hyperplasia, one showed an adenomatous structure, three showed areas of papillary cystadenoma which were thought to be malignant and of the same character and grade of malignancy as that evidenced in the lateral thyroid tumor nodules. One showed papillary adenocarcinoma in the nodule in the lobe on the same side.

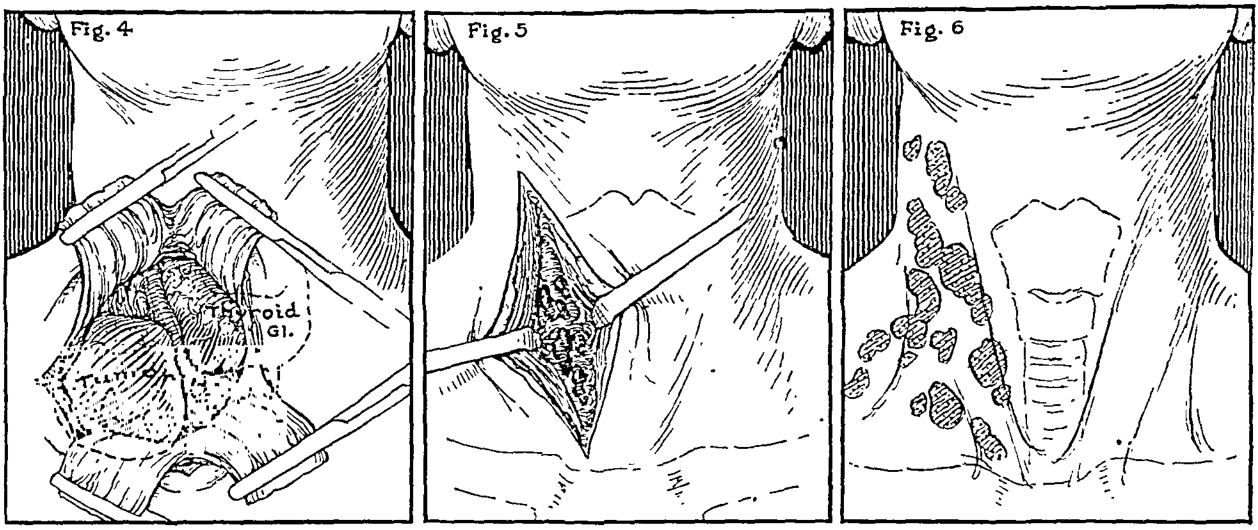
It is, of course, impossible to state in the four patients that showed the same type of structure in the thyroid gland as in the lateral aberrant thyroid which was the primary site of the tumor. Clute and Warren,[8] in reviewing cases of carcinoma of the thyroid seen in this clinic, found 24 per cent of them showing papillary cystadenoma or papillary adenocarcinoma. It is quite possible that a considerable number of these tumors arise from the lateral anlage of the thyroid which normally atrophies, thus having an origin like that of the lateral aberrant thyroid tumors. The degree of malignancy and the prognosis in these cases of papillary cystadenoma of the thyroid and lateral aberrant thyroid are very similar.

The first four of our patients had no subsequent treatment, while the remaining nine all had considerable postoperative roentgen therapy. In spite of the low grade of malignancy we consider it advisable to give all of them this treatment after removal of the tumors.

---

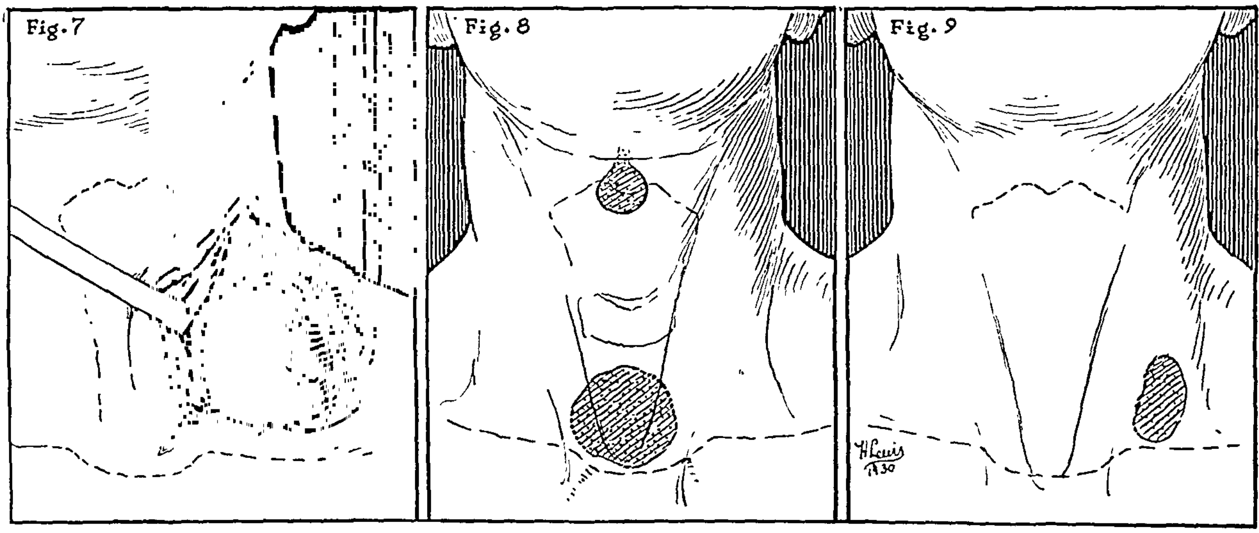
[8] Clute, H. M., and Warren, Shields: Cancer of the Thyroid, Am. J. Cancer **15**: 2563 (Oct.) 1931.

They should receive a course of from four to six treatments in a series six months apart during the first year and if there is no evidence of recurrence after that we feel that it is safe to discontinue treatment but we examine them frequently. It must be admitted that there was no difference in results in the patients treated by x-rays and those who did not receive them, but such therapy is an additional safeguard against recurrence.



Figs. 4, 5 and 6 (cases 4, 5 and 6).—Wide variation in size, number and position of lateral aberrant thyroid nodules.

A follow-up study of these patients has been very instructive and has changed our opinion with regard to the grade of malignancy in these cases. One patient with a simple excision of the tumor is well, without any evidence of recurrence five years after operation. One patient who had local excision together with excision of a similar nodule from the thyroid is well without evidence of recurrence three years after operation and has received no roentgen therapy. One patient with a radical block dissection of the neck received postoperative roentgen therapy and is well two and a half years later. There is one small nodule in the superior pole of the thyroid gland on this side. A biopsy of the gland at the time of operation showed an adenomatous type of structure without involvement with papillary cystadenoma. This patient has a spinal accessory eleventh nerve paralysis. Another patient with a radical dissection of the neck for malignant papillary cystadenoma shows two small nodules two years after operation in spite of repeated roentgen treatment. One patient has a small gland above the incision. This was present immediately after operation and was one of a chain of glands that showed only hyperplasia at the time of operation. All the remaining seven patients are well without evidence of recurrence more than one year postoperatively. One patient was operated on only four months ago, the case being too recent to report. There has been no operative mortality and no patient at present shows any evidence of a tumor possessing malignant characteristics. One patient died sixteen months after operation from a cerebral thrombosis.



Figs. 7, 8 and 9 (cases 10, 11 and 12).—Wide variation in size, number and position of lateral aberrant thyroid nodules.

SUMMARY

Thirteen cases of lateral aberrant thyroid have been reviewed. All showed a similar structure of papillary cystadenoma. In considering this group of cervical tumors, wish to point out the low grade of malignancy as compared with other epithelial tumors involving the cervical glands. These tumors frequently go unrecognized and may be reported as metastatic carcinoma of unknown origin in the cervical glands. It is believed that neck tumors, outside of the thyroid gland showing papillary cystadenoma, are of lateral aberrant thyroid origin and are the result of arrested development. Satisfactory results were obtained by radical removal followed by postoperative irradiation. It is important to recognize them, since a good prognosis can be given.

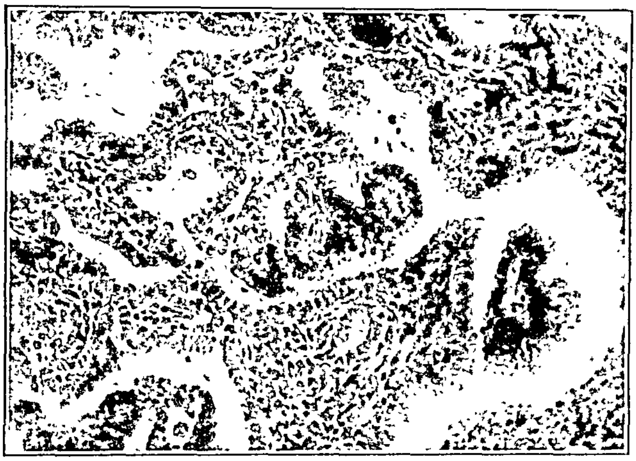


Fig. 10. Typical structure of papillary cystadenoma of a low degree of malignancy. There are few mitotic figures.

CASE ABSTRACTS

Case 1.—Mrs. B. H., aged 70, was seen at the clinic in June, 1925, when she complained of a mass the size of a hen's egg in the left side of her neck. It had been present for three years and there had been a slow growth with extension upward and backward. There had been no subjective symptoms. On examination a hard mass was found above the clavicle on the left side (fig. 1). It was somewhat adherent. The thyroid was normal and there was no adenopathy. The diagnoses of tuberculous cervical gland, Hodgkin's disease and lymphosarcoma were considered.

At operation a mass 8 cm. by 5 cm. was found in the left supraclavicular space beneath the sternomastoid muscle. The muscle was retracted medially and the mass was found to be adherent to the surrounding structures including the internal jugular vein, and appeared malignant. The tumor was removed and she made an uncomplicated recovery and she has had no subsequent treatment. The histologic diagnosis was papillary cystadenoma. An examination five years after operation showed no evidence of either local or general recurrence.

Case 2.—Miss M. R., aged 37, came to the clinic in April, 1929. A subtotal thyroidectomy for exophthalmic goiter had been done sixteen years previously. She apparently had made a good recovery but at one time was reported to have myxedema. A year before our examination she developed dyspnea, precordial pain and auricular fibrillation. Four years previously a tumor had been removed from above her left tonsil. Examination showed an old thyroid scar with a mass 2 inches (5 cm.) in diameter beneath the left angle of the incision (fig. 2). It did not move with deglutition. The right lobe of the thyroid appeared to be enlarged. A preoperative diagnosis of carcinoma of the cervical glands, probably of pharyngeal origin, was made. At operation the tumor was identified outside of the internal jugular vein and common carotid artery, which it displaced medially. The artery was adherent to it. The mass was excised, leaving a small thin portion adherent to the common carotid artery. On exploration of the thyroid, the left lobe appeared of normal size while the right lobe was about three times normal size and appeared hyperplastic. Since the preoperative metabolism test was +30, a right subtotal hemithyroidectomy was done. The pathologist reported that the tissue from the right lobe showed primary hyperplasia with involution and the tumor as papillary cystadenoma in an aberrant thyroid. She died sixteen months after operation with a cerebral hemorrhage, without evidence of recurrence of the tumor.

Case 3.—Miss E. T., aged 20, came to the clinic in November, 1926, complaining of enlarged glands in the right side of her neck noticed one week previously. She had noticed no symptoms related to them. She had lost 20 pounds (9 Kg.) in two years. Examination showed a firm gland just behind the lower insertion of the right sternomastoid muscle (fig. 3). At operation a tumor an inch and a half in diameter was removed from this position. It was not adherent. It presented certain characteristics of thyroid tissue. The thyroid gland was normal and not involved with the tumor. The pathologist reported it as papillary cystadenoma. She received no subsequent treatment and has had no evidence of recurrence in five and one half years.

Case 4.—F. W., a physician, aged 67, was seen in 1927 because of a tumor in the right side of the neck which had been present for twenty years without change in size. A diagnosis of adenoma of the right lobe of the thyroid was made. At operation outside of the thyroid under the sternomastoid muscle was a large, adherent mass 8 cm. by 5 cm. by 4 cm. (fig. 4) which contained a yellowish, mucoid fluid and was made up of a papillary-like structure. There were many veins scattered over the surface of the tumor. It was removed, following which the right lobe of the thyroid was exposed. A similar body 1 inch (2.5 cm.) in diameter was found in the inferior pole. No connection between the two could be demonstrated. The pathologist reported both as papillary cystadenoma. This patient received no subsequent treatment. Three years after operation there was no evidence of recurrence and no nodules could be palpated in the thyroid gland.

Case 5.—Mrs. B. B., aged 41, was seen in March, 1928. In 1921 a left hemithyroidectomy for exophthalmic goiter had been performed and in 1924 a subtotal thyroidectomy was done because of persisting symptoms. One year previously a small recurrent nodule was removed which was reported as an aberrant thyroid. Eight weeks previous to our examination a lump appeared to the right of the larynx. On examination a nodule 1 cm. in diameter was found in this position. There were clinical evidences of myxedema but the metabolism test was normal. At operation, all the deep cervical chains of lymph glands on the right side were found to be enlarged and firm with the same appearance as the lump previously described (fig. 5). They involved the internal jugular vein, so that in doing a radical dissection the vein was removed. All glands between the clavicle and the angle of the jaw were removed,

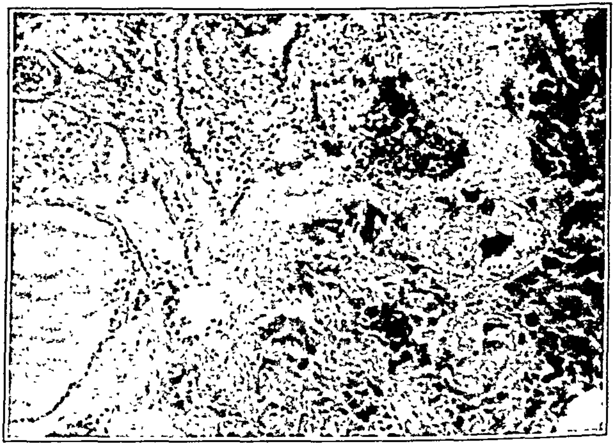

Fig. 11.—Section of aberrant thyroid tissue showing papillary cystadenoma with invasive characteristics. Strands of epithelial cells can be seen invading the stroma. Positive identification as an aberrant thyroid can be made by the presence of colloid in the section.

including some from the occipital triangle. The pathologist reported these glands as showing papillary cystadenoma or multiple aberrant thyroid nodules. He believed that they were definitely malignant. The patient received postoperative roentgen therapy and two years after operation only too small lymph glands are palpable. She has developed mild hypothyroidism.

CASE 6.—Miss F. K., aged 21, came to the clinic in September, 1927, because of enlarged cervical glands. These had been noted six months previously and had gradually increased in size. On examination numerous glands could be palpated in front of, beneath and behind the right sternomastoid muscle (fig. 6). Each was discrete and movable. A diagnosis of Hodgkin's disease was made but biopsy showed papillary cystadenoma or aberrant thyroid. A radical block dissection was then carried out, the internal jugular vein and all palpable glands being removed. It was believed that the glands extended farther beneath the clavicle into the chest. The right lobe of the thyroid was exposed but was not involved. A portion was taken for microscopic section which showed no evidence of a similar structure to that in the glands. She received extensive postoperative roentgen therapy and three years after operation nodules could not be felt in the right side of her neck and her general condition was good. One small nodule could be palpated in the superior pole of the right lobe of the thyroid which was thought to be adenomatous in character. She had a paralysis of the right trapezius muscle.

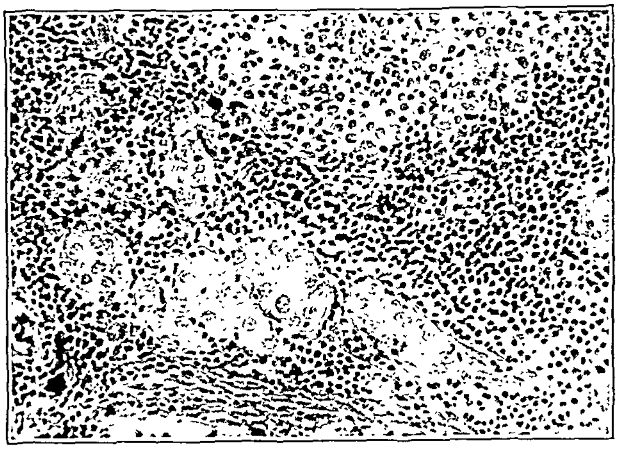

Fig. 12.—Invasion of a lymph gland by papillary adenocarcinoma from an aberrant thyroid. A few mitotic figures can be seen.

CASE 7.—Miss H. B. J., aged 21, seen in April, 1929, stated that a gland had been removed from the left side of her neck eight years previously. Two years before our examination the glands had returned and had slowly increased in size. Two weeks before, a second biopsy was done and was reported as showing hyperplasia of the thyroid tissue. On examination there was a mass of confluent glands varying from 1 to 3 cm. in diameter and extending along the posterior border of the left sternomastoid muscle over its entire extent. A roentgenogram of the chest showed no evidence of metastases. A diagnosis of papillary cystadenoma or aberrant thyroid was made. A radical dissection of the neck was carried out, displacing the sternomastoid laterally; the internal jugular vein and the common carotid artery lay on the surface of some of the glands as well as medial to them. All the glands were excised. They resembled thyroid tissue. The left lobe of the thyroid, while not connected with the gland, contained several firm nodules similar in appearance to the lateral nodule. A left hemithyroidectomy was done. The pathologist reported the thyroid portion as showing papillary cystadenoma. The lymph nodes and lateral masses were also of papillary cystadenoma but were thought to be malignant. She received postoperative roentgen therapy and one year after operation there was no evidence of any swelling in the neck.

CASE 8.—Miss A. V., aged 17, came to the clinic in February, 1930, because of a swollen gland. This had been present for eight years without noticeable change in size. She associated pain and aching in this area with the gland. Examination of the tonsils showed a low grade infection. In the right submaxillary triangle, just behind the angle of the jaw, was a firm, discrete gland which was movable. A diagnosis of chronic tonsillitis and of a tuberculous cervical gland was made. At operation the sternomastoid was found over the mass which was opposite the upper border of the larynx. On exposure it appeared to be thyroid tissue. It lay lateral to the internal jugular vein and common carotid artery but a fibrous band could be demonstrated passing over the vein between the tumor mass and the superior pole. The tumor was removed, together with a portion of the superior pole. Several small lymph nodes in the region of the tumor were removed. The pathologist reported both the portion of thyroid tissue from the superior pole and the tumor mass to be papillary cystadenoma. The lymph nodes around the tumor showed only hyperplasia. One month after operation a small nodule could be felt just above the incision. The patient received postoperative roentgen therapy and one year after operation the small nodule had not changed. There was no evidence of other extensions or of a recurrence.

CASE 9.—Miss R. F., aged 11, came to the clinic in January, 1930, because of lumps in the right side of her neck. These had appeared one and a half years previously. A year before, tonsillectomy had been done without benefit. Nine months previously a biopsy was done and the gland was reported not malignant. Three months before, a second biopsy was done which showed papillary cystadenoma. Previous to our examination she received several roentgen treatments with some decrease in the size of the lumps. All the glands of the right cervical chain were enlarged and varied in size from 1 to 5 cm. in diameter. The thyroid gland could not be palpated separately. A radical dissection was done, removing the internal jugular and all of the glands from the mastoid process to the clavicle below. On the posterior surface of the right lobe of the thyroid was a small cluster of similar tumor masses in the area of the recurrent laryngeal nerve. The entire right lobe and part of the isthmus were removed after isolation and preservation of the recurrent nerve. The pathologist reported this as papillary adenocarcinoma. The patient received postoperative roentgen therapy and one year after operation no glands can be felt and the left lobe of the thyroid appears soft and pliable.

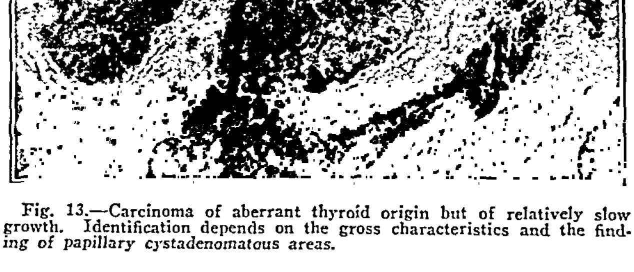

Fig. 13.—Carcinoma of aberrant thyroid origin but of relatively slow growth. Identification depends on the gross characteristics and the finding of papillary cystadenomatous areas.

CASE 10.—L. L. B., a man, aged 52, seen in April, 1930, stated that a lump had appeared above the left clavicle six years previously and had slowly grown in size. It had given no symptoms. At examination there was a large firm tumor 4 inches (10 cm.) in diameter in the left superclavicular region (fig. 7). It appeared regular in outline and did not move when the patient swallowed. The mass was found beneath the sternomastoid muscle and lay lateral to the internal jugular vein. It was cystic in character. No projections were found descending toward the thyroid gland or to the pharynx. The thyroid was normal. The operative diagnosis was branchial cyst. The pathologist reported this as papillary cystadenoma arising in aberrant thyroid tissue. The patient received postoperative roentgen therapy and there is no evidence of recurrence one year after operation.

Case 11.—I. B., a man, aged 32, was examined in June, 1930, because of swellings in the neck. For two years he had noticed a round, nontender swelling in the suprasternal notch. There was a second smaller swelling in the midline under his chin. On examination a cyst 2 by 2 cm. was demonstrated at the level of the hyoid bone in the midline. There was a second swelling 6 by 6 cm. in the suprasternal notch which was freely movable and firm (fig. 8). The diagnosis of thyroglossal cyst and dermoid cyst was made. At operation the upper swelling proved to be a typical thyroglossal cyst, and it was removed with a radical operation. On exposure of the lower mass it was found to be dark blue, coarsely lobulated and cystic. It was located above the sternothyroid and sternohyoid muscles and appeared to have a small pedicle extending below them. The thyroid gland was not involved. There were no other glands. The pathologist reported the upper tumor to be a thyroglossal cyst and the lower one a papillary cystadenoma in an aberrant thyroid. The patient has received postoperative roentgen therapy and has had no recurrence of his thyroglossal cyst. There is no evidence of recurrence in the lower part of his neck one year after operation.

Case 12.—Miss M. F. T. P., aged 48, was examined in July, 1930, because of deafness, sugar in the urine and indigestion. Ten months previously she had noticed a lump in the left side of her neck, and it had increased slightly since that time. On examination she was poorly nourished and there was a fusiform, nontender gland 3 by 2 by 2 cm. beneath the lower attachment of the left sternomastoid muscle (fig. 9). It was thought to be characteristic of the sentinal type of gland associated with carcinoma of the stomach. Roentgen studies of the stomach were negative. At operation the tumor was demonstrated beneath the lower portion of the sternomastoid muscle and beneath the omohyoid and in the area lateral to the common carotid artery and internal jugular vein. It was kidney shaped with a definite hilus, was reddish brown, and had superficial blood vessels and lobulation which suggested thyroid tissue. No other glands could be demonstrated. The thyroid gland was normal. The pathologist reported this as papillary cystadenoma. She received postoperative roentgen therapy and ten months after operation there was no evidence of recurrence.

Case 13.—Mrs. T. C., aged 30, came to the clinic in January, 1931, because of a goiter. She had noticed this swelling two years previously following her last pregnancy. For one year she had noticed increasing nervousness and irritability. There had been no loss of weight and no palpitation nor tachycardia. Her physical examination was essentially negative except for varicose veins and the local condition in her neck. There was a firm, regular mass beneath the insertion of the left sternomastoid muscle on the clavicle. A second nodule could be palpated in the upper pole of the left lobe of the thyroid. The right lobe felt normal. A preliminary diagnosis of metastatic carcinoma was made and a fluoroscopy of the stomach done to rule out this site as the primary origin of the tumor. This showed no evidence of disease. The subsequent preoperative diagnosis was aberrant thyroid. There was insufficient evidence for a diagnosis of hyperthyroidism. At operation the lower tumor was found behind and lateral to the internal jugular vein. In addition to the previously palpated mass, many of the deep cervical lymph glands were found enlarged by the same type of tumor. On exposure they had a deep, blackish tint and were smooth in outline. The glands were removed by a radical block dissection of the left side of the neck, the internal jugular vein being removed. Following this, the tumor was removed from the upper pole of the left lobe of the thyroid. The right lobe was normal. The nodule in the thyroid appeared to have the same characteristics as those of the lateral cervical tumors. The pathologist found the thyroid nodule to be malignant, papillary cystadenoma and reported the same type of structure in all the lymph nodes. There was invasion of the blood vessels in these nodules. This last operation was performed four months ago and she is at present receiving roentgen therapy.

605 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

Dr. C. A. Roeder, Omaha: When a ligature is placed on the superior thyroid artery, there often is an impulse shooting up the sympathetic plexus to the superior cervical ganglion, which is connected with the first, even the second spinal nerve. From here there is a spill-over into the sensory root of the trigeminal, producing pain in the lower teeth. That might be called a thyromandibular reflex. This is of some importance because the pain occassionally may persist for several weeks. The vagopinna reflex is of extreme importance because it indicates that the internal branch of the superior laryngeal nerve is involved in a ligature or clamp. This reflex passes into the ganglion of the trunk of the vagus and on through Arnold's nerve, and ends in Alderman's nerve, producing pain in the lower portion of the pinna, which may persist for several weeks. Traction alone on the superior pole will often produce this reflex. In regard to cases of toxic thyroidism without an increase in metabolic rate, this slide shows a man who had a progressive exophthalmos for one year without any signs of toxic thyroidism. In the meantime, his right orbit was explored by an eye surgeon in search of an orbital tumor. After the condition had been present for one year, the other eye started to protrude and at this time he came into the dispensary, complaining of weakness of only a few weeks' duration. He might have been in the so-called neurocirculatory asthenic state, but he continued his occupation as a truck driver and did not complain of anything during the first year. A girl who had a progressive exophthalmos for eight months or so beforehand, with a negative metabolic rate and no signs of hyperthyroidism or hypermetabolism, the condition being present for six or eight months, now has the other eye protruding. The thyroid is slowly enlarging. The metabolic rate is practically normal, close to zero. Too much reliance must not be placed on one metabolic reading. The average metabolic test in the average hands is of uncertain value and hypermetabolism, hyperthyroidism and toxic thyroidism should not be considered synonymous. In regard to aberrant thyroid, I have never had a case in my experience and naturally cannot say anything about it. This presentation has been most instructive.

Dr. William Barclay Parsons, Jr., New York: I have refused to operate on a number of patients whose symptoms, although closely simulating hyperthyroidism, seemed to be on a basis of psychoneurosis, but who showed a definite preference for hot rather than for cold weather. This is of course not a definite diagnostic point but is often extremely suggestive and may help in reaching a definite diagnosis, as thyroid surgery is not particularly satisfactory in psychoneurotic patients. The evaluation of results in hyperthyroidism, involving as it does individuals of a high degree of nervous organization, is an extremely difficult thing. The vast majority of results that one sees in the literature have been based, unfortunately, on letter reports. Of course in many instances that is all that one can get; but the personal return visit gives one the only accurate idea of what has happened in these cases. In looking over the reports of some cases recently, I was interested to find that a fairly large percentage showed a gradual improvement continuing over a period of time. In about 200 patients, 74 per cent were satisfactory at six months; by one year there were 80 per cent; and at two and three years, this figure had increased to 82 and 89 per cent, the term "satisfactory" being used only for patients with a normal metabolic rate and pulse and a complete return to economic activity. Individuals of age, of long duration of symptoms, with definite cardiac involvement, congestive heart failure, or whatever condition happens to present itself, in my opinion certainly require the graded operations to give them the greatest possible safety. The whole question of malignancy of the thyroid comes into the discussion of tumors of aberrant thyroids. Malignancy of the thyroid is, of course, extremely difficult to diagnose, even microscopically, as there is a large group of borderline cases in which pathologists of considerable experience will not agree on the diagnosis. The removal of adenomas of the thyroid before they have undergone malignant transformation has saved many individuals from carcinoma, and presumably the same holds true with the similar tumors in the aberrant thyroid tissue.

Dr. Frank H. Lahey, Boston: It is a confusing situation to any one who has not had previous experience to find dark discolored tumors in the neck and not to realize that they are aberrant thyroids. They are even as dark, sometimes, as the melanotic sarcomas. It is well to realize that this type of aberrant thyroid which occurs up and down the internal jugular, is often the forerunner of a malignant tumor. It probably explains, as well as the branchial remnants, the origin of primary carcinoma in the neck, and indicates definitely the need of the removal of this type of tumor. I have repeatedly made this statement, that, when one fails to cure patients by operation for hyperthyroidism, either the patients did not have hyperthyroidism in the beginning or not enough thyroid tissue was removed. There is a group of patients in whom a condition exists which simulates thyroid disease and concerning which our medical department has been warning us of late. These are the patients with hypertension. The patient with hypertension has stare and frequently a little exophthalmos; he often has tachycardia and myasthenia and he has a slightly elevated basal metabolism. It is very easy, if he has a goiter, to operate on him under the diagnosis of hyperthyroidism. Therefore, all patients who are borderline patients without striking clinical evidence of hyperthyroidism and who have hypertension should be under suspicion that their symptoms are due to hypertension and not to hyperthyroidism. The same thing is true of neurotic patients, whatever the origin of their condition may be. All patients who lack frank clinical evidences of hyperthyroidism should be under suspicion that they are not patients suffering from hyperthyroidism, and those are the patients in whom basal metabolism determinations should be made repeatedly, and who should have established whether their metabolism remains persistently elevated day after day or tends toward normal. Certainly if one would maintain in a thyroid clinic a series of good results, one must be highly critical of the patients who lack striking clinical evidence of the disease. As to how much thyroid tissue to remove, when a man talks about removing four fifths of the thyroid or five sixths of it, it means that he has not had enough experience in thyroid surgery. There is no fixed rule about how much to remove. One should leave a good deal of thyroid tissue in young children because they need their thyroid tissue for development and they mustn't get myxedema. One should leave a good deal of thyroid tissue in elderly people because old age is related to a slowing up of the activity of the thyroid. Of all the patients who have exophthalmic goiter of the hyperplastic type, in about 90 per cent or a little more the gland will involute with iodine in the form of compound solution of iodine given preoperatively. If one does radical removals in this group in which the gland has involuted well, one will have a high percentage of myxedema. In the remaining 10 per cent in whom the gland does not involute, if one does not do radical removals one will have a high percentage of persistent hyperthyroidism. All this question of hyperthyroidism is based on experience with trial and error. Hyperthyroidism is a disease associated with intangible nervous symptoms. The borderline cases are susceptible of many errors. Therefore, the physician must have in mind always that the burden of proof of conditions due to hyperthyroidism in borderline cases is on himself, and when in doubt he should not operate on these patients on suspicion. They must show definite clinical evidence or persistently elevated basal metabolism rates. When they show that, when one does radical operations on the uninvoluted thyroids and conservative operations on the involuted kind, then one will get good results and one will not have these annoying neurotic patients returning repeatedly and complaining that they are not well postoperatively.

Dr. R. S. Dinsmore, Cleveland: I have found that if a patient comes into the hospital and the pulse curve drops to normal over night, the case is not likely to be one of hyperthyroidism. The typical hyperthyroid patient will have an afebrile tachycardia which will gradually come down to a base line. It is well to remember in a case of acute hyperthyroidism and delirium that, if the delirium has lasted over a period of seventy-two hours, a fairly large percentage of these patients will die in spite of all therapy. I have made it a rule never to operate on a patient who has had a recent psychosis or delirium, but to wait for at least three or four weeks.

Dr. Michael G. Wohl, Philadelphia: Among embryonal tumors of the neck, aberrant thyroid is the most uncommon and is least often diagnosed. Aberrant thyroid usually implies a tumor that is found along the path of embryologic development of the thyroid. This excludes thyroid tissue found in the pleura, abdominal cavity or bone. This is a striking anomaly of pathologic thyroids, especially when a single colloid goiter may be harmless for years and give rise to metastases. In 1917, I was able to collect from the literature reports of twenty cases of tumors of the lateral aberrant thyroid, and I added one case of my own. Billings and Paul since then have reported an additional case and have brought the total number up to thirty-four. The patient whom I had under observation was a girl, aged 19, with a small lump on the right side of the neck, of two years' duration. It was located on a level with the hyoid cartilage beneath the anterior edge of the right sternocleidomastoid muscle. It consisted at operation of five nodules, varying in size from that of a pea to that of a pecan. The microscopic diagnosis was adenocarcinoma. The patient was operated on, the tumor removed, and she was symptom free for two years, after which she was lost to observation. From a theoretical point of view, the occurrence of these tumors in misplaced thyroid tissue emphasizes the frequency with which embryonal tissue is capable of proliferation. The answer, however, is not furnished as to why in one case it proliferates to form a benign adenoma and in another instance a rapidly growing carcinoma. It is worth emphasizing that in most instances of pathologic changes of the lateral thyroid, the thyroid gland proper is healthy and remains free from involvement, except in the case mentioned by Dr. Cattell, in which he said that there was an exophthalmic hyperplastic proliferation in disease of the main thyroid. It is also important to bear in mind that in finding carcinoma in the lateral aspect of the neck, one should rule out the possibility of its being metastatic of the thyroid itself. Although lateral aberrant thyroid is rare, it must be taken into consideration in the differential diagnosis of tumors of the neck. Dr. Cattell is to be congratulated for having the largest single collection of any one of whom I know. I am glad to hear him state that he was able to make a preoperative diagnosis. In making a diagnosis of a lateral aberrant thyroid, one must consider other conditions, as Hodgkin's disease, lymphosarcoma or some other condition of the lymph node.

Dr. M. S. Muskat, Cincinnati: The basal metabolic rate can be specific of hyperthyroidism if properly and carefully executed. Tests must be performed on at least two different days before one issues a report. There are two points that may help to establish a diagnosis. In the first place, many patients come to the physician after already having taken iodine in one form or another, and unless a specific question and investigation is made one may not determine that. The patient will give a history of nervousness, loss of weight, tachycardia, and so on, but he may have had iodine recently; if following the recent ingestion of iodine, a basal metabolic test is made, the rate may be normal or even subnormal, even though it originally had been plus 15 or plus 20. Perhaps after the patient has taken iodine for only a week, the basal metabolic rate is within so-called normal limits or on the normal side. It is important to find out whether the patient has had iodine. In the borderline, doubtful cases, there is another agent that may sometimes be of value. After the patient has had bed rest, bromides, phenobarbital or some other sedative drug, or has been given digitalis to determine whether there is some heart condition, then one should give iodine as a definite therapeutic test, anywhere from three days to two weeks, and should check the patient's basal metabolism rate during that time. The basal pulse rate also should be watched as well as the pulse pressure relationship, and that may give one an additional aid to prove or disprove the presence of hyperthyroidism. There are many patients who have a basal metabolism rate of minus 15 or minus 20 or even more, who are apparently normal. At least it is conceivable that these persons may get hyperthyroidism and their basal metabolism rate may be found to be plus 5 or plus 10 or plus 15, which is considered normal but for them it may be a plus 20 or plus 30 elevation. So I think that here again there must be a definite iodine therapeutic test, checked by the basal metabolism rate, which may be of value in ruling out such cases. I have observed definite cases in which the patients have been benefited by such management.

SUPRAPUBIC PROSTATECTOMY WITH CLOSURE OF THE BLADDER*

ALEXANDER HAMILTON PEACOCK, M.D.
SEATTLE

[Editorial Note.—This paper, together with the paper of Dr. Edwin Davis and the discussion, concludes the symposium on prostatectomy. The papers of Drs. Lowsley and Kirwin and Dr. T. M. Davis were published last week.]

The primary object of prostatectomy in benign hypertrophy is to remove the obstructing adenomatous gland and to reestablish free urethral drainage with the least shock and the lowest mortality.

Before these operations are started a complete study of the patient with days or weeks of preparation is necessary with functional tests, urographic studies, the cardiac estimations, and getting the gastro-intestinal tract into good functional condition. This phase of prostatectomy, its preparation, is the foundation for the tremendously lower mortality over that of twenty-five years ago.

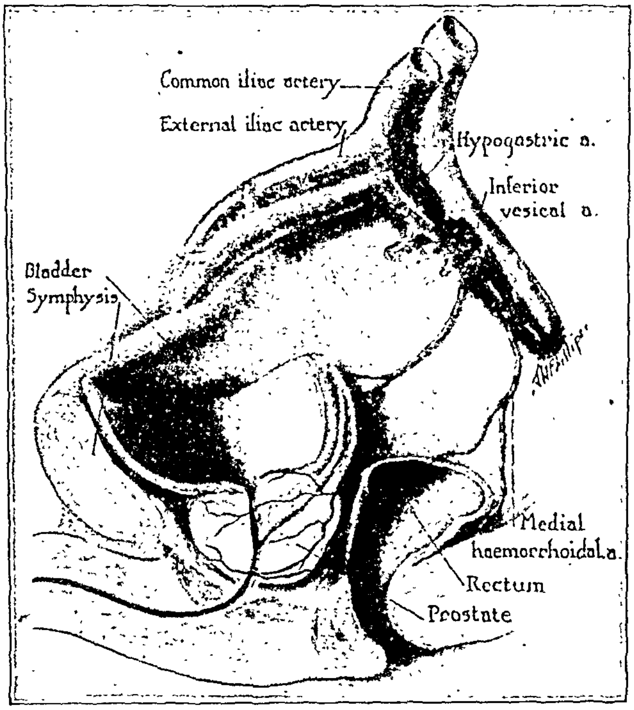

Fig. 1.—Sagittal section of the prostate gland, showing its chief blood supply.

And with each year have come refinements in surgical technic which have been instrumental in producing better functional results, reducing complications, making convalescence more comfortable and operations safer. In the past five years two advances have been made in suprapubic surgery of the prostate; namely, hemostasis of the prostatic cavity by suture, and closure of the urinary bladder. The surgeons who have made these contributions are Thomson-Walker, Deaver, Lower, Judd and Harris.

It is my object in this paper to show that this operation of suture and closure is not unusually difficult, that special instruments are not necessary, and that the technic is surgically correct. The most gratifying result of suturing of the capsule is the immediate control of bleeding. The chief blood supply of the prostate is furnished by the inferior vesicle and the medial branch of the hemorrhoidal arteries. These vessels enter the prostate laterally near the base of the trigon and below the ureteral orifices. Once in the capsule they curve around the prostate and become almost submucous. This accounts for hemorrhages that not infrequently accompany prostatic hypertrophy.

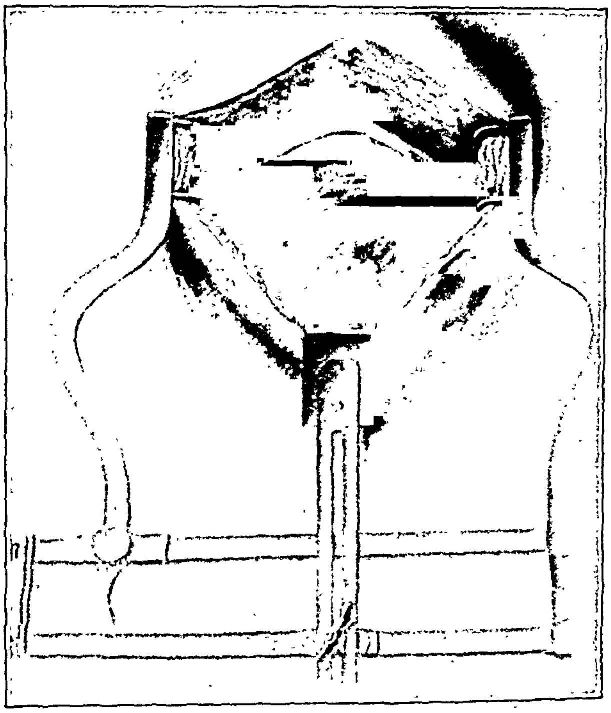

Fig. 9.—Peacock self retaining bladder retractor in position.

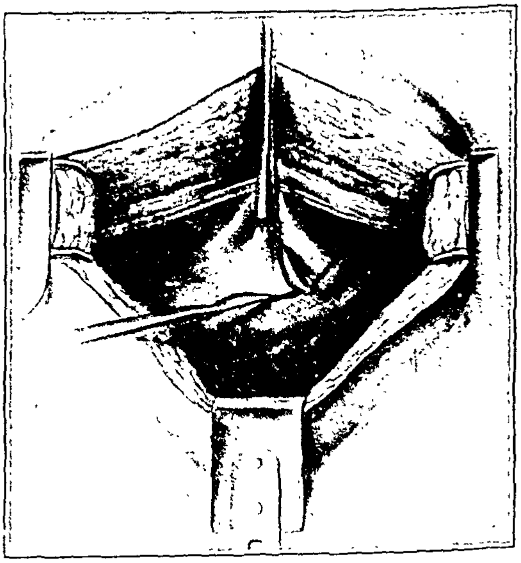

Fig. 10.—The prostate held with a tenaculum and the mucous membrane incised. A catheter marks the internal urethral orifice.

In order to close the bladder, two conditions must be obtained: first, complete hemostasis and, second, unobstructed urethral drainage. How have these conditions been brought about?

---

* Read before the Section on Urology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

* Because of lack of space, this article is abbreviated here by the omission of several illustrations. The complete article appears in the Transactions of the Section and in the author's reprints.

The enucleation of the hypertrophied prostate can be accomplished by separating the gland in toto or into its several parts by means of the fingers or instruments. Some surgeons, as Judd, grasp the prostate with a tenaculum and with a knife or scissors cut the mucous membrane overlying the central lobe; while others tear through the internal urethral orifice, find the capsule and gradually work the prostate free. After the gland has been lifted out of its capsular bed, a cavity is left with ragged edges. This cavity is outlined by a rim which consists of mucous membrane of irregular thickness and is usually torn laterally in several places.

The early method of controlling bleeding from this cavity was packing it for a few minutes, and then depending on the normal contraction of the prostatic capsule, plus clotting. Packing the capsule with strips of gauze was next in order; then rubber bags inflated with air or water of the Pilcher or Hagner type were employed to compress the edges of the capsule against the prostatic bed. At times pressure from bags or gauze fails completely to control bleeding. These agents at times hold the edges of the capsule apart and thus interfere with its normal shrinkage.

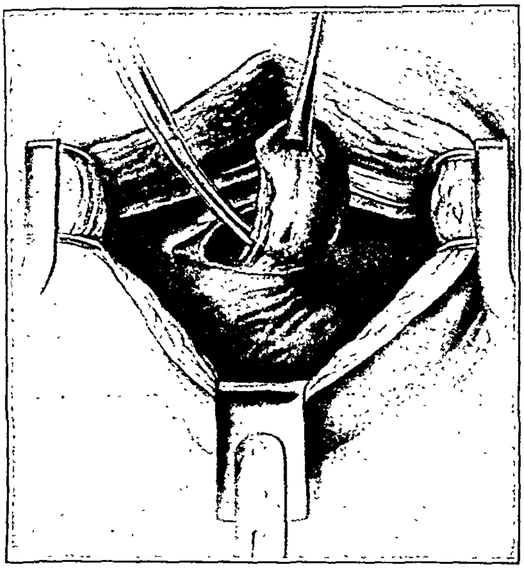

Fig. 11.—Removing a fibroma with scissors.

The next improvement was to bring forward an edge of the capsule and suture it to the end of the severed urethra. The first published article on this step was by Deaver.[1] A few months later S. Harry Harris[2] of Sidney, Australia, gave his technic in the *Medical Journal of Australia*. The various methods of suturing the capsule in their order of publication are as follows:

1. Deaver[1] has an assistant insert a finger in the rectum and push up the prostatic floor. The edges of the capsule are grasped and sutures are made radially to the severed urethra. A soft rubber catheter in the urethra and a suprapubic drainage tube complete the operation. The latter tube is removed when the urine clarifies. Healing is reported in from ten to fifteen days.

2. Lower[3] for years has closed the urinary bladder after operations for calculus and tumor. He handles the prostatic cavity by placing a catheter in the urethra. He places one transverse suture through the edges of the capsule below and three above it. These sutures consist of a thread with a small curved needle on each end; one needle starts at the median line and makes a dot and dash through the prostatic bed to the right, while the other is similarly placed on the left.

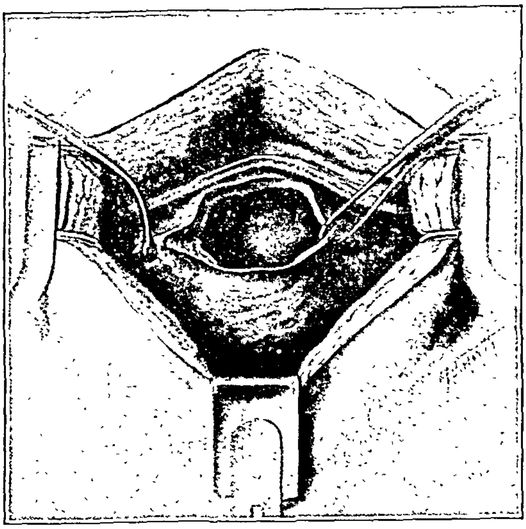

Fig. 12.—The prostate has been enucleated, leaving a cuplike cavity. The edges of the capsule are held with a tenaculum.

3. Judd[4] has popularized the open method of prostatectomy, making a long incision, and wide retraction of the bladder. The prostate is held with a tenaculum and largely enucleated with the aid of instruments. Interrupted chromic sutures are placed in the edge of the capsule. After insertion of a catheter in the urethra, the bladder is closed with a running suture.

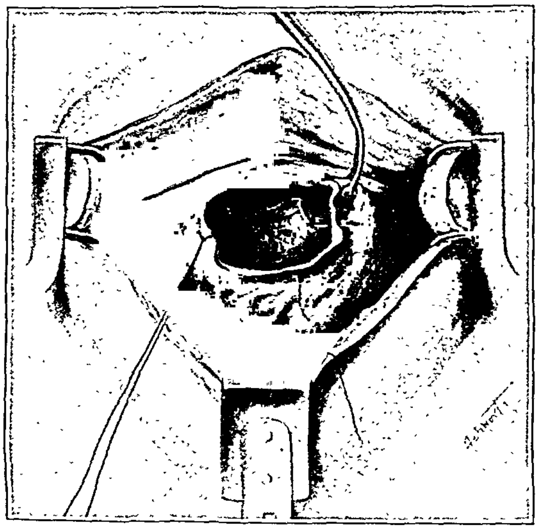

Fig. 13.—Suturing the prostatic bed and capsule.

4. Harris[5] first inserts two lateral sutures in the edge of the capsule. He next puts a suture in the median capsule edge through the floor to the end of the urethra. When tied, this draws a tongued shaped piece of capsule forward. Harris stresses this bringing of the

capsule to the urethra. This part of the operation is not always practical, as the distal portion of the urethra retracts well forward under the pubic arch. The major portion of the prostatic capsule, however, can be tacked down to its new floor and early epithelization of the new urethra is accomplished. Now two transverse sutures are placed anteriorly through the capsule and a catheter is slipped through the urethra. A suture is run through the eye of the catheter and brought up through the abdominal wound. The bladder is now sutured and the incision of the abdominal wall is closed without drainage. Harris depends on Young's boomerang needle and holder to place his prostatic sutures. He also uses a retractor, the blades of which are equipped with electric lights. He reported excellent results in a series of 118 cases at the Pan Pacific Surgical Conference in Honolulu, T. H., in August, 1929.

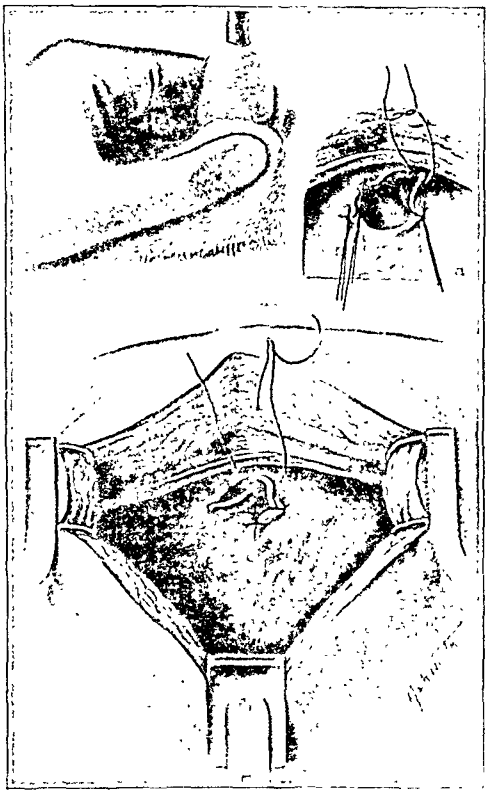

Fig. 14.—Sutures in prostatic capsule reconstructing internal urethral orifice; metal sound in urethra as a guide.

5. All will agree that no operation can be standardized. Wide variations in anatomy, pathology and the condition of the individual tissues call on the ingenuity, experience and judgment of the surgeon. Good exposure is possible in one operating field and very poor in the next. So, in treating the capsule after prostatectomy, different methods of suturing will be necessary from time to time. I have used the Harris technic with some modification in fifty patients, none of whom experienced secondary bleeding.

It has been found that illuminated retractors are not essential to good vision of the prostatic bed. Spinal anesthesia produces a degree of relaxation of the abdominal muscles impossible with any other type of anesthesia. I have modified the self retaining Balfour abdominal retractor by putting on 4 inch L shaped wire blades, which allows the blades to slip under the pubic arch and separate widely the walls of the bladder. It gives a most excellent exposure of the entire bladder. The Young boomerang needle and holder seems almost indispensable in some cases, while in many others an ordinary long needle holder and short curved needle perform just as well or better.

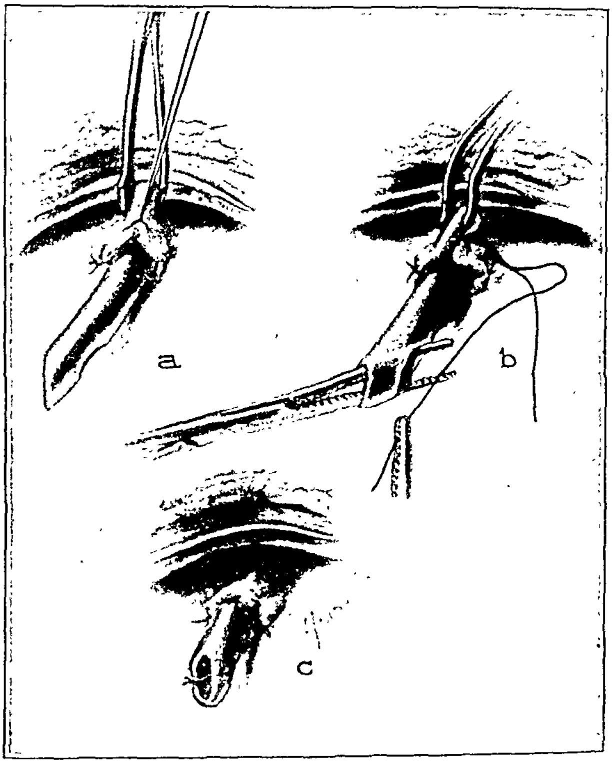

Fig. 15.—Securing the vesical end of an indwelling whistle tip catheter: *a*, one of the prostatic capsule sutures is used for an anchor; *b*, pulling the suture through the eye; *c*, suture tied.

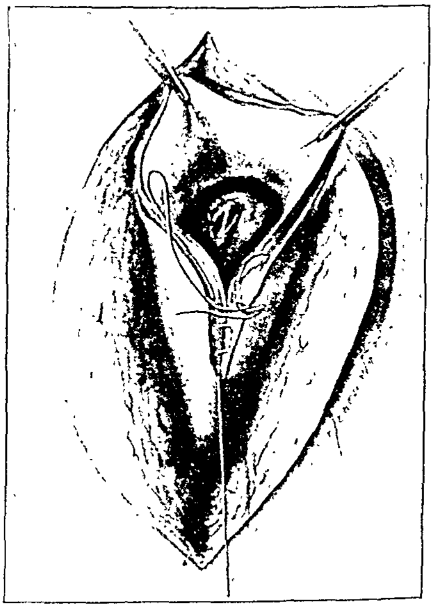

Fig. 16.—Closing the bladder with two layers of Lembert suture.

A number 26 or 28 French whistle tipped catheter gives the best drainage. To anchor it one of the prostatic sutures is used, the ends being passed through the eye of the catheter. As these are of plain catgut, the catheter can be pulled out after three or four days and a smaller one inserted in its place. The bladder is best closed with a double row of Lembert sutures. No drainage of any kind is employed.

RESULTS

The operation in the majority of these fifty cases was done in two stages from seven days to five months apart. The average interval was two weeks. Wounds seemed to heal as well after the second stage of the operation as they did at the first.

The average time for the indwelling catheter was ten days. The incidence of epididymitis was much less with the use of the catheter than without it. This is probably due to much better drainage of the bladder.

The incidence of wound leakage was small. When it did occur, it was very slight and usually indicated an obstructed catheter. The comfort of the patient, the freedom from wet dressings, and the saving in gauze and cotton was considerable.

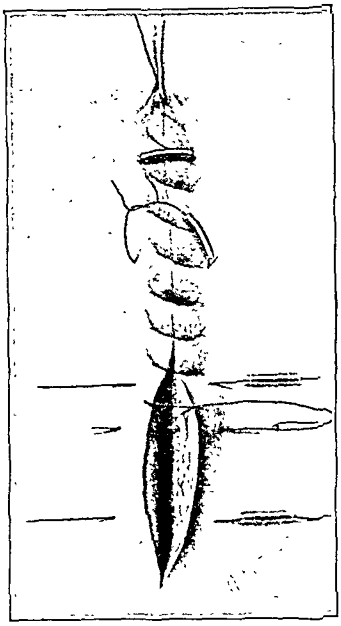

Fig. 17. The skin incision is repaired with interrupted silkworm and dermal sutures, without drainage.

The average time when normal voiding became established was twelve days.

SUMMARY

1. The success of primary closure of the urinary bladder depends on perfect hemostasis of the prostatic bed and good drainage by catheter.
2. Suture of the capsule is surgically correct and can be performed by ordinary surgical skill and instruments.
3. Primary closure of the bladder affords a shorter and more comfortable convalescence.
4. Suture of the prostatic capsule produces better anatomic and functional results.
5. With this method, postoperative bleeding has been practically eliminated.
6. The sloughing postoperative wound is a thing of the past.
7. Objections raised to closure of the bladder can be refuted by the good results of those surgeons now employing the closed method of suprapubic prostatectomy.

1215 Fourth Avenue.

Monsters.—Malformed fetuses have been produced by subjecting the embryo to certain chemicals. Potassium arrests the development of the heart, and sodium produces spina bifida. Scammon wrote that it has been shown that embryonic duplications of all grades and degrees may be produced in certain vertebrate embryos by changes in temperature, by subjection to the x-rays and ultraviolet rays, by pressure, by mechanical separation, by changes in the salt concentration and oxygen content of the surrounding medium, and by a number of other experimental procedures.—Reid, W. D.: The Causation and Prevention of Congenital Heart Disease, *Arch. Int. Med.* 48:721 (Nov.) 1931.

SACRAL BLOCK ANESTHESIA IN PERINEAL PROSTATECTOMY

ITS INFALLIBILITY WHEN ACCURATELY ADMINISTERED *

EDWIN DAVIS, M.D.
OMAHA

It is my purpose in this brief presentation of facts and figures to attempt to justify the title, to the end that sacral block anesthesia in prostatectomy may receive wider recognition, in place of spinal anesthesia and the various forms of general anesthesia, none of which are so free from hazard.

The term sacral block anesthesia, as here employed, refers to the injection of the sacral canal through the sacral hiatus (caudal anesthesia) and, in addition, the injection of the first, second and third posterior sacral foramina on either side. In the total series of 378 cases here reported, each patient received 40 cc. of freshly sterilized solution of procaine hydrochloride 1 per cent through the sacral hiatus, and 10, 8 and 5 cc., respectively, through the first, second and third sacral foramen, on each side. This amount has been employed because it has been found to serve the purpose satisfactorily and without causing any reaction of consequence. Perhaps less would suffice. Details of technic have been purposely omitted since this subject has been covered elsewhere, by a number of authors; more recently and in a complete and detailed manner by Lundy.[1] In no instance in the entire series has any other drug been added to the routine solution of plain, freshly sterilized 1 per cent procaine hydrochloride.

CONFLICTING OPINIONS IN LITERATURE

An excellent historical summary, dealing with the development of sacral block anesthesia, has recently been published by Bumpus.[2] This, there could be no purpose in duplicating. In the present article I shall make a minimum number of quotations from the literature, sufficient to illustrate certain points. With respect to the efficiency of sacral anesthesia, the outstanding impressions which one has after a detailed review of the literature, are as follows:

1. The opinion is widely prevalent that sacral block anesthesia has a certain inevitable proportion of failure (averaging about 15 per cent).

2. There is a surprising discrepancy in opinion on this subject which may be explained, in part, as the result of a confusion in terms between caudal anesthesia and complete sacral block.

3. In general, those reporting excellent results, with a negligible percentage of failure, are those who have had a wide experience with this method of anesthesia.

Illustrating the proportion of failure to anesthetize by the caudal method are the figures from the Brady Clinic published by Berry,[3] who reported 16 per cent failure in 165 consecutive cases, 140 of which were prostatectomies. Shaw[4] had previously reported (also from the clinic of Dr. Hugh Young) 17 per cent of failure in 100 consecutive cases. These figures, however, do not accurately represent the results obtained by the sacral block method, since in each of these series the anesthesia consisted merely of a single injection through the sacral hiatus (caudal anesthesia), using a small volume of a concentrated solution (20 cc. of 3 per cent solution of procaine hydrochloride). Scholl's [5] paper, published in 1921, reported 10 failures in 150 cystoscopic manipulations, and included the statement that "most writers report a fairly high percentage of failure." Bransford Lewis, in discussing Scholl's paper, estimated his own failures at 15 per cent. In their original publication on the use of caudal anesthesia, in 1916, Lewis and Bartels [6] reported 13 prostatectomies with 3 failures and 68 cystoscopic manipulations with 22 failures. Lynch [7] (1918) reported 80 rectal cases with 16 failures, and Brenner [8] 12 failures out of 120, most of which were rectal cases. The latter author included the statement that "all observers report some percentage of failure." In keeping with these opinions is the statement of Labat,[9] with respect to the simple caudal injection, that, although the percentage of failure may be reduced, "it is obvious that there are failures which are unavoidable and uncontrollable, to which no remedy will ever be brought." Labat, however, makes a sharp distinction between caudal anesthesia and sacral block and states that the latter procedure "never fails to produce the desired result."

[4] Shaw, E. C.: Epidural Anesthesia for Perineal Prostatectomy, J. Urol. 15:219 (March) 1926.

Of interest by way of illustrating the discrepancies in the opinion on this subject are the statements by Babcock [10] and by Harris [11] in consecutive chapters of the same volume of Oxford surgery. Estimating the efficiency of "high sacral anesthesia" at only 45 per cent, Babcock adds that "it is evident that it [sacral anesthesia] has such limitations that only very devoted enthusiasts will have the patience to continue its use," while Harris considers that "blocking of the sacral plexus by intrasacral injection is one of the most satisfactory procedures in the field of local anesthesia." They cannot both be right. It is likely, however, that these contradictory opinions may be partially explained on a terminology basis.

It may be judged from the foregoing that the general impression concerning the unreliability of the sacral method may be largely due to the published results following the use of the simple caudal injection, rather than the complete sacral block. Lundy's [12] report (1927), including 318 cases of suprapubic prostatectomy, in which the sacral block method (together with infiltration of the anterior abdominal wall) was employed, shows the excellent results which may be obtained by this method. In this series, 96.5 per cent were successful, in 1.7 per cent supplementary general anesthesia was necessary, while in an additional 1.7 per cent Lundy considers that general anesthesia should have been used. Lowsley [13] has expressed the opinion that the sacral block method gives perfect anesthesia for perineal prostatectomy in 95 per cent of cases. Meeker and Scholl,[14] in 1924, reported a series of 1,817 cases of sacral block anesthesia with 5.33 per cent failure. Of these, 270 were for prostatectomy, with 5.92 per cent failure. The report of Widenhorn,[15] published in 1929, includes 115 cases of prostatectomy, with six anesthesia failures.

PERSONAL EXPERIENCE WITH SACRAL BLOCK ANESTHESIA

My own former impression relative to the efficiency of the sacral block method may be best expressed by the following quotation from a paper I [16] read in 1924:

> There occurs a certain small but constant percentage of failure to obtain complete anesthesia. This percentage decreases as technic improves, yet this fact constitutes probably the most serious objection to sacral anesthesia. There are several factors tending toward poor or indifferent anesthesia, which may be eliminated by careful technic. Certain cases of failure are due to the fact that the operator has not succeeded in introducing the needle through the hiatus and into the lumen of the sacral canal. It is even possible to make the mistake of giving the injection into the subcutaneous tissues dorsal to the sacrum.

This paper included a series of thirty consecutive cases of perineal prostatectomy with seven anesthesia failures, or 23 per cent. At that time a certain percentage of failure was regarded as inevitable, even with the complete block method. In addition to faulty technic, various explanations were offered by different observers. These included (1) anatomic variations, preventing the introduction of the needles; (2) physiologic variations, such as an "immunity" to procaine hydrochloride; (3) decreased permeability of the neural sheaths; (4) increased capacity of the bony canal of the sacrum; (5) failure to use a sufficiently concentrated solution, and (6) an increased amount of fibrous and fatty tissue in the sacral canal, preventing intimate contact between the procaine hydrochloride and the nerve trunks. The real and only reason for these failures, however, is failure to place the needles accurately and unquestionably in the lumen of the canal and of the foramina. This statement is borne out by the figures cited hereafter.

The series here presented consists of 378 consecutive cases of perineal prostatectomy, similarly handled. Each patient, without exception, received sacral block anesthesia, consisting of a caudal injection, and injection of the first, second and third posterior sacral foramina, as already outlined. As indicated in table 1, the percentage of anesthesia failure, which was very high early in the series (20 per cent in the first twenty-five cases), has shown a gradual decrease during the first hundred cases, and has now come to be nil. The total number of failures in the first 100 cases was 12, of which 9 occurred during the first 50. Since the first 100 cases there has been one failure only (case 149), and, following this, there have been 229 consecutive cases without a failure, in a series which is as yet uninterrupted.

As here employed, the term "sacral anesthesia failure" means that supplementary inhalation anesthesia was necessary. Every case in which nitrous oxide or ether was employed has been counted, whether used throughout the operation or whether "only a few whiffs" were given, and whether the general anesthesia was necessary because of actual pain or merely for "psychic" reasons. During the 365 operations in which the anesthesia was considered successful there was neither an ether mask nor a nitrous oxide apparatus in the room. There is therefore no occasion for classifying these anesthesias as successful and "fairly successful." Each anesthesia was a complete success or a complete failure, as determined by whether or not the operation was completed without supplementing inhalation anesthesia.

The feature of practical interest is the gradual decrease in the percentage of failure during the first hundred of the series. In all cases the same operation was performed and the same position on the table was employed. Also the same amount of the same drug in the same concentration was used, as well as the same type of needle and, as nearly as it was humanly possible to determine, the same technic of injection. That is to say, there has been no deliberate modification of technic. The same anesthetist has performed the injections in all cases. Therefore, since all these controllable factors have been constant, the only permissible conclusion is that success or failure is wholly dependent on whether or not the needles have been accurately placed within the caudal canal and the sacral foramina, and on no other factor. There is therefore no occasion for further reference to the percentage of inexplicable failure with sacral block anesthesia. If the anesthetist searches, and continues to search, for the foramina until he finds them and knows that he has found them, the anesthesia will be successful. The percentage of success is therefore a matter of practice and perseverance.

TABLE 1.—*Failures in Sacral Block Anesthesia in Perineal Prostatectomy**

	Failures	
Analysis of First 100 Cases:	Number	Percentage
First 25 cases	5	20
Second 25 cases	4	16
Third 25 cases	2	8
Fourth 25 cases	1	4
Total first 100 cases	12	12
Analysis of Total Series of 378 Cases:		
First 100 cases	12	12
Second 100 cases	1	1
Third 100 cases	0	0
Last 78 cases	0	0
Total 378 cases	13	3.4

Total number of failures in last 278 cases	1 (0.35 per cent)
Total number of failures in last 229 cases	0
Time necessary for complete block:	
Average	12½ minutes
Maximum	30 minutes
Minimum	4½ minutes

* Identical technic in all cases.

OBJECTIONS AND CONTRAINDICATIONS TO SACRAL BLOCK ANESTHESIA

It may be stated without reservation that the generally accepted opinion is that sacral block anesthesia is free from risk, as far as immediate mortality and remote complications are concerned. Furthermore, this statement with reference to freedom from risk applies not only to series reported by those who have had an extensive experience with the sacral block method but also to results obtained by those who employ this method only occasionally. I believe that no one who is informed would object to sacral anesthesia on a hazard basis. Including the series here presented and the total number of simple caudal injections given for various cystoscopic manipulations, my associate, Dr. C. A. Owens, and I have employed this method in well over 1,000 cases, without a fatality, and without a reaction of serious consequence. A discussion of the risk of sacral anesthesia is not complete without mention of the remote possibility of puncture of the dural sac or puncture of a blood vessel. The dural sac terminates at the level of the second sacral segment, so that puncture by a straight needle, introduced through the caudal hiatus, is a mechanical impossibility in the normal case. In order to be safe in cases presenting possible anatomic variations, however, the routine of aspiration before injection should be employed in each instance. I have seen tapping of the dural sac occur once in well over a thousand cases. The same precaution (preliminary aspiration) should be employed with the needle in each foramen, to exclude the possibility of intravenous injection.

The chief objection to the sacral block method is its supposed inefficiency and unreliability. There is no doubt that this objection to sacral anesthesia applies in certain other forms of pelvic surgery, particularly in those procedures involving traction on intraperitoneal organs. Employed in perineal prostatectomy, however, it may be demonstrated beyond question that sacral block anesthesia is wholly and entirely dependable, and that opinions to the contrary are erroneous, and based on too limited experience. Table 1 would seem to establish positively the fact that anesthesia failures (in this particular operation) are dependent on inaccurate technic rather than on some defect inherent in the method itself.

Another objection, from the point of view of the busy surgeon, is that too much time and trouble is supposed to be involved in making the injections into the caudal canal and the foramina (seven injections in all). There are two answers to this objection. In the first place, in whatever field of surgery the occasion for a decision between procedures or methods arises, the method of choice must be that which is safest and most efficient, regardless of the time and effort necessary. Secondly, the impression that the sacral block method is time consuming is erroneous. As determined by accurate records in forty consecutive cases, the average time necessary for making the complete block of seven injections is twelve and a half minutes. This is approximately the time necessary for the induction of ether anesthesia. The maximum time in an unusually difficult case was thirty minutes, and the minimum four and three-quarter minutes.

There is also the generally accepted opinion that there is the occasional individual whose mental make-up is such as to prevent the successful use of local anesthesia, for "psychic" reasons. It is recognized that excitable, nervous patients of this type may permit themselves to become so wholly under the influence of fear and apprehension as to be unable to distinguish between pressure and pain. More or less unsatisfactory anesthesia results are expected with this type of neurotic individual, with any operation done during consciousness. It may be that this objection applies with local anesthesia in general, or with spinal anesthesia, or with sacral block anesthesia in intraperitoneal pelvic surgery, or in surgery involving the dome of the bladder, but it does not apply with sacral block anesthesia in perineal prostatectomy. This series of 378 cases has included the usual percentage of exceedingly nervous and excitable, non-English-speaking Russian Jews. Every one doing surgical work is familiar with this type and knows how difficult it is to gain the confidence of one of these individuals. Since none of these were excluded from the series, and since each of these neurotic individuals went through exactly the same routine as the others, with only one-fourth grain (16 mg.) of morphine, and without general anesthesia, it is clear that nervousness or mental instability does not constitute an objection to the sacral block method.

I know of no contraindications to the use of sacral block anesthesia in perineal prostatectomy.

SACRAL BLOCK VERSUS SPINAL ANESTHESIA

I am not in a position to be able to express an opinion relative to these two methods, based on personal experience with both. The general impression is that spinal anesthesia carries with it a certain hazard of its own, and that a certain percentage of reaction is inevitable, a few of these being serious, and an occasional one fatal. On the other hand, Chute[17] has reported a total series of 840 prostatectomies, with "no immediate fatalities and no remote ones that could be attributed to spinal anesthesia." In discussing this paper, Lundy, who has had an unusually extensive experience with both methods, states: "It seems to me that sacral block is safer than spinal anesthesia." Regardless of how great the inherent hazard in spinal anesthesia may be, the figures reported by Dr. Chute clearly demonstrate that the percentage of mishap may be reduced to a very small minimum in proper hands.

Disregarding the hazard question, however, I believe that the opinion is permissible that the sacral block method (in prostatectomy) is preferable to the spinal method, on an efficiency basis alone. Analyzing the last 512 consecutive cases, Chute has reported that there were forty-three cases, or slightly more than 8 per cent, in which "a little supplementary anesthesia was employed." Barney and Shedden,[18] analyzing a series of 250 prostatectomies in the Massachusetts General Hospital from the anesthesia point of view state: "In any considerable group of spinal anesthesias, an incidence of nearly 10 per cent of spinal reactions is to be expected, of which some are fatal."

My own opinion, based on the general impression relative to spinal anesthesia in average hands and on figures here submitted, is that the sacral block method (in prostatectomy) is more safe and less subject to failure. Moreover, postoperative headache, occurring as a sequela of sacral block anesthesia, is an unheard of complication.

MORTALITY RATE IN PROSTATECTOMY

Since this paper has to do primarily with sacral block anesthesia, a discussion of operative technic and late functional results would here be out of place. It is essential, however, to include table 2, showing the mortality rate, because any given procedure may be justified only by the results obtained. As indicated, there has been a total of 9 deaths out of 378 consecutive cases of perineal prostatectomy, a mortality rate of 2.38 per cent. The largest number of consecutive cases included in this series without a death was 121. None of these deaths have been in any way associated with the anesthesia, since all occurred at intervals of from six days to several weeks after the operation, from such causes as late general sepsis, three cases; renal insufficiency, three cases; pneumonia, one case; pulmonary embolus, one case, and acute cardiac decompensation, one case. Of the three deaths due to general sepsis, two were considered to have been due primarily to lowered resistance secondary to profuse delayed hemorrhage, coming on as late as two weeks after the operation. In the entire series, however, there has been no death resulting directly from hemorrhage, either immediate or late.

This mortality rate represents a faithful and accurate recording of all deaths, due directly or indirectly to the prostatectomy, or occurring from any cause whatever, during the patient's stay in the hospital, with one exception as outlined later. Among the nine deaths there has been included one which occurred on the thirty-ninth postoperative day, in sepsis, associated with the formation of an abscess in the calf of the right leg. One additional death, which occurred on the fifty-first postoperative day (from renal insufficiency), I have considered could be honestly and properly excluded from the series, since the patient was up and fully dressed during the third postoperative week and had been given permission to return home. Although the incision was entirely healed and the urine passing normally through the urethra, the patient voluntarily chose to remain in the hospital awaiting more complete convalescence. Obviously this patient, able to walk, fully dressed, in the hospital corridor, had survived the prostatectomy.

Table 2.—*Perineal Prostatectomy Under Sacral Anesthesia: Immediate Results*

Total consecutive cases	378
Average age	70
Above 80	25
Deaths	9
Mortality rate (per cent)	2.38
Total consecutive cases with no deaths	121
Sacral anesthesia (consecutive cases without failure)	229
Rectal injury	2
Postoperative "shock"	0
Delayed hemorrhage (several days)	10
Epididymitis	42

FACTORS TENDING TO LOWER THE MORTALITY RATE OF PROSTATECTOMY

Chief among the factors tending to minimize the mortality rate in prostatectomy are (1) preliminary drainage, (2) the perineal route, (3) excessive care in hemostasis and (4) sacral block anesthesia.

1. Unquestionably, the most important of these factors is adequate and prolonged preliminary drainage. This item has been attended to with scrupulous care and rigid insistence. The rule requiring a minimum ten day drainage in all cases, regardless of apparent good general condition has not been deviated from in any instance. It was also insisted on that a ten day period of normal temperature precede every operation. In many cases the drainage period extended over several weeks and, in the occasional case, over several months. The suprapubic drainage route was employed in about 25 per cent of cases, in which the retained urethral catheter proved to be intolerable or inefficient, for one reason or another.

---

[17] Chute, A. L.: The Use of Spinal Anesthesia in Urology, J. A. M. A. 96:88 (Jan. 10) 1931.

[18] Barney, J. D., and Shedden, W. M.: A Study of Anesthesia in Prostatectomy, S. Clin. North America 2:1093-1104 (Aug.) 1922.

2. Comparative figures show that the perineal route carries with it a lower hazard than does the suprapubic. It is my opinion that, if for no other reason, this is because abdominal distention or adynamic ileus, so common following suprapubic or abdominal operations, is comparatively rare following operations on the perineum, whether for prostatectomy or for other purposes. In the entire series, this distressing and serious postoperative complication has been conspicuously absent.

3. Immediate postoperative hemorrhage, in every case, has been controlled by means of a combination hemostatic and drainage bag, a detailed description of which has been previously submitted.[19] This rubber bag, inflated with air and maintained in place in the prostatic cavity by means of countertraction against the perineum (without traversing the urethra), provides hemostasis both during and after the operation. Also, in each case, a careful attempt was made to clamp and ligate bleeding points around the bladder neck. For the latter purpose, an excellent opportunity for deliberateness was provided by the elimination of the necessity for haste, as the result of the sacral anesthesia. Emphasis should be placed on the importance of minimizing the loss of blood, for the reason that it is undoubtedly true that, although comparatively few patients die as the direct and immediate result of hemorrhage, there are many fatalities occurring later because of lowered resistance and sepsis, resulting indirectly from the spilling of blood. These remarks refer merely to the control of immediate postoperative hemorrhage, occurring during the first two or three postoperative days. The control of immediate postprostatectomy hemorrhage would seem to be an almost solved problem. Delayed postoperative hemorrhage, however, occurring after a ten day or two week interval, often profuse and massive and coming on suddenly, in a patient considered to be out of danger, constitutes a grave menace and may be considered the chief problem connected with prostatectomy today. At any rate there is no other complication so serious, so unforseen, and which one is so wholly unable to prevent. Fortunately, this is a rare complication (approximately 2 per cent), and one which might well pass unnoticed in a small series.

4. Sacral block anesthesia, the fourth factor in minimizing the mortality rate, unquestionably plays an important rôle. This opinion is justified because there have been no anesthesia deaths in the series, and no alarming anesthesia reactions. The outstanding feature is that these patients return to their beds in the same condition, with respect to circulation and general appearance, as before the operation. Whatever postoperative "shock" may be, this condition is conspicuously absent following the perineal operation, under sacral anesthesia.

SUMMARY

1. The more or less general impression that sacral block anesthesia (in prostatectomy) is not wholly reliable and dependable, and that there is a certain small but inevitable percentage of failure, is erroneous. This mistaken idea may be explained in part by a confusion between the simple caudal injection and the complete sacral block, and, in part, by inaccuracy in technic, without recourse to theories with respect to anatomic and physiologic variation.

2. Sacral block anesthesia, accurately administered and with the needles unquestionably in the foramina, is uniformly and invariably dependable for perineal prostatectomy. This statement is based on the fact that it has been possible to run an as yet uninterrupted series of 229 consecutive cases of perineal prostatectomy, without the necessity for additional anesthesia in a single instance, and without drug narcosis other than one-fourth grain of morphine.

3. The sacral block method is applicable in all cases of prostatectomy. It has not been necessary to exclude a single case on account of fear or nervousness or mental excitability on the part of the patient.

4. Sacral block anesthesia carries with it no hazard which is inherent in the anesthesia itself, provided the most elementary form of caution (aspiration before injection) be employed, in avoiding puncture of the dural sac or blood vessels.

5. The average time necessary for injecting the caudal canal and the three sacral foramina on each side (seven in all) is twelve and a half minutes.

6. The method of anesthesia which may be made invariably dependable, which has no inherent anesthesia hazard and no complications or sequelae, which is simple in its technical application and is not time consuming should be the method of choice.

7. Sacral block anesthesia has been a material factor in maintaining a mortality rate as low as 2.38 per cent (nine deaths) in a consecutive series including 378 cases of perineal prostatectomy.

CONCLUSION

Sacral block anesthesia is the ideal method of anesthesia for perineal prostatectomy.

Medical Arts Building.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. LOWSLEY AND KIRWIN, T. M. DAVIS, PEACOCK, AND EDWIN DAVIS

Dr. Alexander Randall, Philadelphia: Concerning the history of instrumental prostatectomy, starting with Young's punch, one finds that Young conceived the instrument to remove bars and small obstructive lobules. Stepping from that into the treatment by electrical cauteries, and taking Collings' instrument as an example of this, he devised his instrument for the excision, or even the incision, of obstructions at the vesical neck. It is on record that both these men have decided to limit their instruments' use to median bars, to small localized hypertrophies, to the relief of cicatrices, and to handling, in a palliative way, malignant tumors. I am convinced that no instrument now in use or yet to be devised will ever perform a complete prostatic adenectomy, as is accomplished by open operation today. As against this is the possibility that partial removal will give clinical results to which may rightly be applied the word cure. My only criticism of Dr. Davis's method is the question of its stability and the possibility that partial removal and temporary results, with the likelihood of gradually recurring obstructions, will lure one into a false security. I fear he will have a recurring morbidity and that the operation will have to be repeated. That is not really a criticism, for such a method could be repeated with safety to the patient. Therefore, though I think his method is a stimulating advance, I wish to leave it with these warnings: It is a highly technical procedure; it cannot remove all the hypertrophied prostate; and I imagine that, in the hands of the majority of the men who purchase an instrument expecting success, it will meet with failure. Dr. Peacock's paper is an interesting exposition of a hoped for technical advance. It has long been an axiom that the more one pretties up a prostatectomy, the higher one shoves up the mortality. One must realize that it is not the existence of hypertrophic prostatic tissue in the body that is the trouble, but the effect it produces by urinary obstruction. Therefore one cannot conclude that with the removal of the prostate one has removed the patient's clinical trouble. There follows after the removal

the delicate readjustment of the effects of that obstruction, which have to be most carefully dealt with. If any one thing has brought prostatectomy to its present success, it has been the understanding of preoperative drainage. If anything will carry it further, I think that the greatest factor will be competent postoperative drainage, and for that reason I fear his procedure.

---

[19] Davis, Edwin: Distensible Bag for Hemostasis and Drainage Following Perineal Prostatectomy, J. Urol. 18:201 (Aug.) 1927.

Dr. R. M. Nesbit, Ann Arbor, Mich.: Two and a half years ago, in working with Dr. Hugh Cabot, I went over the records of 450 patients who had been operated on for prostatic obstruction, with drainage, and found that 17 per cent had epididymitis. At that time my associates and I started performing vasectomy on all patients as a preoperative measure and since then these patients, over 100, have shown an incidence of less than 1 per cent of epididymitis. In the one instance that has occurred there were chills and fever following operation and immediately preceding the epididymitis, and it was felt that probably the infection was blood borne.

Dr. Hermon C. Bumpus, Jr., Rochester, Minn.: I shall discuss the paper of Dr. T. M. Davis because I just visited his clinic and saw him operate on four patients, and a number who had been operated on previously were kind enough to demonstrate themselves. Dr. Davis has in no way exaggerated his results or the ease of the procedure. When, in the eighteen eighties, surgery of the prostate was first attempted, partial prostatectomy was the rule. It soon became apparent that, as then practiced through a suprapubic incision, partial removal did not completely relieve obstruction. Therefore, complete removal of the gland was undertaken and success followed, for it is axiomatic that when residual urine is completely removed results are good. The modern punch operation, as practiced by Dr. Davis, by removing all obstruction does completely relieve residual urine and hence is likewise successful. If obstruction is relieved, all indications for removing the gland in toto disappear. An elderly man will never acquiesce to the loss of his prostate when he learns that his neighbor has been relieved of all symptoms of obstruction by this simple procedure.

Dr. O. S. Lowsley, New York: I have been using regional anesthesia since 1921, and good anesthesia is always obtainable if the anesthetist gives a sufficient amount of the agent used. It has been worked out that procaine hydrochloride is destroyed in the liver, and one can use a large amount without any danger if it is given slowly. I consider the method an excellent one. With regard to Dr. T. M. Davis's paper I wish to register a protest against the use of this instrument by every one. A protest also is in order against his using it in every case. The laryngologists have given up using the same type of operation for tonsils. Why? Because they have had to go back when they have taken out only a portion and take out the whole tonsil later. That is why Dr. Davis and others will have to give up this instrument. It cannot take out the whole prostate. One subjects old men to procedure that is a great strain for two or three hours and they go home. They would probably rest at home as well as in a hospital in the average case, but I think that there will be a group of recurrences on this that will make them give it up, as Dr. Max Stern, who devised this instrument that Dr. Davis uses, did in adenomatous hypertrophy of the prostate. I wish to commend my New York confrères who take a more conservative view. Dr. Kirwin, Dr. Collings and Dr. Stern are all convinced that this type of prostate should not be operated on in the manner described by Dr. Davis. In connection with my demonstration of a method of operative intervention in suprapubic prostatectomy, I attempted to demonstrate that the intra-urethral method of removing the prostate is to be avoided, owing to the danger of tearing into the plexus of Santorini. In conclusion, I again object to patchwork at the vesical orifice. Whether the sphincter is destroyed or not, the vesical orifice will resume its function. If sutures are put in, they cause scar tissue and delay the resumption of function of the internal vesical sphincter.

Dr. J. H. Morrissey, New York: This past week, I had an opportunity of seeing the work and immediate results obtained by Dr. Davis. The general condition of some eight patients, based on the criteria by which one judges these patients, was certainly an improvement on the results which I know I should have had in the same interval. My main objection to any punch procedure in the past has been based on the assumption that the element of drainage to combat existing or postoperative infection is disregarded. I can now see that this fear is groundless, as the procedure itself provides better drainage than the patient has had previously, and in the presence of developing infection it also looks after this complication satisfactorily. I think that there are limitations to Dr. Davis's method. The loops are weak; the electrical knowledge and the patience required are something that the average genito-urinary surgeon does not possess. The fact that Dr. Davis had four instruments on the table indicates to my mind that they must break, and he was prepared for such an emergency. Of course, the perfect radio knife is that which cuts and cauterizes, checking bleeding points at the same time. That will come eventually. We have all seen a great advance and development in the various trends in electrical instruments used in urology. We must be careful not to disregard or belittle the work of a new, honest and earnest investigator who is trying to give a choice in the method of removal of obstructive prostates, a choice as to whether the prostate shall be resected, as he calls it, punched out, removed or, as happens in too many cases, yanked out in two or three seconds.

Dr. A. J. Crowell, Charlotte, N. C.: Every one realizes that progress is being made in the handling of prostatic patients. The day is not far distant when prostatectomies will largely be a thing of the past. I have been as skeptical of prostatic resection as any one, but I now know that there are great possibilities in this procedure. This operation has a definite field in prostatic surgery. It is not suitable for every case, but it is applicable in at least 90 per cent of the cases requiring surgery. Since Dr. Davis came with us January 1 of this year, my associates and I have done only four prostatectomies in operating on sixty-two patients. I wish to show a cystogram of a large median lobe prostate which Dr. Davis operated on, last Tuesday, with the tissue removed (24.6 Gm.), to demonstrate the amount of tissue that can be removed by this method when the hemorrhage is controlled. Undoubtedly, a new era in the management of prostatic patients is opening. The resection instruments at present are imperfect, but possibilities have been demonstrated by them and they will rapidly be improved so that any skilled urologist can do this work successfully.

Dr. Albert E. Goldstein, Baltimore: In discussion of the paper of Dr. T. M. Davis, several things should be stressed. The first is something that Dr. Morrissey mentioned, that one patient walked into the clinic that morning and was operated on. To me that was a dangerous procedure. The one thing I try to do is to accomplish preliminary drainage. Operating on patients immediately on their coming to the clinic will get one into trouble. For years preliminary drainage has been practiced, and one should be cautious in carrying this out. If one is perfectly satisfied to repeat this operation, it is probably all right to go ahead. One must consider what the condition is. It is probably an adenoma to begin with, and it will recur if one removes only one section at a time. Furthermore, this method will be used by those who cannot possibly perform a prostatectomy on patients, so they will resort to the Davis apparatus and again there will be trouble. In discussing Dr. Peacock's paper, I wish to stress that the one thing that has put urology on its present sound basis is the free drainage that has been used in all cases. I think one should use drainage irrespective of what type of operation one is going to perform. If one feels that the bladder should be closed, there is one method Dr. Peacock did not mention. No one mentioned closure in the perineal prostatectomy. I have removed the prostate and, while I did not close the urethra with the capsule, I closed the wound and packed the capsule for hemostatic purposes. It seems to me that if the wound is going to break down, which it will and did in 26 per cent of my cases, one is less apt to have trouble if there is room for drainage or if there is trouble in the way of hemorrhage.

Dr. George R. Livermore, Memphis, Tenn.: I have always maintained that the punch operation is indicated only in patients with obstruction of the median bar. In patients who have a hypertrophic prostate and whose condition will not permit, or who will not submit to operation, I have been endeavoring to reduce the obstruction by means of Collings' electrotome, and have had some success. I feel that this pro-

cedure of Dr. Davis is worthy of consideration. In regard to reaction, all urologists know that any patient in whom a catheter or sound is passed is likely to have a rigor and high fever. How Dr. Davis can use a metal instrument and burn out pieces of the prostate and not get any reaction is beyond my comprehension. In all urethral and bladder instrumentation, I give from 7½ to 10 grains (0.5 to 0.65 Gm.) of methenamine four times a day, and in addition often give 31 grains (2 Gm.) intravenously. This procedure has markedly reduced reactions and in some cases eliminated them entirely.

DR. A. I. FOLSOM, Dallas, Texas: Dr. Randall did not go far enough back into history to include it all. Bottini was the first man who ever advocated this procedure; Georges Luys came after him, and then came Young with his cold punch, but I think one of the most important contributions for the relief of this condition is generally overlooked, and that is the work of John Caulk of St. Louis, who instituted the method now being perfected. He has been saying for ten years that there were things about prostatectomy that we urologists did not understand. He has told us that after removing even a small section of the gland there is relief, so far as passage of urine is concerned. I think the future of urology will place John Caulk's work at the watershed among the procedures furnishing relief for these patients. I do not believe that Caulk's punch is the final answer to the problem. The next step was Collings' electrotome, and then came McCarthy with his loop. I have been using that; it is simply a quick means of doing what Dr. Davis is doing, and I have been increasingly surprised to find the extent to which I can go. I am operating on patients today whom a year and a half ago I should not have considered operable at all. Dr. Davis makes a mistake in attempting to make this a simple solution of all prostatic cases. He is wrong in this; I do not care what method is used. The fundamental purpose is preliminary drainage. He is emphasizing the wrong thing. These patients should be handled just as carefully, with preliminary preparation and care and with after-care, as those in whom the prostate is removed. I wish to cite the case of a patient with a large adenoma which I should not have considered removing at all in this way two years ago. However, the old gentleman had an almost complete heart block, and the internist to whom I referred him said that it would be impossible to remove the prostate safely. I explained this to the patient but he was so very uncomfortable that he wished us to do anything we could. I used this type of procedure, and it is now eight weeks since the operation. The bladder is normal and the residual urine is 1 ounce. He gets up only twice at night and is well. There is much to be learned about this operation. We must take it up carefully and seriously, but I think we are standing at a most interesting place in prostatic surgery.

DR. GIDEON TIMBERLAKE, St. Petersburg, Fla.: I saw Dr. Davis at work, and was surprised that he did the operation with only one assistant. If his method does give drainage we are coming to it certainly.

DR. LEO L. MICHEL, New York: The trouble with the Stern resectoscope lies in the inconstant radio current. The same voltage at different times gave different degrees of heat to the operating loop. It required a certain constant heat degree to control hemorrhage, and, because of this imperfection, hemorrhage was a frequent complication. Stern used this procedure in middle lobe intrusion, malignant intrusion and fibrotic bladder necks. Later, Dr. Stern gave up this operation in middle lobes. There was too much danger from hemorrhage, but when the current worked well his results were fine. Dr. Davis and R. Wappler have perfected the radio current. The present current permits a constant measured heat degree, thereby completely controlling hemorrhage. The operating loops of Davis are larger than Stern's, enabling one to remove larger pieces of tissue in a shorter time, and I believe with Dr. Davis that he can successfully attack almost any type of prostatic overgrowth with the present apparatus. With the radio current perfected, the results depend on the experience and skill of the operator in the manipulation of his instrument.

DR. W. S. PUGH, New York: When Dr. Stern and Dr. Collings first brought out their resectoscopes, they were a failure in true hypertrophy. The patients had recurrences, some in six months, some in a year, and were worse off than before. Regardless of what instrument is used, there will be hemorrhage in some instances. I have had two very severe cases, one with almost complete exsanguination, after using Collings' instrument. That occurred within twenty-four hours and in a second case there was severe hemorrhage after eight days. One should adopt a very liberal ground in prostatectomy. It is silly to say that one should use any single method in every case. There is a place for all methods.

DR. EDWIN DAVIS, Omaha: There seems to be no doubt that the contribution of Dr. T. M. Davis overshadows all else that has been heard this morning. This carries with it all the conviction that he has given us something of value. Time will tell the value of prostatic enucleation versus prostatic resection, and in the last analysis we may arrive at the solution of the problem.

DR. T. M. DAVIS, Greenville, S. C.: Dr. Randall spoke of recurrences. In sixteen of the cases reported, a prostatectomy had been done previously and there had been recurrences. The number that have recurrences following prostatectomy is not accurately known. I shall probably have some recurrences in this series of cases. As to purchasing an instrument and performing the operation without experience, every one who buys other instruments cannot use them skilfully without experience. I do not operate on every patient. In patients with extremely large bilateral lobes in which it is impossible to observe the posterior border with the cystoscope, I do not attempt to operate. As to Dr. Stern giving up the use of his instrument, I do not know about that. He deserves great credit for its invention. The Wright brothers invented the first airplane and their first flights were only a few hundred feet. They were by no means the man that flew an airplane from New York to Paris. All patients receive appropriate preliminary treatment. Some men come in with a small median bar, who show normal conditions on chemical analysis of the blood and a very small amount of residual urine, and there is no reason why they cannot be operated on without delay. One can do a decompression afterward if one wishes. There is no interference with the urinary output and one gives proper preliminary treatment before operation. As to why the patients do not have a reaction, I do not know but apparently they do not. Whether there is anything in connection with the current is a question. Whether that prevents a reaction I do not know, but the patients are very comfortable after this procedure and only 7 patients out of 246 have had to have a hypodermic after operation for relief from pain. Morphine is ordered if required, in every instance, but only seven patients have complained at all. If they have any discomfort to amount to anything it is usually in the third week, when the epithelium begins to grow back, and this is easily relieved by tincture of belladonna. This treatment has some action on the tissue that we do not know about. Many carcinomas are arrested; I do not know why. They do not seem to metastasize as rapidly after this treatment, and the gland does shrink. Another thing is that if one institutes adequate drainage one can see the prostate secretion pour out during sectioning and it is more than just a removal of that much tissue.

DR. T. J. KIRWIN, New York: There is a middle case. To take out enlarged prostates when one cannot get the cystoscopes over the top of them is something I do not think Dr. Davis would attempt, and neither should I.

DR. A. H. PEACOCK, Seattle: This argument about the construction of the internal urethral orifice is not only one of surgical instruments and pathology, but a matter of skill and workmanship of the individual. No rule can be laid down for any one operation. I think many of us feel that if we have no particular skill in using some of these special instruments it is safer for us to visualize the orifice suprapubically in those cases in which it is possible. In reply to Dr. Randall's criticism relative to closing the bladder, I wish to state that we do get perfect drainage with a large catheter and many of the objections are fancied and not real. I urge you to try closing cystotomies and am sure if you do, you will be satisfied with your results.

the delicate readjustment of the effects of that obstruction, which have to be most carefully dealt with. If any one thing has brought prostatectomy to its present success, it has been the understanding of preoperative drainage. If anything will carry it further, I think that the greatest factor will be competent postoperative drainage, and for that reason I fear his procedure.

Dr. R. M. Nesbit, Ann Arbor, Mich.: Two and a half years ago, in working with Dr. Hugh Cabot, I went over the records of 450 patients who had been operated on for prostatic obstruction, with drainage, and found that 17 per cent had epididymitis. At that time my associates and I started performing vasectomy on all patients as a preoperative measure and since then these patients, over 100, have shown an incidence of less than 1 per cent of epididymitis. In the one instance that has occurred there were chills and fever following operation and immediately preceding the epididymitis, and it was felt that probably the infection was blood borne.

Dr. Hermon C. Bumpus, Jr., Rochester, Minn.: I shall discuss the paper of Dr. T. M. Davis because I just visited his clinic and saw him operate on four patients, and a number who had been operated on previously were kind enough to demonstrate themselves. Dr. Davis has in no way exaggerated his results or the ease of the procedure. When, in the eighteen eighties, surgery of the prostate was first attempted, partial prostatectomy was the rule. It soon became apparent that, as then practiced through a suprapubic incision, partial removal did not completely relieve obstruction. Therefore, complete removal of the gland was undertaken and success followed, for it is axiomatic that when residual urine is completely removed results are good. The modern punch operation, as practiced by Dr. Davis, by removing all obstruction does completely relieve residual urine and hence is likewise successful. If obstruction is relieved, all indications for removing the gland in toto disappear. An elderly man will never acquiesce to the loss of his prostate when he learns that his neighbor has been relieved of all symptoms of obstruction by this simple procedure.

Dr. O. S. Lowsley, New York: I have been using regional anesthesia since 1921, and good anesthesia is always obtainable if the anesthetist gives a sufficient amount of the agent used. It has been worked out that procaine hydrochloride is destroyed in the liver, and one can use a large amount without any danger if it is given slowly. I consider the method an excellent one. With regard to Dr. T. M. Davis's paper I wish to register a protest against the use of this instrument by every one. A protest also is in order against his using it in every case. The laryngologists have given up using the same type of operation for tonsils. Why? Because they have had to go back when they have taken out only a portion and take out the whole tonsil later. That is why Dr. Davis and others will have to give up this instrument. It cannot take out the whole prostate. One subjects old men to procedure that is a great strain for two or three hours and they go home. They would probably rest at home as well as in a hospital in the average case, but I think that there will be a group of recurrences on this that will make them give it up, as Dr. Max Stern, who devised this instrument that Dr. Davis uses, did in adenomatous hypertrophy of the prostate. I wish to commend my New York confrères who take a more conservative view. Dr. Kirwin, Dr. Collings and Dr. Stern are all convinced that this type of prostate should not be operated on in the manner described by Dr. Davis. In connection with my demonstration of a method of operative intervention in suprapubic prostatectomy, I attempted to demonstrate that the intra-urethral method of removing the prostate is to be avoided, owing to the danger of tearing into the plexus of Santorini. In conclusion, I again object to patchwork at the vesical orifice. Whether the sphincter is destroyed or not, the vesical orifice will resume its function. If sutures are put in, they cause scar tissue and delay the resumption of function of the internal vesical sphincter.

Dr. J. H. Morrissey, New York: This past week, I had an opportunity of seeing the work and immediate results obtained by Dr. Davis. The general condition of some eight patients, based on the criteria by which one judges these patients, was certainly an improvement on the results which I know I should have had in the same interval. I urge you to try closing cystotomies and am sure if you do, you will be satisfied with your results.

ACCESSORY SINUS INFECTION IN SUSPECTED PULMONARY TUBERCULOSIS *

JOHN D. OSMOND, M.D.
CLEVELAND

In making roentgenologic examinations of many chests, one finds evidence of chronic infection that is nontuberculous in origin. Most of the patients who are referred for roentgen examination of the lungs are sent for one purpose; namely, to determine whether or not pulmonary tuberculosis is present and to what extent. Formerly, the roentgenologist was content with his diagnosis when he could rule out a pulmonary tuberculous infection. Now, in order to be of greater service to the referring physician and to the patient, he must try to find the origin of the chronic infection that is causing the lung symptoms. The lung changes may represent chronic bronchitis, bronchial asthma, or bronchiectasis. The origin may be in the upper respiratory tract, especially the accessory sinuses.

During the past four years my associate Dr. James H. West and I have been impressed by the number of chest patients whose clinical symptoms suggested early tuberculosis but whose chest roentgenograms revealed increased connective tissue branching out from each hilus region with no parenchymal involvement. The linear markings were broad and short and there was thickening of the bronchi at the bases. Most of the patients were adults. Out of 1,377 chest patients examined, one or more roentgenograms of the sinuses were made in 124 cases. Of these, seventy-six had definite sinus complications. Seventeen had signs of tuberculosis and sinusitis. All the sinus examinations were made on our own responsibility; only recently are requests being made to examine the sinuses in addition to the stereoscopic chest studies. In addition to this list of chest cases, about an equal number of similar patients were examined at St. Vincent's Charity Hospital. At first, no sinus examination was made until after the chest roentgenograms were studied. If the patient looked well nourished and had a chronic cough, we made a single roentgenogram of the sinuses in the Waters position; later it became our custom to take a short history at the time of the fluoroscopic examination. If the patient gave a history of frequent head colds and increased expectoration, a sinus examination was clearly indicated. The number of chest patients for whom we made one or more sinus roentgenograms steadily increased each year during the series from 1927 to 1930 inclusive. In 1927 we selected only nine patients; in 1930 there were fifty-four. Stereoscopic chest studies were made in all cases. A surprising number of sinus complications were found. A sinus examination was not made in any case giving gross fluoroscopic evidence of tuberculosis.

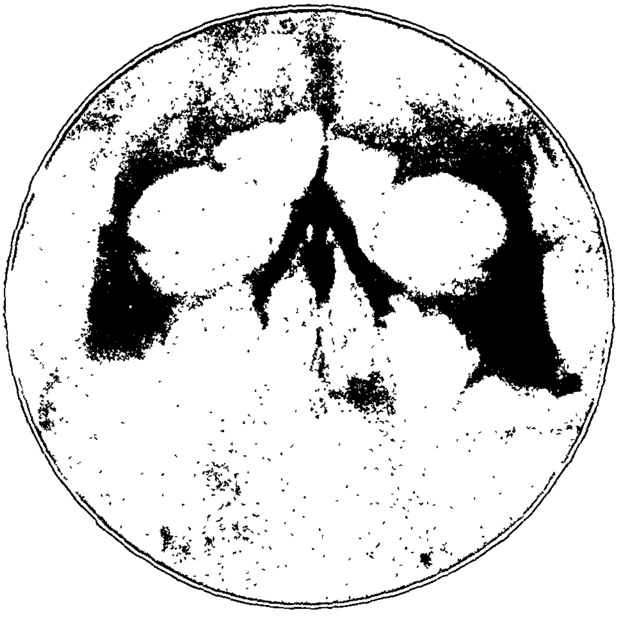

Fig. 1 (case 3).—Active sinusitis with pus in each antrum, more in the right than in the left.

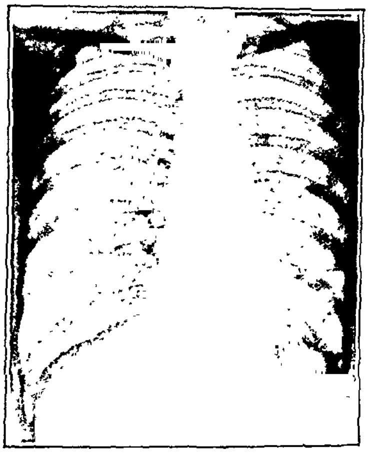

Fig. 2 (case 3).—Lung changes of nontuberculous origin. Patient's symptoms disappeared with treatment of her sinusitis. The case had been diagnosed clinically as an active pulmonary tuberculosis.

Fluoroscopic examination alone, without stereoscopic roentgenograms, is not reliable for detection of early pulmonary tuberculosis. The early lung changes are not visible on the fluoroscopic screen and much valuable time may be lost in beginning the proper treatment of early tuberculosis.

Since this paper was begun, four months ago, four helpful references have been found in the literature regarding the relation of sinus infection to respiratory disease. Knight,[1] Schwartz[2] and Mullin[3] referred mostly to the adult, and Wasson[4] has written several excellent articles regarding the infant chest and the development of bronchosinusitis in children, and they all clearly show that one may expect to find lung changes in the adult which had their origin years before in sinus infection and reinfection, or some other infection of the upper respiratory tract.

A patient may be unaware of the presence of a sinusitis. Pain is not necessarily a symptom. The only subjective symptom may be a moderate postnasal dropping of mucus and a tinge of yellow in the nasal secretions. When such symptoms obtain for more than a month, a sinus examination will reveal chronic sinusitis in a high percentage of cases.

I shall consider briefly the anatomy of the lung and the use of a few terms. The use of the word hilus as used in this paper refers to the fan-shaped area including the root of the lung and extending peripherally about an inch beyond the bifurcation of the bronchi. The lymph nodes that most frequently concern the roentgenologist are the bronchopulmonary glands

located at the bifurcation of the bronchi. When these glands enlarge or change in appearance, they are more easily detected than the more centrally placed bronchial or mediastinal glands, because they are nearly surrounded by air. The linear markings that extend outward from each hilus are made up of artery and bronchus bound together by connective tissue. The vein that accompanies the artery and bronchus plays little part in differential roentgen diagnosis, and the distribution of the nerve branches does not show on the roentgenogram. Changes in these linear markings are sometimes called bronchial thickening or increased fibrosis, but in chronic infection it is due mostly to increase in connective tissue. The older the patient the more connective tissue, and the older the patient the more chronic the infection. When this broad but short increase in the linear markings is general at each hilus, it is typical of nontuberculous infection. A typical tuberculous infection shows an area of mottling somewhere in the parenchyma and enlarged lymph glands at the hilus draining this area. Some fibrosis can usually be found between the distal focus and the enlarged glands.

The rhinologists have received much assistance in the diagnosis of sinus disease since the roentgenologists have been making sinus examinations before and after the injection of iodized oil. Such roentgenograms detect thickening of the membrane lining the sinuses and indicate the degree of thickness of the hyperplastic tissue. Moreover, certain indentations and irregularities indicate the presence of polyps. Collections of pus in walled off areas of hyperplastic tissue in an antrum will probably never disappear until a radical operation removes the chronic infected tissue from the sinus. It is difficult to think of prolonged nasal disease and some cases of asthma without associated sinus infection. Polyps in the nose or antrum mean chronic infection and will eventually give rise to lung changes and chest symptoms.

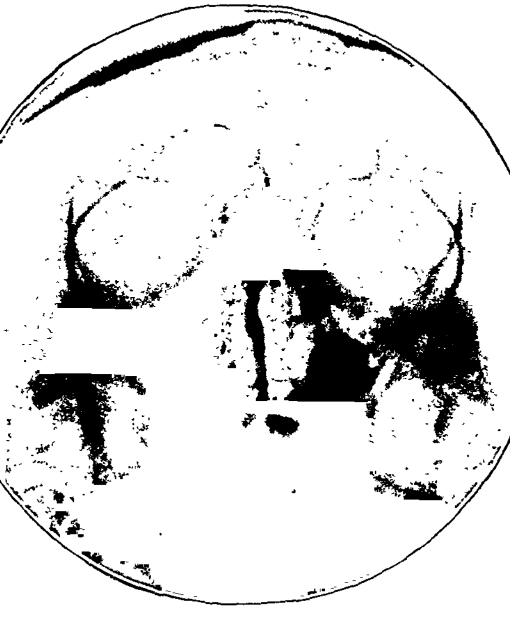

Fig. 3 (case 4).—Injection of iodized oil in each antrum showed thickened membrane of a chronic sinusitis. Symptoms disappeared after bilateral Caldwell-Luc operation.

Mullin and Ryder have shown experimentally that the lymph channels drain the antrums and frontal sinuses into the bronchial and mediastinal glands by way of the submaxillary, internal jugular and carotid route, and Mullin[3] has further stated that protracted flooding of the lymph channels with infectious material from the hyperplastic maxillary sinus tends to produce a chronic peribronchitis and, if neglected, a bronchiectasis will follow. However, in my opinion, the more usual route of bronchial infection is a spreading downward of the infectious material through the trachea and the bronchial branches.

Every rhinologist knows that influenza causes many cases of sinusitis and that acute infectious diseases such as measles and whooping cough may cause a sinusitis.

Every roentgenologist, when requested to give a roentgen treatment for enlarged bronchial glands following whooping cough, should include a roentgenographic study of the sinuses when he makes his stereoscopic chest studies preliminary to treatment.

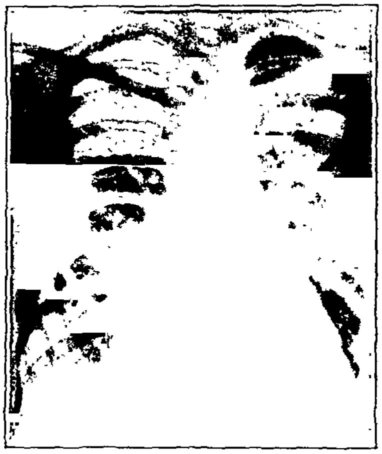

Fig. 4 (case 4).—Nontuberculous infection with bronchiectasis, relieved by treatment of sinusitis.

Every physician who is called on to examine clinically a chest should include acute and chronic infection of the upper respiratory tract as the possible source of the present lung symptoms. Tracheal and bronchial irritation may follow within a few hours after the onset of an acute rhinitis or pharyngitis. Stereoscopic roentgenograms will detect very early bronchopneumonia, which may develop within twenty hours in influenza. In this series, we are entirely concerned with the subacute and chronic stages of bronchial infection, which can best be described by giving a short history of a few cases and reporting the roentgen observations:

CASE 1.—In June, 1927, we examined the chest of a young woman, aged 22. The roentgenograms showed a hazy infiltration of the bronchial branches throughout both lungs, particularly in the posterior branches in the second interspace of each upper lobe. We considered it a very early tuberculous infection. No history was taken of the case. We examined the same patient two years later after taking the following history: She began to have frequent colds at the age of 10 years, and began to cough at 15. Her tonsils were removed six months later and the colds recurred. At 19, polyps were removed from the nose. Chest symptoms became worse and the cough increased. She spent three months in the Warrensville tuberculosis sanatorium in the early part of 1927. There was no history of roentgen examination of the sinuses. A year later there was much expectoration of a yellow and green mucus. The patient had a temperature of 99.6 F., a frontal headache, and deafness in the left ear. Our report was as follows: "Stereoscopic examination of the chest shows a slight thickening of the bronchial branches extending up from each hilus and evidence of bronchiectasis in each lower lobe. There is no evidence of tuberculosis. Examination of the sinuses shows a marked cloudiness of each antrum and some haziness of both frontals and the ethmoids, indicating a chronic sinusitis with pus in each antrum." Polyps were removed and an antrotomy was performed by a rhinologist, May 20, 1929; a bilateral Caldwell-Luc operation was done November 12. The patient has greatly improved.

Case 2.—In August, 1929, we made a roentgenographic study of the sinuses of a man, aged 29, who for years had had a recurring nasal discharge and chronic cough. He had the idea that he could throw it off eventually and had not sought medical aid. He gave no history of a previous pneumonia. His roentgenograms showed a general cloudiness of all the sinuses and evidence of a chronic sinusitis. Later, a chest study was made which showed a chronic bronchitis and bronchiectasis and no tuberculosis. Antrotomy was done. Lavage was done for six weeks. Sinus and chest symptoms improved.

Case 3.—Early in January, 1930, a man came for advice concerning a young woman who was a school teacher in a neighboring city and who had come to Cleveland for the Christmas vacation, was taken ill, and was at present in a small hospital. Her case had been diagnosed as pulmonary tuberculosis by two physicians in the hospital and also by a city physician. She gave a history of beginning to cough in November, and soon after reaching Cleveland had a temperature of 104 F. Three days later she had entered the hospital and two weeks later was told by her physician that she had tuberculosis. My advice to the friend was that the patient would surely receive good care in the hospital, but if anything radical was proposed, a consultation could be requested. January 25, after being told that she must spend three months in the City Hospital and then enter the tuberculosis sanatorium, she insisted on a consultation. The report of her roentgen examination is as follows: "Stereoscopic examination of the chest shows a generalized thickening of the bronchial branches in the right lung and a slight thickenig of the bronchial branches extending up from the left hilus. There is also a slight haziness along the vertebral bronchial branches extending up into the right apex. In our opinion, these lung changes are nontuberculous in origin. *Examination of the sinuses shows a marked haziness of each* antrum and a slight haziness of each frontal and all of the ethmoid cells, indicating an active sinusitis with pus in each antrum. The sphenoid is comparatively clear. In our opinion, the lung changes are due to the sinus infection." She was referred to a rhinologist, who washed out each antrum. She gained 10 pounds (4.5 Kg.) in two weeks. Examination was made February 6 with iodized oil. A Caldwell-Luc operation was performed, February 10. The patient has had three separate chest examinations by different roentgenologists in Cleveland since the antrum operation, in order to satisfy every one concerned, and to be allowed to continue teaching school. All three roentgen reports have been negative for pulmonary tuberculosis.

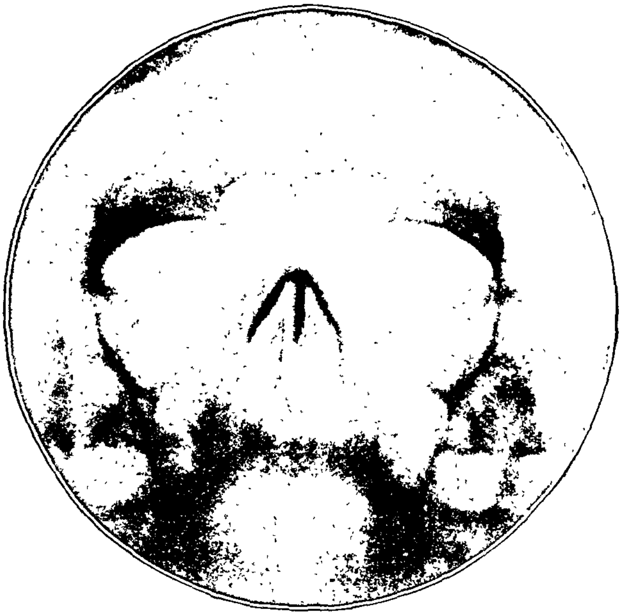

Fig. 5 (case 5).—Chronic hyperplastic thickening of membrane of each antrum with polyp formation; relieved by bilateral Caldwell-Luc operation.

Case 4.—In February, 1930, we examined the chest of a boy, aged 14, who had a chronic cough and expectorated considerably, and whose sputum had been repeatedly examined for tubercle bacilli, with negative reports. He had had repeated colds for five years. His sinuses had never been examined. There was no history of pneumonia. The report of our roentgen study was as follows: "Stereoscopic examination of the chest shows a general thickening of the descending bronchial branches in each lower lobe and a lesser thickening of the ascending bronchial branches from each hilus, indicating some nontuberculous infection and a bronchiectasis in the lower lobes. There is no evidence of tuberculosis in either lung. The heart is crowded to the left side of the median line by a depressed sternum. The apexes and costophrenic angles are clear. Roentgenograms of the sinuses show marked evidence of chronic sinusitis of each antrum with hyperplastic thickening of the membrane. There is also some haziness of the ethmoid cells. The frontal sinuses and the sphenoids are clear. In our opinion, the chronic sinusitis is the cause of the bronchitis and bronchiectasis, and in our opinion the lung condition will rapidly improve with treatment of the sinuses. . . . Injection of the right antrum with iodized oil shows a very thick and irregular membrane, indicating the presence of probable polyps in the antrum. Injection of the left antrum shows that the membrane is not quite as thick as in the right, but it is irregular also and suggests the presence of polyps." A bilateral Caldwell-Luc operation was performed February 11. The cough disappeared; the patient rapidly gained weight.

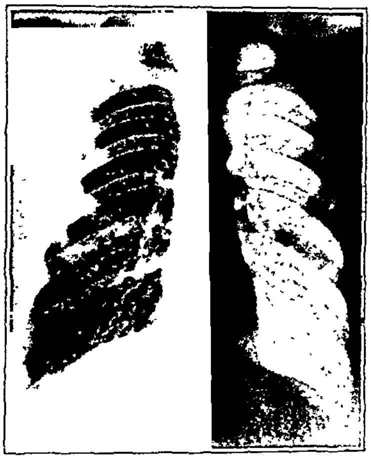

Fig. 6 (case 5).—Nontuberculous infection. Patient had been treated for more than two years in a tuberculosis sanatorium. No evidence of any pulmonary tuberculosis at this examination.

Case 5.—This report is too interesting to leave out of the series examined in the years 1926 to 1930 inclusive, although this patient was examined in March, 1931. He had recently been referred to Dr. E. P. Edwards, who could find no clinical signs of pulmonary tuberculosis. His diagnosis was an infection of the upper respiratory tract which was responsible for the chest symptoms, and he referred the patient to us for a roentgen examination of the chest and sinuses. The patient, aged 35, was discharged eleven months ago from a tuberculosis sanatorium where he had spent the greater part of two years. He has colds continually; also frequent headaches, especially above the eyes. There was much nasal discharge and expectoration. The tonsils were removed three and a half years ago. The report of the roentgenographic study is as follows: "Fluoroscopic examination of the chest shows no evidence of fluid in either costophrenic angle and there is normal excursion of the diaphragm on each side. Stereoscopic roentgenograms show a generalized fibrosis branching out from each hilus and of the ascending and descending trunk shadows in each lung. There are no parenchymal changes, and in our opinion the fibrosis is due to a chronic nontuberculous infection. Roentgen examination of the sinuses shows a marked increased density of each antrum, evidently due to thickening of the membrane from a chronic sinusitis. Injection of iodized oil in each antrum indicates polyp formation." A rhinologist then did a bilateral Caldwell-Luc operation, and polyps were found in each antrum.

These histories are typical of a sinus chest infection. The clinical symptoms may closely simulate active pulmonary tuberculosis. Râles and elevation of temperature are present. A careful history should prompt a roentgen examination of the sinuses in at least 9 per cent of chest cases examined. Fluoroscopic examination of the chest has very limited differential diagnostic value in determining early tuberculosis and no value in distinguishing early tuberculosis from chronic infection. When a known sinusitis exists, a stereoscopic chest study is indicated to determine the degree of pulmonary changes due to chronic infection. These roentgenograms have immense comparative value for later examinations.

10515 Carnegie Avenue.

ABSTRACT OF DISCUSSION

Dr. Henry K. Pancoast, Philadelphia: The finding of sinus disease means, of course, that infection in the lower respiratory tract is being kept up by a constant source from above. All realize that a sinus examination is quite essential in cases in which one finds lower respiratory changes, especially in the lower lobes, in both adult life and in childhood, and even in infancy. It is quite important to go into the history of these patients to determine what the underlying cause of the condition may be besides the constant source of infection from above. The patient may have had recurring pneumonia, a severe attack of influenza, or a lung abscess. These conditions may have caused interstitial change in the lungs, as a result of which dilatation of the bronchi may have resulted, with an approach to or an actual development of bronchiectasis. Oftentimes it is necessary for the bronchoscopist to aid in making a definite diagnosis of the underlying lung condition. Pleurisy with resulting adhesions and limitation of the movement of the dome of the diaphragm on one side may make the lower lobe on that side a vulnerable spot for recurring and continued infections. The frequency with which cases such as have been shown are referred for examination by asthma clinics shows also another side to the question. No doubt many of the patients suffer from allergic reactions and that aspect of the case may be cleared up by study in an asthma clinic. On the other hand, many persons with supposed asthma are referred to roentgenologists for examination and they find sinus conditions, or obtain histories of previous conditions which could have produced interstitial changes in the lungs. They may even find pneumonoconiosis or tuberculosis.

Dr. Leon T. Le Wald, New York: Dr. Osmond has brought up two important subjects in his paper. One of them is the limitation of the fluoroscope in examination of the lungs. I think that point cannot be stressed too much; not only is it impossible to make an accurate early diagnosis of pulmonary tuberculosis, but I have seen the other mistake made of a wrong diagnosis from a fluoroscopic examination alone. There was a case in the federal courts just the other day in which the question came up whether a man had healed tuberculosis or not. A doctor went on the stand and testified that the man had a cavity and, therefore, that he had an active tuberculosis. His opinion was based on fluoroscopic examination alone. Two roentgenologists went on the stand and testified that careful stereoscopic films showed there was not a cavity and that the several healed fibrotic lesions gave a somewhat circular shadow that was definitely resolved on the stereoscopic films into overlapping shadows. In spite of that fact, owing to the sympathy of the jury, I understand this man was awarded war risk insurance for total disability amounting to $10,000 on that fluoroscopic examination, which was inaccurate. I hope the case may be appealed and that Dr. Osmond will testify to what he said here. The other point is that I don't think the roentgenologist need hesitate when a case is sent to him for diagnosis of the respiratory tract to make a roentgen examination of the sinuses when he feels it is a necessary part of the examination. If one sends a patient to an ophthalmologist for presbyopia and asks to have glasses fitted and the ophthalmologist simply prescribes glasses without looking at the retina, overlooking albuminuric retinitis or a detached retina or a hemorrhage, he would be considered negligent. I don't want to go so far as to say that the roentgenologist, if he didn't make a sinus examination and the sinus lesion existed, would be regarded as not having done his full duty. A case cited by Dr. Pancoast of a button in a child's nose is an excellent example of a dramatic incident. If that had been overlooked by the first roentgenologist and another roentgenologist had found the button, the first roentgenologist would probably be considered not to have made an adequate examination.

Dr. Kenneth Allen, Denver: It is quite possible for a child or a young adult to have nasal accessory sinus disease combined with pulmonary tuberculosis, so that if one examines the chest and suspects a chronic infection of nontuberculous type in the respiratory tract and then examines the sinuses and finds that they are diseased, one must be a little careful not to say immediately that the case is not tuberculosis. One differential point in the study of these chests, especially the early adult type of individual, is that, in the nontuberculous chest infection which accompanies nasal accessory sinus disease, the thickening of the trunk shadows has a tendency to be symmetrically distributed. Another differential point is that the nontuberculous intensification of trunk shadows is more marked near the hilus, diminishing peripherally, whereas tuberculosis is asymmetrical, the disease more often reaching the periphery and not diminishing from the hilus outward. Furthermore, the tuberculous case has a tendency to show enlarged lymph nodes near the hilus, whereas the nontuberculous infection has not. I believe one must still consider the possibility of tuberculosis, even though there is sinus disease, and these chest signs among others will help in the differentiation.

Dr. John D. Osmond, Cleveland: Physicians in general practice must gradually become accustomed to looking for complication of sinus disease such as I have described, or in the examination of all chest cases. There is a tuberculosis clinic outside of Cleveland where in twenty-five cases examined the physician found four sinus complications. It just adds evidence to what has been stated with regard to this condition.

EFFECTS OF SPINAL ANESTHETICS ON THE SPINAL CORD AND ITS MEMBRANES

AN EXPERIMENTAL STUDY *

LOYAL DAVIS, M.D.; HALE HAVEN, M.D.
J. H. GIVENS, M.D.
AND
JOHN EMMETT, M.D.
CHICAGO

Based on the suggestion by Corning,[1] in 1885, that the intervertebral injection of cocaine solution would produce anesthesia sufficient for operations on the urethra and perineum, and on the perfection of the method of lumbar spinal puncture by Quincke[2] in 1891, the production of surgical anesthesia was established by the intrathecal injection of cocaine by Bier,[3] in 1899, and by Tait and Caglieri[4] in 1900. The development of stovaine by Fourneau,[5] in 1904, and of procaine (novocain) by Einhorn,[6] in 1905, not to mention the many other compounds used, and the clinical and technical methods developed by Barker,[7]

Babcock,[8] Labat,[9] Pitkin[10] and others have served to establish spinal anesthesia firmly as an anesthetic agent in the armamentarium of the surgeon.

That the newer anesthetics and the methods of their administration and control have less disagreeable pharmacologic and physiologic manifestations than cocaine and its nearer relatives may be admitted. However, surprisingly little is to be found in the literature concerning the possible pathologic changes in the spinal cords of human beings or animals that have been subjected to intrathecal injections of the newer spinal anesthetics.

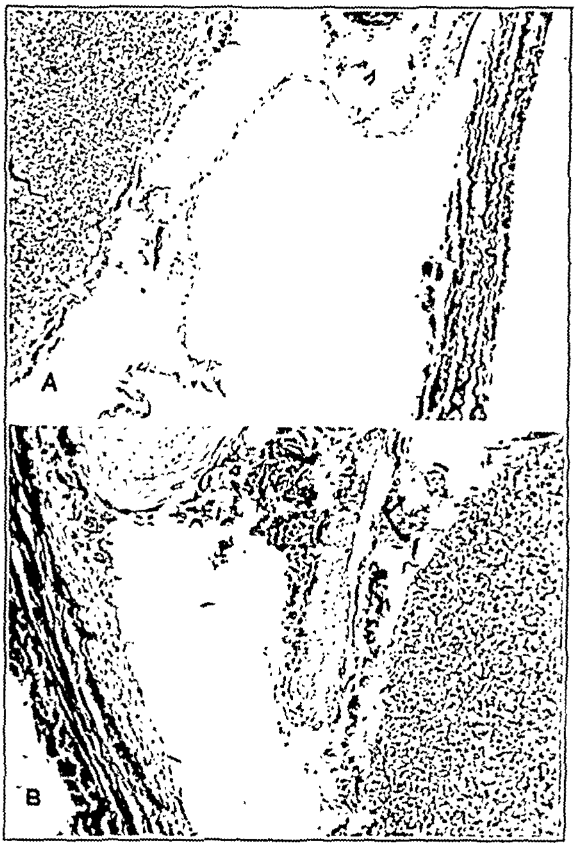

Fig. 1.—*A*, lumbar enlargement of the spinal cord of a dog seven days after injection of spinocaine into the lumbosacral dural sac; a moderate degree of inflammatory reaction is present. *B*, region of the lumbar enlargement thirty days after the injection of spinocaine showing fibrotic scarring on healing of an inflammatory reaction; van Gieson stain. Reduced from a photomicrograph with a magnification of 110 diameters.

Wossidlo[11] injected 5 per cent procaine hydrochloride into the subarachnoid space of dogs and found definite changes in the Nissl substance and the nucleus of the ganglion cells at intervals extending to twenty-four hours after injection. Pitkin[10] has reported no macroscopic or microscopic changes in the spinal cords of dogs that came to autopsy two, four, five and nine days after the injection of 5, 10 and 20 per cent solutions of procaine hydrochloride.

The preparations of spinal anesthetics in most common use among surgeons today, namely, nupercaine and such preparations as spinocaine, gravocaine and scurocaine, which contain procaine as the chief constituent, were selected to form the basis of this study. Dogs, as nearly as possible of the same general size, weight and age, were selected as the experimental animals. Each dog was injected with one ampule, or one full human dose of one of the aforementioned compounds. The animals were then killed by bleeding at intervals of twenty-four hours, seventy-two hours, seven days, thirty days and ninety days after the injection. The cords were removed and preserved in solution of formaldehyde for histologic study. Other animals were injected with a dose comparable to that given a human being as computed on a relative basis according to body weight. These dogs were killed three weeks and five weeks after injection. All the injections were made into the subarachnoid space in the lumbosacral dural sac, with a technic essentially the same in all respects as that used in performing lumbar puncture on the human being. Clear spinal fluid was obtained each time before injection and no anesthetic was used other than a preliminary hypodermic of morphine sulphate. Laminectomies were not performed in any instance. Control animals were used in which lumbar puncture alone was done. In all, thirty-seven animals were studied.

In all the dogs the paralysis and sensory loss were limited to the posterior extremities. Blood pressure tracings were not taken. There were no marked untoward effects noted except in those animals of the first group which received the injection of spinocaine. All of these dogs showed repeated tonic spasms in the fore limbs with hypernea which resembled the convulsions caused by strychnine. These spasms were absent in the animals of the second group which received the smaller dosage of spinocaine, but these too had hypernea.

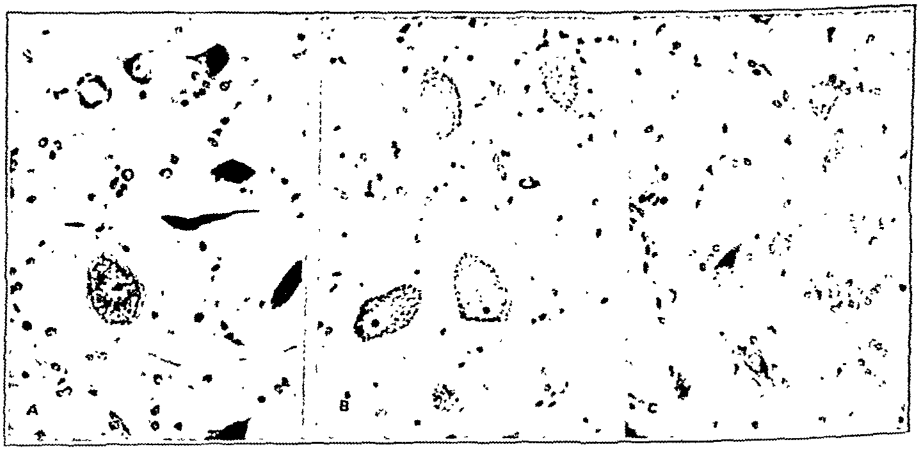

Fig. 2.—*A*, acute swelling in an anterior horn cell from the lumbar enlargement of the cord twenty-four hours after the injection of scurocaine. *B*, moderate swelling, eccentricity of the nucleus, dustlike Nissl substance about the nuclei and agglutination of Nissl substance about the periphery. Region of the lumbar enlargement three weeks after the injection of gravocaine. *C*, pale staining of the anterior horn cells with washed out appearance of the Nissl substance and edema of the nuclei; lumbar region, seven days after the injection of spinocaine. Cresyl violet stain. Reduced from a photomicrograph with a magnification of 325 diameters.

[11] Wossidlo, E.: Experimentelle Untersuchungen über Veranderungen der Nissl'schen Granula bei der Lumbalanästhesie, Arch. f. klin. Chir. 86: 1017-1053, 1908.

Five animals died within twenty-four hours after the injection irrespective of the drug injected and after apparently having recovered the use of their paralyzed extremities. These were not considered as part of the test group but the histologic picture present differed in no way from that in the dogs that were killed at the end of twenty-four hours. All the animals of the first group had complete anesthesia of the posterior limbs together with a complete paralysis. Those of the second group, which received the smaller doses of the anesthetics, showed a good anesthesia of the posterior limbs in all cases but never a complete paralysis.

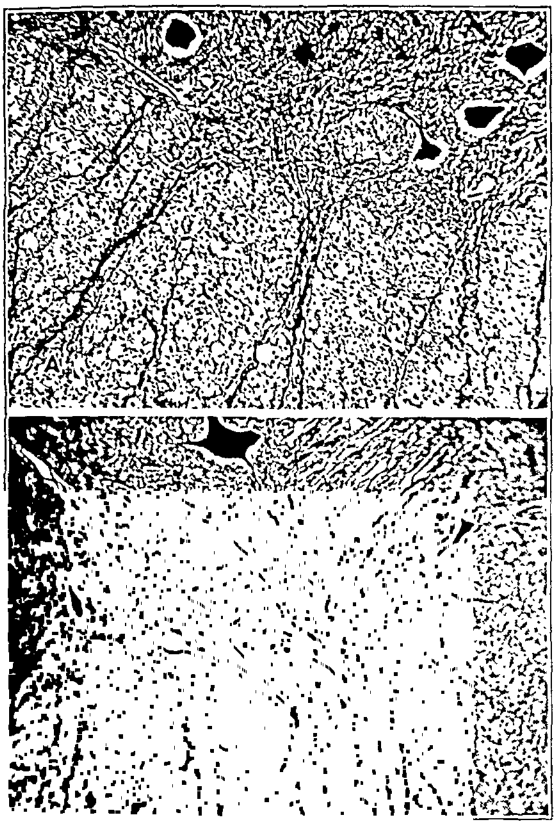

Fig. 3.—*A*, normal axis cylinders in the region of the anterior roots; cervical enlargement seven days after the injection of gravocaine. *B*, swollen and fragmented axis cylinders in the region of the anterior roots in the same animal; lumbar enlargement, seven days after the injection of gravocaine. Davenport stain. Reduced from a photomicrograph with a magnification of 95 diameters.

For the histologic studies, sections were taken from the middle of the cervical enlargement, the mid-dorsal region, the middle of the lumbar enlargement and the sacral region. These were stained by the hematoxylin-eosin, van Gieson, cresyl violet, Cajal silver stain method as modified by Davenport for embedded material, and the Marchi method.

The most constant change from the normal control picture was the apparent meningeal reaction, which was present to a variable degree in each case. It was more marked in those animals which had received the larger doses than in those of the second group. This consisted for the most part of an inflammatory reaction in the arachnoid with a thickening of the membrane and collections of proliferated arachnoidal cells and of plasma cells in the interstices of the membrane (fig. 1 *A*). In some areas there were collections of polymorphonuclear cells, but no bacteria could be found after diligent search. For the most part, the exudates were of the lymphocytic type. In the animals killed after thirty and ninety days, organization of this inflammatory reaction with fibrotic scarring of the meninges could be seen (fig. 1 *B*). This reaction was most marked in the lumbar and sacral regions of the cords examined and gradually diminished through the dorsal and cervical segments.

The changes observed in the ganglion cells are comparable to those described by Spielmeyer[12] following the use of stovaine intraspinally, but were not quite as pronounced as the changes described by him. Occasionally a cell was seen in an acutely swollen condition in the cords of the animals that received the larger doses and that were killed from three to seven days after injection (fig. 2 *A*). The most common picture found was a moderate degree of swelling of the cells, an edema of the nuclear membrane, an eccentricity of the nucleus and a finely granular appearance of the Nissl granules about the periphery of the cell (fig. 2 *B*). This was present in the anterior horn cells of the lumbar and sacral segments of all the animals irrespective of the size of the dosage or the drug injected. This condition is recognized as being a stage of retrograde degeneration. Spielmeyer was able to show that it was due to the action of the anesthetic solution on the anterior roots. We observed also an almost complete failure of some of the smaller cells to stain. The Nissl granules had a faded appearance and the nuclei of the cells stained lightly or not at all (fig. 2 *C*). How-

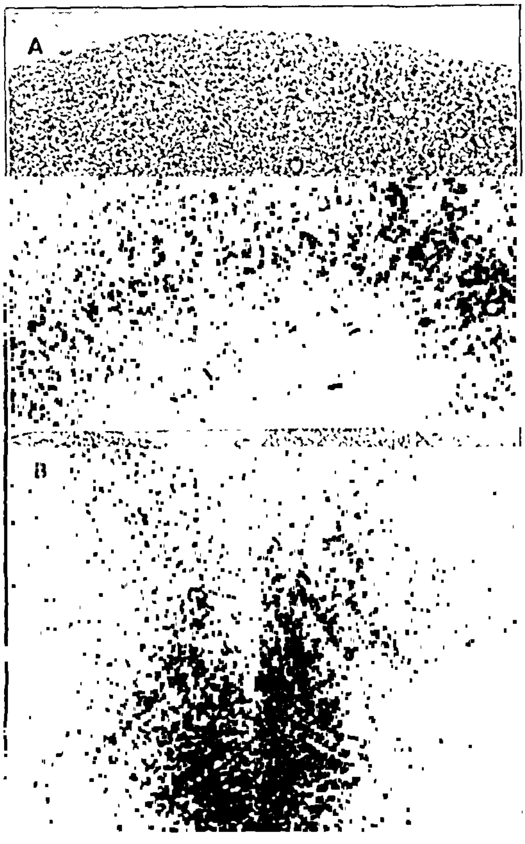

Fig. 4.—*A*, late stages of Marchi degeneration in the anterolateral region of the lumbar cord three weeks after the injection of scurocaine. *B*, degeneration in the posterior columns of the lumbar region three weeks after the injection of nupercaine. Marchi stain. Reduced from photomicrographs with a magnification of 65 and 75 diameters.

[12] Spielmeyer, W.: Veränderungen des Nervensystems nach Stovainanästhesie, München. med. Wchnschr. 55:1629-1634, 1908.

ever, in the cords of those animals killed ninety days after injection we were able to find but few abnormalities in the appearance of the ganglion cells.

After impregnation by the silver stain the axis cylinders showed no abnormalities in the cervical and dorsal regions (fig. 3 *A*). In the lumbar and sacral regions there were swelling and fragmentation of the axons in animals killed after twenty-four and seventy-two hours, seven days and three weeks (fig. 3 *B*).

Specimens of the cords removed twenty and thirty days after injection and stained by the Marchi method revealed the same general picture of degeneration of the fiber tract as shown by Spielmeyer in his experiments with stovaine. The peripheral zones of the cords were affected in all cases to some degree (fig. 4 *A*). In the sacral regions the Marchi bodies were scattered rather diffusely throughout the cord. In the lumbar region the affected fibers were for the most part about the periphery of the cords and were more marked in the zones near the exit of the roots from the cord. In two animals, one with the smaller dosage of nupercaine and one with the larger dosage of spinocaine, an area was noted in the posterior columns in the lumbar region suggestive of ascending root degeneration (fig. 4 *B*). These areas were not seen, however, in the dorsal or cervical regions of the same cords.

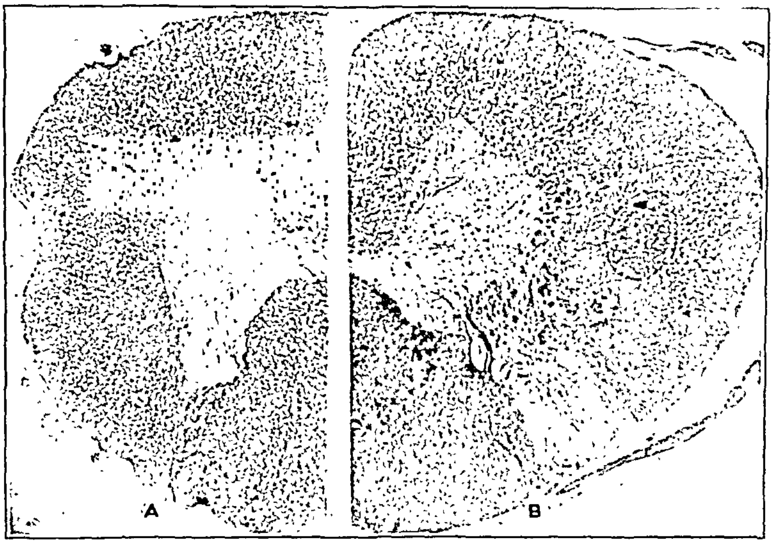

Fig. 5.—*A*, demyelinated zone about the periphery of a cord incubated in 1: 100 spinocaine solution in physiologic solution of sodium chloride. *B*, control incubated in physiologic solution of sodium chloride alone, showing no zone of demyelination. Weil stain. Reduced from a photomicrograph with a magnification of 27 diameters.

Since Weil[13] has recently shown that hemolytic toxins are also myelolytic and in view of the myelin changes noted in the Marchi stained sections of these animal cords, it was decided to conduct the following two experiments:

Following the technic used by Weil, pieces of spinal cord were removed from an animal killed by bleeding and subjected to incubation in various dilutions of these spinal anesthetics. Other pieces were incubated in physiologic solution of sodium chloride as controls. Aseptic precautions were used throughout. The dilutions varied from 1 : 10 to 1 : 200 parts of the anesthetic solution in sterile physiologic solution of sodium chloride. The pieces of cord, after eighteen hours' incubation, were fixed in solution of formaldehyde, embedded in celloidin, and stained with Weil's stain. A zone of demyelination was present about the periphery of all the cords subjected to incubation with the anesthetic solutions, while those incubated in the physiologic solution of sodium chloride alone failed to show this (fig. 5).

Experiments were also performed to determine the hemolytic action of the anesthetic solutions used in the animal experiments. Test tubes containing dilutions of the anesthetics in physiologic solution of sodium chloride, from 1 : 10 to 1 : 320, were set up with controls of physiologic solution of sodium chloride alone. To these were added washed corpuscles of human blood. They were then placed in an incubator at 37 C. for one and a half hours after which time hemolysis was found to be complete in all the tubes except the controls. Similar dilutions and controls were allowed to stand at room temperature for eighteen hours. After this time the control tubes were noted to consist of a layer of corpuscles which had settled in the bottom with clear saline solution above them. The tubes with the anesthetic solutions in them were seen to have a smaller layer of corpuscles in the bottom, a variable layer of reddish coloring above this, and clear fluid on top. An equal amount of the clear fluid from the top was decanted off from each of these tubes into another tube and each diluted with an equal amount of distilled water. The clear fluid was also decanted from above the corpuscles of the control tubes and diluted to the same degree. An equal amount of distilled water was placed in a third tube and an equal amount of physiologic solution of sodium chloride was placed in a fourth tube. To each of these tubes was added five drops of 1 per cent nile blue sulphate solution. The tubes containing the distilled water, the physiologic solution of sodium chloride and the decanted solution from the control tubes were all colored a light blue by the diffusing dye. Those tubes which contained equal amounts of clear fluid decanted from above the hemolysis taking place in the bottoms of the tubes containing the anesthetic solutions were all colored green by the dye diffusing through the solution. This was due to the lipoids which were freed in the solution by the lytic action of the anesthetic solutions on the walls of the red cells. These lipoids apparently diffused through the solution faster than the red color of the hemolysis.

SUMMARY

The spinal anesthetic solutions in common use today are hemolytic as well as myelolytic and would seem to act on the myelin of the nerve fibers as they do on the lipoids of the red blood cell membrane causing its dissolution.

After the injection of the spinal anesthetics in most prevalent use today into the spinal dural sacs of dogs, we have observed the following changes:

1. A varying degree of inflammatory reaction in the leptomeninges.
2. Passive changes in the ganglion cells of the gray matter of the cord similar to those seen in retrograde or so-called wallerian degeneration.
3. Swelling and fragmentation of the axis cylinders.
4. Signs of degenerative changes in the fiber tracts of the cord.

---

[13] Weil, A.: Die Wirkung von Schlangengiften auf Nervengewebe, Arch. f. exper. Path. u. Pharmakol. **154**: 228-238, 1930.

The fact that the last three of these changes were not pronounced in the cords of animals which were allowed to live ninety days speaks against their permanent nature. This is also suggested by the incomplete picture of degeneration in the ganglion cells and the absence of Marchi evidence of degeneration in the cervical and dorsal segments. However, the inflammatory changes in the leptomeninges were so constantly present that they cannot be overlooked.

We hope to extend these studies to the spinal cords of human beings and to incorporate our results with those clinical observations which have been made in a careful neurologic examination of patients who have been operated on under spinal anesthesia. In many instances neurologic complications have been present for as long as a year after the injection of the spinal anesthetic.

COMMON ANOMALIES OF DUODENUM AND COLON: THEIR PRACTICAL SIGNIFICANCE

RESULT OF EIGHT YEARS' COMBINED CLINICAL AND ROENTGEN STUDY *

JOHN L. KANTOR, M.D.
NEW YORK

This paper embodies the result of eight years' study of those anomalies of the digestive tract susceptible of roentgen demonstration. At various times Drs. Samuel Schechter and Jerome A. Marks have collaborated in this research. The material used for this study comprises a consecutive series of 3,000 private patients complaining of digestive disorders, approximately three fifths of whom had test meals and roentgen surveys in addition to the routine history and physical examination. The statistical method of attack was employed throughout in the belief that this would yield results most likely to be objective in nature and most open to confirmation or refutation by others. Having no preconceived notions to establish, we have been satisfied with presenting the facts first, leaving the matter of speculation to follow later. Nevertheless, before proceeding to a more detailed consideration of individual anomalies, it may be of value to formulate certain generalizations that have grown out of our study:

1. Anomalies may be regarded as expressions of organic constitutional inferiority or, in other words, points of actual or potential weakness in the body structure.

2. Anomalies may be divided into three classes: those incompatible with life (congenital atresia of the bile ducts), those compatible with life but not with robust health (high grade visceroptosis), and those compatible with life and health under favorable circumstances (uncomplicated Meckel's diverticulum).

3. The general tendency seems to be for the body as a whole to compensate for the presence of an anomaly. Hence symptoms do not occur unless this compensatory mechanism breaks down. This break may result from any of the following causes:

(*a*) Mechanical factors, such as strangulation of a silent Meckel's diverticulum.

(*b*) Infection, which may change a diverticulosis into a diverticulitis.

(*c*) Juxtaposition of two or more anomalies, such as the presence of ectopic gastric mucosa in a Meckel's diverticulum, which may lead to hemorrhage or perforation.

(*d*) Old age and increasing asthenia, especially prominent in the case of all hernias and herniations, in which the weak spots exist from birth but the fully developed condition occurs later in life.

(*e*) Associated functional instability. When neuroses and anomalies coexist, the former furnishes the underlying functional instability—the break in compensation—and the anomaly furnishes the particular digestive symptomatology for the clinical picture.

4. Because of variations in the compensatory mechanism, the symptomatology of anomalies is not continuous or progressive as in ordinary diseases. Thus, anomalies may cause symptoms in some of their owners all of the time, and in all of their owners some of the time, but are under no obligation to cause symptoms in all of their owners all of the time. This is the chief single differential between an anomaly and an acquired lesion and is of great importance in appraising the practical significance of anomalies.

In this paper we plan to bring up to date our original observations on anomalies of the colon and to present, in addition, some new data concerning the subject of duodenal bands.

DUODENAL BANDS

Historical Outline.—The occurrence of structures variously described as veils, membranes, adhesions, bands or ligaments in the right upper quadrant of the abdomen has long been known to anatomists. As far back as 1845, Huschke[1] described the ligament (ligamentum hepaticoduodenale) which bears his name. Since then, noteworthy anatomic studies have been contributed by Ancel and Sencert,[2] Harvey,[3] Bryant,[4] Makai[5] and Diebold.[6] In the past twenty-five years, surgeons have rediscovered these structures, the most important contributions being those of Morris,[7] Konjetzny,[8] Harris,[9] Homans,[10] Bainbridge,[11] Widerøe,[12] Taylor,[13] and the Kelloggs.[14] A careful roentgen study was made by Cole[15] in 1922. The outstanding clinical contributions are those of Niles,[16] and Duval, Roux and Béclère.[17] Transduodenal bands in children were studied clinically by Neff and Haden,[18] and were discussed at a symposium before the New York Academy of Medicine by Stockard,[19] Imboden,[20] Haynes[21] and Farr.[22] Despite the work done to date, it seems safe to say that this condition, especially its clinical picture, is not yet well understood by the profession at large.

Description and Roentgen Appearance.—Duodenal bands represent anatomically the unabsorbed portion of the free edge of the lesser (hepatogastric) omentum and are called variously hepatoduodenal, hepatocolic or cystocolic ligaments, depending on the actual course of the anomalous membranes. They either cross or are attached to the duodenum in its first or second portion. When the first portion alone is involved, various deformities of the cap are produced in the roentgen appearance. This group is not discussed here, the present study dealing exclusively with bands involving the second portion of the duodenum. The latter cause a characteristic roentgen appearance (fig. 1) when the patient is examined in the erect anteroposterior position immediately after the stomach has begun to empty the opaque meal. Under these circumstances the second portion of the duodenum appears pulled out to the right (for a varying distance and at a varying angle) instead of descending parallel to or behind the antrum of the stomach, as in the normal condition. In extreme cases the entire second portion is displaced in this fashion, but in others only the uppermost part and less often some other segment of the descending limb is so involved. In many cases a sharp angle results between the fixed upper and the free lower portion. This arrangement acts as a point of irritation or transient obstruction. Marked stasis, such as is usually described in the literature under the term "duodenal obstruction," is not noted. Retroperistalsis was observed in at least 10 per cent of our cases. Adhesions to the hepatic flexure of the colon were occasionally demonstrable. The most common associated anomaly is a low cecum, which we observed twice as often (36 per cent) as in our unselected material (18 per cent).

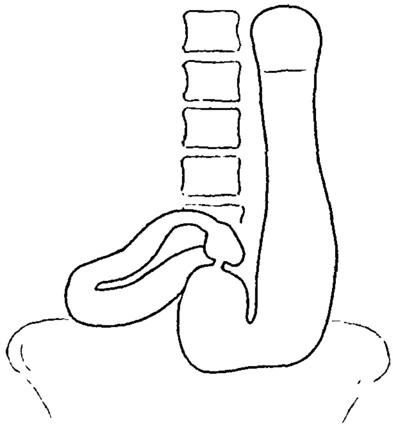

Fig. 1.—Roentgen appearance of duodenal bands pulling second portion of duodenum to right.

Most of the bands in the right upper quadrant are undoubtedly of congenital origin, although of course it would appear that acquired adhesions may also occur. Harvey found that the development of the cystocolic fold reaches a stable condition sometime previous to birth, and Bryant has shown that the incidence of these bands in the fetus is practically the same as that in the adult up to the age of 40 years. Makai found them frequently in infants and young children.

Incidence.—Adhesions of the second portion of the duodenum were encountered 85 times in our series of 1,754 roentgenographed patients, an incidence of 4.8 per cent. A search of the literature discloses no exactly comparable figures, but anatomic studies of the bands in this neighborhood, viz., hepatoduodenal, hepatocolic and hepatoduodenocolic, reveal an incidence of from 15.5 to 30 per cent. In fact, Bryant has shown that the hepatocolic ligament is the most frequent congenital adhesion in both sexes and at all ages. This discrepancy between the roentgen and the postmortem evidence can probably be explained either by the fact that adhesions of the first portion are excluded in our present series, or because the existence of some of the bands may have been overlooked at examination. The presence of duodenal bands was operatively confirmed in six of our cases.

Table 1.—*Duodenal Bands*

Incidence	Per Cent
General, in 1,754 roentgenographed patients	5
Sex:	
Females	79
Males	21
Habitus:	
Asthenics	53
Sthenics	8
Associated low cecum (general incidence 18%)	36
Clinical Features	Per Cent
Nausea (general incidence 15%)	44
Headaches (general incidence 23%)	44
Vomiting (general incidence 20%)	41
Vertigo (general incidence 3%)	20
Constipation (general incidence 46%)	54
Pain, upper abdominal (general incidence 28%)	40
Appendicitis, operation (general incidence 17%)	17
Appendicitis, "pus" (general incidence 16%)	8

Sex.—Sixty-seven of our patients (79 per cent) were females and 18 (21 per cent) were males. Practically the same incidence is reported by other clinical observers. Thus, Niles gives 80 per cent females in thirty-nine cases, and Taylor gives 74 per cent females in forty-seven cases chiefly of this variety. On the other hand the anatomists report that the distribution of these bands is approximately equal between the sexes (Bryant, 297 cases), or else decidedly favors the males (Harvey, 20 cases; Ancel and Sencert, 124 cases; Makai, 100 cases). The explanation of this discrepancy is not yet at hand.

Habitus.—In our group, forty-five patients (53 per cent) were asthenic and but seven (8 per cent) were sthenic.

Symptoms.—Only ten (11.7 per cent) of our cases showed no symptoms that could be definitely referred to the presence of duodenal bands. In the majority of cases the symptoms are characteristic enough to constitute a fairly definite clinical picture. The manifestations may be described as falling into two groups: reflex or toxic, and local. The former have been described in the literature under the name "duodenal migraine." They are in every way comparable to the reflex manifestations of low cecum. Nausea was present in thirty-eight cases, an incidence of 44 per cent, which is to be contrasted with a general incidence of 15 per cent in our 3,000 unselected cases. Headaches were also present in 44 per cent, to be compared with a general incidence of 23 per cent. Vomiting, frequently of bile, was present in thirty-five cases, an incidence of 41 per cent, as against a general incidence of 20 per cent. Vertigo was present in 20 per cent, as against a general incidence of 3.5 per cent. Constipation occurred in forty-six patients, an incidence of 54 per cent) somewhat higher than the general frequency of this complaint (46 per cent).

[22] Farr, C. E.: Developmental Peritoneal Bands in Children, unpublished manuscript, 1931.

All these complaints are closely linked with the nervous instability of these patients, as in the case of low cecum, which will be described later.

The local symptoms are epigastric distress or pain. Pain occurred in forty-four cases, or 40 per cent, but, as associated organic lesions could not be excluded in thirteen cases, the incidence of pain due to bands as such is perhaps to be conservatively estimated as being nearer 25 per cent. In any event, our observations correspond closely to those of Niles (30 per cent "painful cases"). The pains are either of the hunger type suggestive of duodenal ulcer or of the more irregular and spasmodic type resembling gallbladder disease. However, their intensity seems to be less than in organic lesions. As may be expected, they are referred to the middle and right portions of the epigastrium. They are sometimes relieved by food and by the recumbent prone or right lateral position.

A previous appendectomy had been performed in 30 per cent of our cases (general incidence, 17 per cent), and a pus condition (general incidence, 16 per cent) was revealed in only 8 per cent of this number. The high incidence of this operation, which has also been pointed out by Taylor and Niles, may possibly be explained by the relatively frequent association of low cecum, a condition in which the incidence of previous appendectomy is unusually high.

Explanation of Symptoms.—It has been emphasized that in the cases we are discussing there is no gross obstruction but rather a relatively mild irritation of the duodenum associated with transient stasis or reversal of motility. Clinically, it is well known that a small delay high in the intestinal tract may be followed by more widespread systemic upset than a much greater stasis lower in the bowel. It has been shown experimentally by Ivy,[23] Keeton,[24] Wheelon[25] and others that the nausea, vomiting and many related symptoms (all of which may occur in the cases under discussion) are elicited by duodenal stimulation or irritation. It is particularly interesting to note that, of the sixty patients in whom Keeton injected solutions into the duodenum, twenty-six, or 43 per cent, showed nausea. Since this figure corresponds exactly with the incidence of nausea and vomiting in our cases, it may possibly represent the actual average frequency of response by vomiting to duodenal irritation in the human subject.

The association of low cecum with duodenal bands (also mentioned incidentally in some of Taylor's protocols) may still further increase the temporary duodenal stasis. The possible mechanism involved will be discussed later.

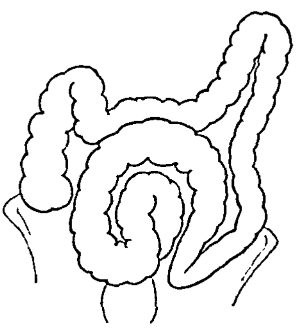

Fig. 2.—Redundant colon: large central pelvic loop.

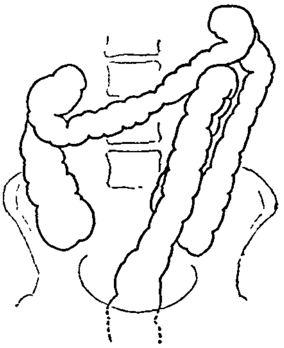

Fig. 3.—Redundant colon: double splenic flexure with straight efferent loop.

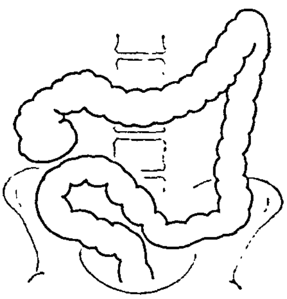

Fig. 4.—Redundant colon: pelvic loop to right.

Treatment.—Medical management suffices to control the symptoms in most cases. The treatment should be directed toward correcting the ptosis and malnutrition, improving the nervous stability and restoring the colon function. Rest in the prone position after meals, and hot saline drinks in the fasting state are sometimes helpful. If conservative measures fail, results may be expected from surgical therapy. The procedure consists essentially of division of the adhesions; in some cases short circuiting operations are needed. Four of our own patients were operated on, all with relief, the longest period of observation being three years. In Taylor's cases, 32 per cent of the patients were cured and 52 per cent were much relieved. The operative mortality was 2 per cent. Niles "knows of no abdominal condition which affords a greater assurance of relief by surgery." It is obvious that such good results can be secured only by careful study, observation and selection of cases.

REDUNDANT COLON

Description and Roentgen Appearance.—The redundant colon (dolichocolon) is one which is too long to fit into the body of its owner without undergoing reduplication. The distal colon is the part usually though not invariably affected, the most common variety being an enlarged sigmoid loop centrally placed and rising well out of the pelvis (fig. 2). Two subvarieties are encountered often enough to receive the descriptive terms "double splenic flexure with straight efferent loop" (fig. 3) and "pelvic loop to the right" (fig. 4). Kinks of the colon, presumably due to adhesions, are rather frequent. Of these, 107 cases were encountered in our series but have been excluded from the group of true redundant colons and are not here discussed. Hirschsprung's disease differs from the redundant colon by the presence of enormous dilatation of the affected loops in the former.

The diagnosis of redundant colon is made by roentgen examination after the opaque enema to show the form, and after the opaque meal to show the function, of the large intestine. The amount of enema fluid necessary to fill to the cecum averages 46 ounces in redundant colons and has reached as high as 120 ounces. These figures are to be contrasted with the average 38 ounces required to fill the normal colon completely.

In many cases the stomach is displaced and deformed. The usual displacement is to the right and, since the cardiac end is fixed, the resulting appearance has been termed "cascade" stomach. In some cases the stomach is inverted or rotated on its horizontal axis so that it becomes retort shaped.

[25] Wheelon, Homer: Symptoms Associated with Duodenal Retention and Reverse Motility, J. A. M. A. **86**: 326-330 (Jan. 30) 1926.

Incidence.—In 1,614 roentgenographed patients, 258 cases of redundant colon were encountered, an incidence of 16 per cent. Analysis of this relatively large group shows that the anomaly affects both sexes (54 per cent females) and both extremes of habitus (28 per cent sthenics vs. 24 per cent asthenics) with approximately equal frequency. Previous discrepancies may be explained on the basis of insufficient material.

Clinical Picture.—Since the publication of our first study [26] in 1924, other clinicians (Larimore,[27] White,[28] Gauss,[29] Dagnino [30]) have agreed that this anomaly probably represents a definite entity with a constant incidence and clinical picture. Although, as with all anomalies, symptoms may be absent or variable, the combination of constipation, pain and gas distress is characteristic.

Table 2.—*Redundant Colon*

INCIDENCE	Per Cent
General, in 1,614 roentgenographed patients	16
Sex:	
Females	54
Males	46
Habitus:	
Sthenics	28
Asthenics	24
CLINICAL FEATURES	**Per Cent**
Constipation (general incidence 46%)	69
Gas distress (general incidence 38%)	70
Pain, abdominal (general incidence 47%)	52
Pain, right lower quadrant (general incidence 9%)	12
Tenderness right lower quadrant (general incidence 19%)	24
Appendicitis, operation (general incidence 17%)	19
Appendicitis, "pus" (general incidence 16%)	16

The constipation, which is present in 69 per cent of cases (general incidence, 46 per cent), usually dates from birth, is characterized by long intervals between stools (often one week), and is on the whole not associated with marked systemic or general upsets. Gas distress is present in 70 per cent of cases as against a general incidence of about 38 per cent in our unselected material. There is often localized distention corresponding to the redundant loop, or else belching in a misdirected effort to relieve pressure in the splenic flexure.

Pain is present somewhere in the abdomen in 52 per cent of the cases (general incidence, 47 per cent). It is always due to superimposed spasm proximal to the point of redundance and may be associated with localized colitis, especially in patients who have acquired the cathartic or enema habit. The pains may suggest carcinoma, heart disease, gallbladder disease or appendicitis. Pain in the right lower quadrant was present in 12 per cent (general incidence, 9 per cent), and tenderness in the right lower quadrant occurred in 24 per cent (general incidence, 19 per cent). Appendectomy was performed in 19 per cent as compared to a general incidence of 17 per cent in our basic 3,000 cases.

Volvulus, although not encountered in this series, can occur only when the mesentery is elongated, as in redundant colons. It is our opinion, confirmed by the actual observations of several surgeons, that this accident usually follows violent efforts at purgation, resulting in irregular and atypical peristalsis.

Treatment.—The management of redundant colon consists essentially in the withdrawal of all forms of colonic abuse and the restoration of normal function by conservative procedures. The details of this therapy have been published elsewhere. The prognosis for relief is good. Surgical intervention should be reserved for cases of volvulus only.

THE HIGH CECUM

Description and Roentgen Appearance.—The cecum may be arrested in its embryologic descent at any stage between the liver and its normal resting place, which is the middle of the right iliac fossa. Since subhepatic ceca are rare (fig. 5)—we encountered but twenty-one cases in which the cecum was at or above the iliac crest—we have included all ceca occupying a position not lower than the upper third of the iliac fossa in a group which we have arbitrarily designated "high cecum" (fig. 6). The exact roentgen criteria delimiting this group have been published elsewhere.[31]

The diagnosis of high cecum is best made roentgenologically nine hours after the ingestion of an opaque meal. In some cases the cecum is attached to the liver, but the proximal transverse colon hangs down, festoon-like, in such fashion as to resemble a normal ascending segment. This may cause confusion unless observations are made in the right oblique position. In some 4 per cent of cases (general incidence, 2 per cent) the vacant right iliac fossa is occupied by a loop of pelvic colon. This arrangement has already been described as a subvariety of the redundant colon. Its recognition is of some clinical importance because it may still further confuse surgeons in their attempt to locate the ectopic appendix in emergency operations in cases presenting high cecum.

Table 3.—*High Cecum*

INCIDENCE	Per Cent
General, in 1,583 roentgenographed patients	6
Sex:	
Males	73
Females	27
Habitus:	
Sthenics	71
Asthenics	5
CLINICAL FEATURES	**Per Cent**
Headaches (general incidence 23%)	18
Vomiting (general incidence 20%)	20
Constipation (general incidence 46%)	35
Appendicitis, operation (general incidence 17%)	24
Appendicitis, "pus" (general incidence 16%)	36

Incidence.—In our series of 1,583 roentgenographed cases, high ceca were observed in 102 (6 per cent). Males predominated strikingly over females (73 per cent vs. 27 per cent), as did sthenics (71 per cent) over asthenics (5 per cent).

Clinical Picture.—On the whole, this group is composed of robust individuals remarkably free from the common manifestations of functional digestive upset. In this respect they offer a striking contrast to the group of patients with low cecum next to be described.

Using headaches and vomiting as typical expressions of functional digestive disorders, we find that the incidence of these complaints (18 per cent and 20 per cent, respectively) is about that in normal ceca (i. e., in the general series) but is decidedly less than in low ceca.

Recalling the high incidence of constipation in redundant (long) colon, viz., 69 per cent, it is interesting to observe that constipation occurs in but 35 per cent of cases of high cecum. Since this figure is also appreciably lower than the general incidence of constipation in nonselected cases, it would appear safe to make the generalization that constipation varies directly as colonic length.

The relation of high cecum to appendicitis is interesting. In the first place, the appendix being located at or near the liver, instead of in the right iliac fossa, the clinical picture may resemble acute cholecystitis more than appendicitis. Furthermore, the presence of actual inflammation ("pus appendix") is over twice as likely (36 per cent) in high cecum as in the average appendectomy case (16 per cent) and more than three times more likely than in low cecum (10 per cent).

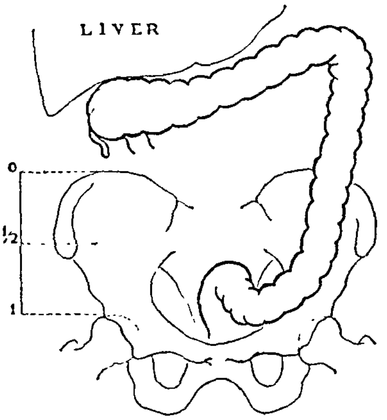

Fig. 5.—High cecum: subhepatic position (rare).

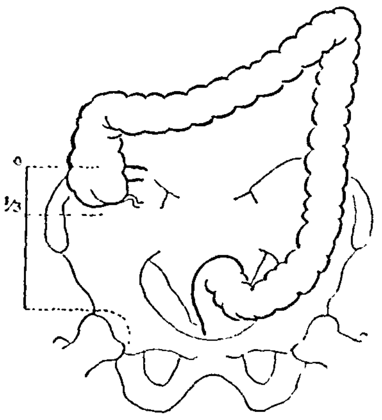

Fig. 6.—High cecum: common variety.

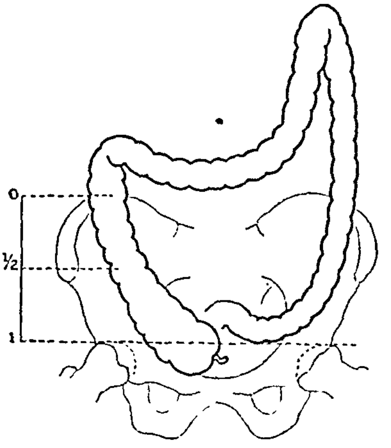

Fig. 7.—Low cecum, showing roentgen landmarks.

Treatment.—High cecum, as such, requires no treatment. One should take no chances with symptoms suggesting appendicitis and must be prepared to find the appendix high in the abdomen.

THE LOW CECUM

Description and Roentgen Appearance.—The low cecum is the result of embryologic hyperdescent, the organ prolapsing below the right iliac fossa into the true pelvis. The anomaly furnishes a complete and striking contrast to the high cecum just described.

The diagnosis of low cecum is best made nine hours after the ingestion of the standard opaque meal. This anomaly may be said to exist when the cecal tip reaches down to or below the midpelvis, as determined by a horizontal line connecting the tops of both acetabular cavities on the standard prone film (fig. 7). In accordance with our concept that the low cecum represents a true overgrowth rather than a local expression of ptosis, the length of the cecocolon in these cases is increased from the average 7 inches (17.8 cm.) in the normal cecum to an average of 9 inches (22.9 cm.), with the maximum reaching 13 inches (32.5 cm). The cecal tip was fixed in 32 per cent of the cases. The rest of the cases showed a mobility of more than 1 inch (2.5 cm.).

The most common associated anomaly was represented by duodenal bands, as previously described, which occurred in 11 per cent of cases; i. e., over twice the general incidence.

Incidence.—The low cecum is the most common anomaly of the colon. It was observed 284 times in our series of 1,581 roentgenographed patients, an incidence of almost 18 per cent. Women make up 72 per cent of the patients, and asthenics predominate over sthenics in the proportion of four to one (48 per cent to 12 per cent).

Clinical Picture.—Low cecum is, we believe, responsible for a definite symptomatology. The complaints are of two orders; namely, general and local. The general symptoms are those ordinarily regarded as reflex or toxic in character. Chief among these are vomiting, which occurred in 43 per cent (general incidence, 20 per cent), and headache, which occurred in 38 per cent (general incidence, 23 per cent).

The vomiting in these cases is habitual and rather easy, being provoked by strain, fatigue, emotional excitement, dietary indiscretion, menstruation and headaches. The patient may take this symptom so much for granted that she may fail to mention it in the history unless specifically questioned.

Table 4.—*Low Cecum*

INCIDENCE	Per Cent
General, in 1,581 roentgenographed patients	18
Sex:	
Females	72
Males	28
Habitus:	
Asthenics	48
Sthenics	12
Associated duodenal bands (general incidence 5%)	11
CLINICAL FEATURES	**Per Cent**
Vomiting (general incidence 20%)	43
Headaches (general incidence 23%)	38
Pain, right lower quadrant (general incidence 9%)	13
Tenderness, right lower quadrant (general incidence 19%)	23
Appendicitis, operation (general incidence 17%)	24
Appendicitis, "pus" (general incidence 16%)	10

The headaches are often of the migraine type and are caused by the same factors as is the vomiting. Both these major manifestations may be represented by less severe symptoms. Thus, vomiting may be replaced by nausea, train sickness or car sickness, and headaches by vertigo. These patients often exhibit other stigmas of physical, nervous or emotional instability.

The local symptoms are referable to the right lower quadrant. Spontaneous pain in this region, which occurs in 9 per cent of all patients, is observed in 13 per cent of cases of low cecum. Tenderness in the right lower quadrant is also present more often (23 per cent) than in the general series (19 per cent). When cecal stasis is associated with low cecum, the figures increase to 21 per cent and 28 per cent, respectively. It is undoubtedly for this reason that patients with low cecum constitute the most frequently appendectomized group of colon anomalies (24 per cent vs. 17 per cent, general incidence). Appendix removal is obviously unwarranted in most cases because: (1) There is nothing in the history of low cecum on which a diagnosis of appendicitis can be properly based, and (2) the observations at operation show the smallest proportion of "pus" cases of any group of colon anomalies that we have studied; namely, 10 per cent as against a general incidence of 16 per cent and an incidence in high cecum of 36 per cent.

Explanation of Symptoms.—In our original article [32] on low cecum, no explanation was offered for the symptoms encountered. Although it can hardly be claimed that the problem of mechanism has been solved, it is felt that progress has been made in the intervening six years. According to our present conception, the explanation is somewhat complicated and probably embraces the following considerations:

1. The local symptoms are presumably caused by cecal or proximal colon stasis.[33] These conditions are from one and a half to three times more common in low than in normal or high cecum. The pain and tenderness may therefore be readily explained by increased intracecal tension (local spasm).

2. To account for the reflex toxic symptoms, two distinct hypotheses are conceivable. According to the first, the cause resides in the cecum, cecal stasis with absorption of a toxin being the responsible factor. The available evidence is against the acceptance of any such hypothesis. Not only has no toxin been identified, but actual analysis of cases has shown that it is only in low ceca that cecal stasis is associated with increased frequency of headache and vomiting. Cecal stasis in normal or high ceca does not act so. Therefore the symptoms cannot be due to stasis as such, because this should be equally operative in all locations of the cecum.

According to the second hypothesis, the cause of the symptoms resides in the duodenum, where transient stasis is produced, no gross obstruction taking place. The transient retentions are assumed to result from the intermittent drag of the low cecum, the pressure being mediated through any of the structures that cross the second or third portion of the duodenum. These structures are the transverse mesocolon, crossing the second portion, and the right and middle colic artery, the superior mesenteric artery, and the root of the mesentery of the small intestine crossing the third portion. According to this view, the actual occurrence of symptoms would be favored by such features as the erect posture, stasis in the cecum, mesenterialization (hypofixation) of the ascending colon with increased mobility of the cecum, and the presence of duodenal bands. The latter adhesions would, by fixing the duodenum, tend to "step up" the effect of colonic dragging so that subminimal stimuli might become effective. The possible rôle of colonic hyperfixation has not yet been adequately appraised but is now being studied.

This theory receives perhaps its chief support from the publications of Bloodgood,[34] Kellogg, Quain,[35] Carslaw,[36] McConnell,[37] Nesbitt [38] and Duval, who have observed the rôle played by "prolapsed ceca," "giant ceca," and "right coloptosis" in the production of gross duodenal obstruction. Bloodgood, for example, actually resected the right colon in eleven cases of chronic dilatation of the duodenum and found these patients well, up to fifteen years later. Other surgeons have performed colopexy, with relief in similar obstructive cases. As already mentioned, in none of our patients were the symptoms so pronounced as to warrant surgical intervention.

Treatment.—The medical management of low cecum consists in treating the asthenic habitus, controlling the neurosis, fattening the patient, and relieving the cecal stasis, which may be accomplished by treating the distal constipation when present, thus clearing the track ahead.

Surgical treatment may be considered in those rare cases which, after careful study and prolonged and conscientious conservative treatment, show no evidence of improvement, though the patients demand that something be done for their relief. Under such circumstances, colofixation may be attempted.

SUMMARY

1. Statistical data resulting from eight years' combined clinical and roentgen study are presented for the following anomalies: (*a*) transduodenal bands, (*b*) redundant colon, (*c*) high cecum, and (*d*) low cecum.

2. The chief clinical aspects of transduodenal bands are their occurrence in asthenic women, their association with "duodenal migraine," and their mimicry of duodenal ulcer and gallbladder disease.

3. The chief clinical aspects of redundant colon are its occurrence in all builds and both sexes, its association with marked constipation and, less strikingly, with pain and gas.

4. The chief clinical aspects of high cecum are its occurrence in eupeptic sthenic males, and the ectopic position and increased tendency to inflammation of the appendix.

5. The chief clinical aspects of low cecum are its occurrence in asthenic women and its association with headaches and vomiting, and discomfort in the right lower quadrant.

6. An explanation is offered for the mechanism of the production of the toxic or reflex symptoms in low cecum.

7. The general significance of digestive anomalies is summarized.

GRIPPAL INFECTIONS

POSTFEBRILE CARDIOVASCULAR DISTURBANCES, USUALLY UNRECOGNIZED: REPORT OF CASES *

CLARENCE L. ANDREWS, M.D.
ATLANTIC CITY, N. J.

Many patients come to Atlantic City to recuperate after grippal infections, and they offer an unusual opportunity for study of the postfebrile and convalescent stages of this interesting disease in various types of people.

There seems to be a feeling on the part of many physicians that "grip" is nothing more than a systemic cold and, because of the time honored relationship between acute colds and beginning respiratory disease, that the severity of an attack of grip is always dependent on the involvement of the bronchial tubes and the lungs, and all other complications have no further significance than that they do occur; if a patient escapes pneumonia or other complications of the chest, he is quite all right.

There is, to begin with, a marked variance of opinion concerning what an attack of grip may do, and unless the possibility of a general infection is suspected, complications other than those of the respiratory system will not be appreciated.

Are other organs besides the lungs apt to become involved in grippal infections or do the various systems of the body show changes following every acute illness, regardless of what it may be? That is, does the heart muscle become impaired during grip, whether recognized or not, or must one presume that the recuperative powers of the myocardium are so great following any infection that one cannot say that heart disease exists, until a greater disturbance has taken place than is usually manifested by cardiac weakness or impairment of function?

These are important questions as far as treatment is concerned and should be answered intelligently, if there is to be hope of doing more for incipient myocardial disease in the future than has been done in the past.

The clinical interpretation of physical observations in heart disease has likewise passed through many phases during recent years and may help to explain why many physicians do not consider that myocardial disturbances have occurred during such acute diseases as grip unless the heart shows outspoken evidences of structural changes.

One diagnostic dogma regarding the efficiency of the heart muscle has been replaced by another, only in turn to be superseded by a newer conception of what has happened or by a more concise means of interpreting clinical facts.

Prior to thirty or thirty-five years ago, only organic valvular lesions were accepted as indicating definite cardiac disease. Any heart not showing such defects was considered normal. Hypertrophy and dilatation were the results of incompetent valves and were rarely thought to be of primary origin.

Following the advent of the x-rays and of cellular pathology, a second group of heart diseases was added because cardiac enlargement could be demonstrated without the presence of valvular abnormality.

With the introduction of the electrocardiogram, a third group, which was not suspected before, came into being; namely, disturbances in heart muscle and nerve conduction, and evidences of coronary disease.

During the World War, a fourth group was encountered, which did not show any valvular abnormality, or enlargement on roentgen study or any disturbances detectable by the electrocardiogram. The patients in this group were physically unfit, nevertheless, and were as much of a cardiac riddle as any type had been in the past. Through lack of a better name, this condition was called cardiovascular asthenia, or the effort syndrome.

Several years ago, Christian added another group of incipient myocardial disease, with beginning hypertrophy without other evidences of heart abnormality. Christian felt that a heart that enlarged, from any cause whatever, was no longer normal and that, although enlargement was generally regarded as a physiologic step in normal compensation, it was, in reality, beginning myocardial retrogression.

It is my purpose to discuss another type of cardiac instability or weakness following grip, which apparently is not appreciated or generally recognized. These cases presented none of the usual evidences of cardiac disease; that is, they showed no leaky valves, no increase in the size of the heart under roentgen study, and no changes in the electrocardiogram; they were not of the effort syndrome type, and they were not what Christian referred to as early hypertrophy.

Moreover, the patients did not give histories of previous hypertension or hypotension and were not beyond 50, when myocardial changes incident to age are expected to begin. In other words, they were selected from individuals who were physically fit, prior to their attack of grip.

They all showed a marked weakness of the cardiovascular system following exercise and were physically incapacitated until this disturbance was corrected. Hence there is ample clinical evidence to make one believe that these conditions if allowed to go too long become important etiologic factors in heart muscle weakness, if they do not develop into definite myocardial disease.

There is a tremendous difference between grip and the old fashioned systemic cold. If this fact were better appreciated, many of the circulatory tragedies that come into our offices might be prevented. Moreover, there seems to be no relationship between the duration of an attack of grip and the degree of myocardial weakness that follows. In fact, some patients who are not conspicuously ill have the most prolonged convalescence, or experience the greatest difficulty in recovering. Those who have pneumonia or severe bronchitis seem to react best or recover soonest.

Because of the nondramatic symptomatology of these apparently trivial illnesses, many physicians ascribe the weakness and nervous upheaval of the patients to other causes, such as added expenses, increased worries and the desire to get back to business, all of which, of course, means that the patient is not properly examined.

Is the thought too far afield to suggest that there is considerable clinical evidence to make one feel that the virus of grip, or whatever the organism may be, attaches itself to the tissues of the body in some unknown manner, where it may inflict damage to the myocardium by toxic absorption over a long period of time? Such a possibility would help to explain the marked circulatory weakness found in patients presenting the nonsevere forms of grip who have previously been all right. If this attachment does not occur, how

---

* Read before the Section on Practice of Medicine at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

can one explain the profound physical incapacity of these patients for so many weeks and months?

They all present practically the same type of history and date their weakness and loss of "pep" from their attack of grip several weeks or months before. Hence there is no illness (except possibly rheumatic fever or acute endocarditis) in which the physician should make so certain that the patient is not harboring a focus of infection that might enter the blood stream and damage the heart muscle, as in grip.

I wish to make an earnest plea for more serious consideration and thought being given these milder forms of grip during the convalescent stage. One sees individuals who have not felt well since their attack of grip, as long ago as ten years; yet many emphasize the fact that they were not critically ill. They probably got up too soon, or long before the processes of repair had taken place. Today, their chief abnormality is myocardial weakness. Hence one must presume that the milder forms that are now seen, if neglected, may show the same type of clinical symptoms in ten years.

One of the worse habits in clinical procedure is to allow certain diagnostic dogmas to become so firmly fixed in mind that nothing else can be seen. The feeling that most heart defects are dependent on valvular disease, that myocardial inefficiency is in proportion to the enlargement of the heart, and that the pulse rate is a true index of heart muscle tone has done more to cloud the true significance of early myocardial changes following acute infections than anything else.

Unfortunately there are no detectable means of accurately measuring myocardial disease. The muscle may be severely damaged and yet not show any specific evidence of what has occurred. This is best shown by referring to the myocardial changes during pneumonia. What is it that so weakens the pneumonic heart? No one knows, unless it is a toxic condition. Nothing is found that enables the pathologist to say "This is a pneumonic heart." So it is with grip. The heart muscle is markedly weakened, but nothing specific is seen.

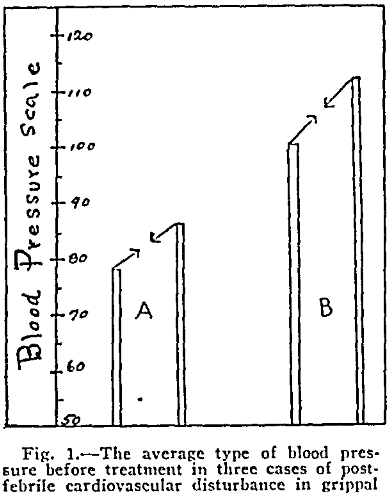

Fig. 1.—The average type of blood pressure before treatment in three cases of postfebrile cardiovascular disturbance in grippal infections: *A*, diastolic pressure poorly supported, indicating lack of muscle tone; *B*, systolic pressure like pulsus alternans, weak muscle, poor tone.

There is too great a tendency on the part of many to get away from the fundamentals of diagnosis that characterized the skill of the clinicians of a few decades ago. They did not practice short cuts to diagnosis but sought what they found. Today we have canned diagnosis as well as canned soup. If the can is empty there is no soup.

All physicians have patients with loud cardiac murmurs who live to a ripe old age; others with myocardial degeneration who show little evidence of muscle change, and still others with normal pulse rates, who present little suggesting cardiac injury but who later prove to have been severely hit. What one sees or hears alone, therefore, may not reveal the true status of heart muscle efficiency or explain all about cardiac disease. Muscle weakness is the most common of heart defects, and valvular leaks the most rare.

Although one may not feel that all heart muscle change is myocarditis, there is, nevertheless, no organ of the body more in physiologic sympathy with toxic absorption and bacterial invasion than the heart. The fact that the myocardium may ward off serious bacterial injury and may recover from every toxic strain, if given a fair chance, does not prove that the muscle has not been involved or should not be most carefully guarded for weeks and months after the febrile stage has subsided.

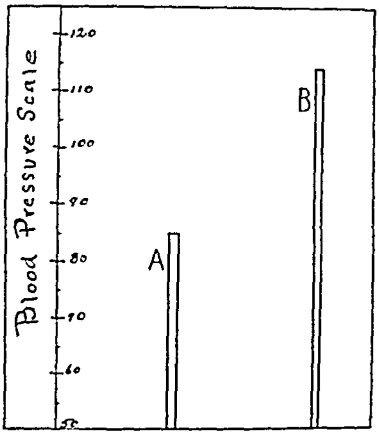

Fig. 2.—The average type of blood pressure after treatment in three cases of postfebrile cardiovascular disturbance in grippal infections: *A*, diastolic pressure, better supported or better tone; *B*, systolic pressure, better supported or better tone.

REPORT OF CASES

A typical case is taken from each of the three principal groups:

1. A patient who was acutely ill for four or five days and got up without return of fever.
2. A patient who was acutely ill for three or four days, got up, and the fever returned. He was in bed three or four days a second time.
3. A patient who was acutely ill for five or six days, got up, returned to work and forced herself along for two months, when her condition was diagnosed as nervous breakdown and she was sent home; as she still did not improve, she came to the seashore.

Case 1.—A. B., a white man, aged 38, the office manager of a manufacturing concern, complained of great physical weakness following the slightest effort and of loss of pep. The family history was irrelevant. He had always considered himself physically fit. He had played golf and had gone on long trips in the mountains, without fatigue. The present illness began rather suddenly, four weeks before, with aching pains and chilly and cold sensations, followed by perspiration. The temperature was 103 F., the pulse 76, and respiration 17. There was no cough or any upset of the gastro-intestinal tract. After the patient had been in bed four days, with temperature ranging from 101 to 103 F., he perspired profusely and the temperature became normal. He got up the following day and came to the seashore. He kept out in the open, walked, went to shows and window shopped but did not improve.

On physical examination the patient appeared well nourished and did not look ill; the face and skin showed good color, but the whole superficial circulation was dilated and of poor vasomotor tone. The chief interest centered about the heart, which was not enlarged; the sounds were sluggish and distant; the pulse was 70 and was regular in rate and rhythm. The blood pressure was 115 systolic and 90 diastolic but was poorly supported, as in pulsus alternans. After hopping on one foot thirty times, the patient became very tired and short of breath. The blood pressure was 120 systolic and 85 diastolic, which is not a normal response.

Treatment consisted of limiting the patient's activities to the lobbies and porches of the hotel; rest in the afternoon, and tonic doses of digitalis and nux vomica to tone up the heart muscle. One week later, the blood pressure was about the same but was better supported, and the heart tone was much improved. After another week the patient felt fine.

CASE 2.—R. S., a white youth, aged 18, a college student, a member of the tennis and ball teams complained of a mean, tired feeling and inability to do anything without becoming short of breath. The family history was unimportant. An appendectomy had been done a year previously with good results. The patient had always been active at college in tennis and ball games; he took the physical examination on entrance to college and was pronounced quite fit.

Five weeks before there had been a sudden onset of aching all over. At that time the temperature was 103.2 F., the pulse rate 78 and the respiratory rate 20; there was no cough or intestinal upset. After the patient had remained in bed for three days, with temperature ranging from 100 to 103, he perspired freely and the temperature became normal. After he had been up for twenty-four hours, the fever returned, and he was in bed three more days. He went home for a week to get away from work but did not gain. He still felt mean and weak, came to the seashore and. was out every day but did not improve.

The patient appeared well nourished. He did not look very ill. The skin was warm, with superficial circulation dilated and of poor vasomotor tone. The heart was not enlarged, but the sounds were distant and the long pause was shortened; there were no murmurs; the pulse was 76, and regular in rate and rhythm. The blood pressure, which was 105 systolic and 78 diastolic, was poorly supported. The patient hopped on one foot thirty-five times and became quite tired and short of breath. The blood pressure was then 115 systolic and 80 diastolic.

After treatment consisting of restricted exercise, tonic doses of digitalis and nux vomica for one week, the patient felt much better. The blood pressure was 110 systolic and 80 diastolic and of better tone and support. Two weeks later the patient felt fine and went back to school.

CASE 3.—A. T., a white woman, aged 38, a school teacher, complained of great weakness and inability to walk to and from school as she had done previously. The family history was irrelevant.

She had always been well and strong and had walked a mile to and from school each day for years.

The present illness began four months before with acute grip; the patient had ached all over and had a dry nonproductive cough. The temperature was 103.5 F., the pulse rate 80 and the respiratory rate 19. She had been in bed six days, with temperature from 100 to 102.5, she perspired freely and the temperature became normal. One day later she went back to school but had to force herself along after two months. The school physician said that she had a nervous breakdown and sent her home. She was at home for several weeks but did not gain and came to the seashore. She was out in the open all the time but had no strength and did not improve.

On physical examination the patient appeared nervous and weak, but she did not look very ill though she said that she had no strength and could not walk much. The chief interest was the heart and circulation. The heart was not enlarged, but the sounds were faint and "tic tac" in quality; the pulse was 82, regular in rate and rhythm. The blood pressure was 110 systolic and 90 diastolic and very poorly supported.

The patient danced about the office for two minutes and had to stop. The blood pressure did not rise but remained about the same; the pulse rate was 112. She felt very tired after ten more minutes.

Under treatment consisting of rest in bed for three days, then about the hotel and porch, and tonic doses of digitalis and nux vomica three times a day, the patient improved rapidly. Two weeks later she went home, but not to work till two more weeks. When seen one year later, she was quite all right. At that time the blood pressure was 120 systolic and 80 diastolic.

CONCLUSIONS

1. Grip is regarded by many physicians as a systemic cold, and patients are allowed to get up much too soon.
2. Unless outspoken murmurs are present, heart enlargement is demonstrable, edema persists, or changes in the electrocardiogram are found, the heart is pronounced normal.
3. Myocardial weakness is the most common of heart defects and organic leaks of the valves are the most rare.
4. Even the mild forms of grip offer potential possibilities of myocardial disease and show evidences of lingering infection in the body tissues.
5. The most effective treatment that I have found consists of rest and tonic doses of digitalis and nux vomica (not with the idea of digitalization) to tone up the heart muscle and vasomotor system.

1616 Pacific Avenue.

ABSTRACT OF DISCUSSION

DR. W. S. THAYER, Baltimore: If one considers the results of recent investigations, one must assume that, whatever the infectious agent may be, the virus is probably filtrable. What the organisms are may be unknown, but certain things are known about their clinical effects. The immediate symptoms of the infection last, for instance, apparently a short time; the primary symptoms of influenza or of a bad cold are of but a few days' duration—the "three days' fever," as influenza was called at the outset in the American Expeditionary Forces. After this the patient often recovers with little appreciable after-effect. On the other hand commonly, after several days, when he thinks himself well, he breaks down again, is febrile and manifests the symptoms of secondary infections of all sorts, which in the graver epidemics are usually due to infections with a malignant streptococcus. In other words, a bad cold, or whatever one calls it, or an attack of "grip," seems to diminish the resistance of the individual in a remarkable way, and this diminution of resistance is shown in grave secondary infections, commonly in the sinuses or lungs, but in a surprising number of instances, in the heart. When one looks back over a large number of instances of subacute streptococcal endocarditis, it is rather remarkable how often those symptoms are traced to an ordinary infection of the upper respiratory tract. But more than that, we are perfectly familiar, as Dr. Andrews has set forth clearly, with the rather striking debility, physical and nervous, which sometimes follows apparently mild infections of the upper respiratory tract, and often the more severe ones. To come more specifically to the heart, one of the commonest experiences in the life of a physician is to observe the following course of events in one of his patients with old rheumatic heart disease, or in an individual with a serious myocardial change, who is going along on an even keel, and has been going along on an even keel for a long time: The patient has an infection of the upper respiratory tract which may not seem to be grave, and compensation is immediately upset. One is apt to fancy that the bronchitis and pulmonary congestion are responsible, but the failure of compensation that one sees after relatively mild infections of the upper respiratory tract is often striking. What the average results of a bad cold or of an attack of grip are is unknown because, ordinarily, little attention is paid to them. I am reminded in this connection of the significant observations made in convalescent camp 2 during the war, by Dr. Bridgeman, who showed, among other things, that in a considerable number of cases the average length of time that it took for a boy of fighting age in good condition to get back into class A after an ordinary attack of tonsillitis, with or without sinusitis, was about a month. How many people take three weeks' vacation after an attack of tonsillitis? Yet it is quite clear that from an economic standpoint, the average man should do so.

DR. THOMAS MCCRAE, Philadelphia: During the past winter, what was called influenza was supposed to be prevalent in many parts of the country. For example, in Philadelphia, morbidity returns showed a large number of cases labeled influenza and a considerable number of deaths were considered the result of influenza. In a fairly large medical service during the winter I did not see a case which I felt could be called influenza. An inquiry came from the health department as to why we were not reporting our cases of influenza, to which the answer was sent back that we did not have any such cases. A great many cases were sent in with that diagnosis, but on study a majority proved to be streptococcic infections and a certain number pneumococcic infections of the upper respiratory tract. How much of secondary infection is due to the streptococcus I do not think any of us know as yet. My suggestion would be that the majority of these cases are instances of infection of the upper respiratory tract, some caused by the streptococcus, some by the pneumococcus, and some possibly by both. What happened in these patients? Had they definitely cardiac damage? Were they patients who possibly had had a chronic focus of infection and in whom the acute infection was enough to make material difference for the time being; or how much may have been due to vasomotor disturbance? My feeling would be that the condition is probably caused by a combination of these two factors, with vasomotor disturbance perhaps playing a considerable part. I think we would all agree with Dr. Thayer that the lesson to remember is that acute infections of the upper respiratory tract may be a comparatively serious matter, and that a period of rest afterward is essential. We know how difficult it sometimes is to secure that rest, but we ought to be certain that these patients are back to a reasonable normal before we permit them to get out of bed.

Dr. L. G. Rowntree, Rochester, Minn.: There are various groups at work in this country investigating the nature of the common cold. It seems to me that this is one of the points of attack on this problem, because it is difficult to say what is a common cold and what is influenza. I wish to emphasize the importance of influenza and of the common cold in relation to disease in general. This might best be emphasized by specific instances. A father said to me, "Why is it that I who have had gallstones, have an attack of jaundice, and my son, who has nephritis, has an attack of interstitial nephritis, after colds?" Colds are responsible for exacerbation of preexisting disease, whenever they are found in the body very frequently. On the other hand, they may initiate disease just as frequently. When the disease does not localize in an individual organ it may attack the body as a whole—and I am inclined to feel that the illness of Dr. Andrews' patients was of the body and the mind, in many instances, as well as of the heart. The question arises as to what should be considered an indication of trouble. Dr. Thayer's suggestion as to prolonged rest is an excellent one, but I do not believe that it will be followed generally. If, however, one recognizes exhaustion following cold as of equal importance with organic disease and then applies Dr. Thayer's rest remedy, I believe that it would save an infinite number of patients from an infinite amount of illness. This exhaustion may go on, literally for years in many cases, and it may incapacitate the patient sometimes for a year, sometimes for life. Hence it is a serious problem. I should like to ask Dr. Andrews one question. These patients have gone to the seashore. Is not the seashore environment an important factor in the recoveries reported, as well as the rest, the massage and the drugs employed?

Dr. Moses Salzer, Cincinnati: I should like to ask the author what he means by tonic doses of digitalis.

Dr. F. R. Taylor, High Point, N. C.: It has been stated that some of these cases of so-called influenza have been found to be streptococcic or pneumococcic infections, and I am eager to know how that determination is arrived at. I have always assumed that one might find streptococci or pneumococci in the upper respiratory tract in any one. I should like to know how to determine whether the infection is due to these organisms which one finds or to infectious agents which Dr. Thayer has spoken of, which one cannot find.

Dr. F. C. Atwood, New Haven, Conn.: I should like to ask Dr. Andrews whether he has had any experience in the use of a convalescent serum in the treatment of influenza.

Dr. Clarence L. Andrews, Atlantic City, N. J.: My cases were based on a group of patients whom I saw never earlier than two weeks following their illness. They were sent to the seashore because they did not gain at home. I tried to check the etiologic factors, but the data varied so much that they were discarded. If you recall what I said, none of the patients showed any of the usual evidences of cardiac disease or any etiologic factors except a history of so-called grip. I emphasized grip rather than influenza because of the uncertainty of what causes it. I merely used the term that every one else uses. I do not know myself what causes it; and so far as I know, no one else does. My idea in presenting the paper was not so much to point out the cause of grip as to emphasize the cardiac disturbances which follow these mild types. The same group of physicians would probably regard them as unimportant even if streptococcic in character. What I wish every one to do is to watch the cardiovascular system. I do not know whether the condition is caused by myocardial or vasomotor disturbances, by a depression of the suprarenal balance or by a combination of all three. I believe that there is a big nervous "let down" or, as Dr. McCrae said, a combination of everything. Answering Dr. Salzer regarding digitalis, I do not use a specific dose but just enough to tone up the muscle. All know what a poorly toned muscle is like; it cannot hold itself. I rarely give more than 10 drops and never with the idea of digitalization. Dr. Rowntree mentioned the great importance of finding the cause; but, as previously stated, I saw these cases too late for that. All these patients do well at the seashore, if they do not overexert themselves. The question of Dr. Taylor is really the question of Dr. McCrae; that is, how to determine whether the infecting organisms are streptococci or pneumococci. Of course, my paper did not deal with the causes. Answering Dr. Atwood, I have had no experience in the use of a convalescent serum in the treatment of influenza.

EXPERIMENTAL SHOCK

A STUDY OF ITS PRODUCTION AND TREATMENT *

ALFRED BLALOCK, M.D.
J. W. BEARD, M.D.
AND
G. S. JOHNSON, M.D.
NASHVILLE, TENN.

A great deal of confusion has arisen from the use of the term "shock." Conditions that are probably little related to one another are classified together under this general heading. Several recent workers have suggested other terms in an endeavor to lessen the misunderstanding. Until the factors that are responsible for the decline in the volume of circulating blood and the drop in the blood pressure are better understood, it would probably be advisable to designate the initiating agent as, for example, shock following trauma to an extremity, shock following burns, or shock following injury to the central nervous system.

Shock resulting from injury may be roughly divided into two types: (1) primary shock, in which a low blood pressure follows immediately, and (2) secondary shock, in which at least an hour usually elapses between the time of injury and the development of a low blood pressure. It is the latter type with which surgeons are most frequently confronted, and this paper is limited to a consideration of it. Many theories have been offered in an effort to explain the mechanism of the production of secondary shock. These include the theories of (1) vasomotor exhaustion, (2) inhibition, (3) fat embolism, (4) acidosis, (5) acapnia, (6) suprarenal hyperactivity and hypo-activity, and (7) toxemia. Probably the theory with the largest number of supporters at the present time is the last one mentioned, which maintains that the decrease in the blood volume and the decline in the blood pressure following injury to large areas of tissue are due to the absorption of toxins into the general circulation. These toxic products are thought to be similar to histamine in their actions.

---

* From the Department of Surgery of Vanderbilt University School of Medicine.

* Read before the Section on Surgery, General and Abdominal, at the Eight-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

The experiments that probably gave the strongest support to the toxic theory of shock were those performed by Cannon and Bayliss,[1] in which one of the posterior extremities of cats was traumatized by striking. An hour or more following the injury, the blood pressure declined to a low level. Amputation of the two posterior extremities by symmetrical cuts made across the upper thighs and determination of the difference in weight indicated that there was not a sufficient loss of fluid from the blood stream into the injured area to cause the decline in the blood pressure. Section of the upper lumbar cord in some experiments showed that the fall in blood pressure was not due to a general effect of the trauma on the circulation brought about by nervous impulses. Since the femur was not broken, fatty embolism seemed unlikely. It was believed that the continued fall in blood pressure following the trauma was due to the absorption of depressant substances.

MECHANISM OF PRODUCTION

The results of experiments that were performed in studying shock by other methods suggested that the experiments just quoted might have been wrongly interpreted. In the first type of experiments, performed by Blalock and Bradburn,[2] the oxygen content of the blood from various veins of the body was determined after a low blood pressure had been produced by a variety of means. The oxygen content of the blood from the femoral vein of a traumatized extremity was much higher than was that of the opposite nontraumatized extremity. The oxygen content of blood from the portal vein was much higher after a low blood pressure had been produced by trauma to the intestines than after a proportionate decline in blood pressure had been obtained by other methods. The alterations that were produced by trauma and by the injection of histamine were quite different. In the second type of experiments, the cardiac output and blood pressure were determined before, during and after the production of a low blood pressure by (1) hemorrhage, (2) trauma to an extremity, (3) trauma to the intestines, (4) burns and (5) the subcutaneous injection of histamine. In the experiments on hemorrhage and on the various types of injury there was a rather large decrease in the output of the heart before any significant alteration in the blood pressure occurred. When histamine was injected, the alterations appeared in the reverse order, there being first a decrease in the blood pressure followed later by a decline in the output of the heart. In these and in all experiments to be reported in this paper, the animals were profoundly anesthetized, usually by soluble barbital, and they did not give any evidence of pain during the experiments. At the completion of the experiments they were killed.

In view of the results that have just been reported, experiments were then performed on dogs by the use of the method of Cannon and Bayliss. Eight such experiments were performed. The trauma was instituted by striking one of the posterior extremities. It was evident that the loss of fluid was not limited solely to the area directly traumatized, as there was swelling of the loose tissues in the groin and flank. After intervals of time following the trauma, varying from one to six and one-half hours, there was a decline in the blood pressure to a low level. The method of determining the amount of fluid that was lost into the traumatized area was different from that described by Cannon and Bayliss in that the amputations were performed at higher levels. The method briefly was as follows: A midline abdominal incision was made, the symphysis pubis was divided with a saw, the bladder and rectum were removed, the abdominal aorta and vena cava were doubly ligated and divided, a high transverse abdominal incision was made extending across the vertebral column, the posterior portion of the body was divided into two parts by a longitudinal section of the vertebral column, the tail was discarded, and the weights of the two posterior portions were determined. The average difference in weight of the traumatized and nontraumatized parts equaled 5.2 per cent of the body weight. In other experiments in which the tolerance to graded hemorrhages was determined, the results indicated that the loss of blood into the injured extremities had been sufficient to account for the decline in the blood pressure.

In an effort to eliminate the possibility of the absorption of toxic products from the traumatized extremity, experiments of a slightly different nature were performed. The femoral artery was isolated in the groin, the head of the femur was removed, and a tourniquet was placed tightly around the thigh, constricting all structures except the artery, which was left outside the tourniquet. The extremity was then traumatized distal to the constriction. The impression was gained that less trauma was necessary for the production of a low blood pressure in these experiments than in those in which no tourniquet was applied. The difference in the weights of the two extremities showed that there was sufficient hemorrhage into the injured area to cause the decline in the blood pressure.

Other types of injuries were then studied. These included (1) mild trauma to an extremity, (2) trauma to the intestines and (3) burns. Following mild trauma to an extremity, there is an accumulation of fluid in the injured tissues. When the intestines are passed continuously between the fingers, a copious weeping of fluid from the peritoneal surfaces results. Dogs do not blister when burned, but a great deal of fluid escapes into the subcutaneous tissues beneath the burned skin. The composition of the fluid that escaped from the blood stream, after these three types of injury, was determined. It was found that the fluid had almost exactly the same composition as the plasma of the blood. It is especially significant that the protein content of the two was practically identical. This is important because it is the protein of the plasma that is largely responsible for maintaining the osmotic pressure in the blood stream. Without it the filtration pressure in the capillaries would cause the loss of most of the fluid from the blood stream and no fluid would be attracted to it.

The experiments on mild trauma to an extremity were performed because those on severe trauma were probably not of sufficient duration to take into account the possible late action of protein decomposition products that are slow in exerting their effects. One cannot be certain that these experiments were of sufficient duration (average, thirty-two hours and sixteen minutes), but the length was limited by the fact that the animals were deeply anesthetized and would have died eventually from the anesthetic alone. After the blood pressure had declined to a low level, the difference in weight of the two posterior extremities was determined by the same method as was used in the experiments on severe trauma. The average difference amounted to 3.66 per cent of the body weight. As has been stated, the fluid that escaped into the injured part had in the main the same composition as the blood plasma. Experiments were then performed on the graded removal of blood plasma, in which the loss that produced death was determined. The results indicated that the loss of plasma into the injured area following mild trauma to an extremity had been responsible for the decline in blood pressure.

---

[1] Cannon, W. B., and Bayliss, W. M.: Note on Muscle Injury in Relation to Shock, Nat. Health Insur., Med. Research Com., Spec. Rep. Ser. no. 26: 19-23 (March) 1919.

[2] Blalock, Alfred; and Bradburn, Hubert: Distribution of the Blood in Shock: The Oxygen Content of the Venous Blood from Different Localities in Shock Produced by Hemorrhage, by Histamine and by Trauma, Arch. Surg. 20: 26-38 (Jan.) 1930.

In the experiments on trauma to the intestines, the amount of fluid that escaped through the exposed and injured peritoneal surfaces as well as the excess of blood that accumulated in the traumatized intestines was roughly determined. Comparison of these results with those obtained in plasmapheresis experiments of approximately the same duration indicated that the loss of plasma from the circulating blood stream had been responsible for the decline in the blood pressure. We do not mean to imply that the temporary decline in blood pressure that is frequently encountered in abdominal operations is usually due to the loss of fluid through the exposed peritoneum. This condition is probably more closely related to primary shock, in which there is a decrease in the circulating blood volume due to the passage of blood into large areas of dilated capillaries.

In animals that were very deeply anesthetized by soluble barbital, the amount of plasma lost into a burned area that was restricted to one side of the body was determined by dividing the body into symmetrical halves and weighing them. Comparison of the results of these experiments with those obtained in studying the effects of plasmapheresis indicated that the loss of plasma had been sufficient to account for the decline in blood pressure. Most of these experiments were less than twenty-four hours in duration. In view of the results of these experiments, it seems possible that the early beneficial effects following the use of tannic acid and epinephrine in treating burns may be due to the lessening of the loss of fluid from the weeping surface rather than to the prevention of the absorption of toxins. It seems likely that deaths occuring within twenty-four hours following a burn are due in the main to the loss of plasma through the injured capillaries. In burns associated with longer survival periods, toxins probably exert their effects.

Experiments by Harris and Blalock[3] showed that there is an increase in the water content of the tissues at the site of injury and a decrease elsewhere. After trauma to an extremity there is an increase in the water content of muscle in the injured area and there is a decrease in the water content of skeletal muscle in other parts of the body. There is an increase in the water content of the subcutaneous tissues of a burned area, and the subcutaneous tissues elsewhere lose water.

The observations recorded thus far indicate that the local loss of fluid at the site of injury is the most important factor in producing the decline in blood volume and blood pressure in shock. Evidence for the action of toxins was not found in these experiments. Following severe trauma, the fluid that was lost consisted in the main of whole blood. When the injury was less severe, the fluid that escaped through the damaged capillaries had approximately the same composition as the plasma of the blood.

TREATMENT

There are two methods by which the low blood pressure in shock may be elevated: the giving of vasoconstrictor drugs and the addition of fluids to the circulating blood stream.

The Giving of Vasoconstrictor Drugs.—If we limit our consideration to the shock that develops following trauma and remember that the blood pressure is low because there is a decrease in the blood volume, treatment that is not directed toward increasing the blood volume does not seem correct. The blood supply to organs is already lessened because of the decrease in the circulating volume of blood and the vasoconstriction that is usually present, and further vasoconstriction that follows the giving of drugs decreases still more the total blood flow to organs, even though the blood pressure is raised. The increase in blood pressure that follows the injection of a vasoconstrictor drug is usually sustained for only a short time. It is well to remember that the repeated injections of large amounts of epinephrine will produce shock in previously normal dogs.

The Addition of Fluids to the Circulating Blood Stream.—Since there is a diminution in the volume of blood in the circulation in shock, treatment should be directed toward increasing this amount. For this purpose, blood and so-called substitutes for blood have been employed. The results following the use of most of the substitutes have not been very encouraging. Theoretically, a solution of acacia should most nearly fulfil the conditions, but there are some objections to its use.

The fluid that has probably been used more frequently than any other in treating shock is physiologic solution of sodium chloride. It has been known for a long time that salt solutions as well as other crystalloids do not remain in the blood stream even of normal dogs very long after their injection. This information has explained, in part at least, the fact that favorable responses in the blood pressure frequently do not follow the intravenous injection of salt solution. We have the impression that at times in patients with low blood pressures the condition is actually worse a short time following the introduction of the fluid than it was before. Studies were carried out in an attempt to obtain more information on the cause of failures. The effects of various other solutions were studied but, because of lack of space, only isotonic saline solution will be considered here.

The type of injury that was chosen for these experiments was that of trauma to the intestines. When the intestines are continuously passed between the fingers and no fluid is introduced intravenously, since the fluid that is lost through the exposed peritoneum has the same composition as the plasma of the blood stream, there is practically no alteration in the amount of protein in a unit volume of plasma. However, there is a large decrease in the total amount of plasma in the blood stream and hence a great diminution in the entire amount of protein. When isotonic salt solution is injected continuously intravenously while the intestines are being traumatized, there is a decrease in the total amount of plasma and at the same time a decrease in the percentage of protein in a unit volume of plasma. In other words, the injected salt solution, as it escapes, takes protein with it, resulting in a dilution of the protein in the fluid that remains in the blood stream. This, of course, decreases the ability of the blood stream to increase its volume, by attracting fluid to it because of the diminution in the osmotic pressure.

---

[3] Harris, P. N., and Blalock, Alfred: Experimental Shock: X. Observations on the Water Content of the Tissues of the Body After Trauma and After Hemorrhage, Arch. Surg. **22**: 638-648 (April) 1931.

We were then interested in determining the effects in normal dogs, anesthetized by morphine, of the intravenous injection of large amounts of physiologic solution of sodium chloride. The fluid was injected continuously intravenously for four hours at the rate of 10 cc. per kilogram of body weight per hour. Studies were performed before, during and after the injection of the fluid. In the animals in which there was no decline in the blood pressure at any time during the experiments, there was a slight increase in the entire amount of plasma, a slight decrease in the percentage of protein and no alteration in the entire amount of protein in the blood stream. On the contrary, when at any time during the course of an experiment the blood pressure declined, owing to the anesthetic or unknown cause, a rapid loss of protein from the blood stream was found. Hence one sees in the presence of a low blood pressure that the capillaries allow the escape of protein even when there has been no gross injury to the vessels.

When whole blood or blood serum is injected intravenously in the presence of a low blood pressure resulting either from trauma or from an unknown cause, protein is lost through the capillary walls. But protein is being added to the circulation in the blood that is being injected, and this compensates at least partially for the amount that is being lost.

Vanderbilt University Hospital.

ABSTRACT OF DISCUSSION

Dr. Jacob Markowitz, Washington, D. C.: Cannon and Bayliss are eminent names in physiology. As a teacher of physiology I have been teaching that surgical shock is the result of a toxin which is liberated in traumatized tissues. I was therefore surprised and pleased to hear that this conclusion of Cannon and Bayliss is erroneous. I say pleased because these experiments are much simpler, and, other things being equal, simple explanations are more apt to be true. It is a fact that the injection of histamine will induce a condition which is very similar to surgical shock, and it is a fact that there is present in the animal body a good deal of histamine. Any one who has worked with shock in animals soon realizes that histamine as such could not be responsible for surgical shock, for a simple reason. Herbivorous animals do not react to an intravenous injection of histamine by a fall in blood pressure, and herbivorous animals in general are notoriously prone to the development of shock. The tendency has been to look on the condition of shock in more or less of a diagnostic sense. No one would suppose that to call the patient collapsed would be making a diagnosis. There is no more reason, I suppose, to call "shock" a diagnosis. While every one who has written on the subject has urged that the word "shock" be abandoned for medical literature, it still persists. I should like to suggest instead of the word "shock" that one use the term "collapse with hypotension." It is true that these terms do not indicate all the features of shock, but in my opinion they are better than the word "shock." The number of papers on the subject of shock is legion. Many of them are profound and many contain nothing. It is my belief that this discussion of Dr. Blalock and his collaborators will stand the test of time.

Dr. Frederick A. Bothe, Philadelphia: Three observations which the authors made were of utmost importance: First, there was an increase in the fluid content of the injured area. The fluid, on analysis, was chemically the same as blood plasma. Second, the results obtained in experimental trauma indicated that the loss of plasma into the injured area was responsible for the decline in blood pressure. Third, if during an experiment the blood pressure declined because of the anesthetic or an unknown cause, a rapid loss of protein from the blood stream occurred. This showed an altered permeability of the capillaries in the presence of a low blood pressure, though there was no gross injury to the vessels. Adolph recently found an increase in the water content of the tissues as the result of low blood pressure in the absence of trauma. From these observations the question arises, Does the low blood pressure precede the escape of the plasma, or does some plasma escape before the blood pressure is altered? What part the sympathetic nervous system plays in the fall of the blood pressure is still unknown. The results obtained by operations on the sympathetic nervous system in the treatment of vascular diseases of the extremities has stimulated further study of the function of this system. Ferguson and North are at present conducting research work in the Department of Research Surgery of the University of Pennsylvania, which may help in the solution of this problem. Though their work is not completed, they observed that, if the splanchnic nerves alone are paralyzed, a momentary slight drop in blood pressure occurs, which is so rapidly compensated that it is practically negligible. If the splanchnic and the sympathetic nerves to the lower extremities are paralyzed there is a fall in the systolic pressure averaging about 12 mm. of mercury. If in addition the sympathetic nerves above the fifth thoracic nerve are paralyzed, the blood pressure falls proportionately to the number of sympathetic nerves paralyzed. These observations indicate that paralysis of the splanchnic nerves alone is not responsible for "splanchnic shock." In more profound cases blood transfusion is the best therapeutic agent to supply the constituents necessary to combat this reaction, as manifested by the physiologic changes.

Dr. Alfred Blalock, Nashville, Tenn.: The fact that not every decline in blood pressure is due to the loss of fluid through the walls of the capillaries should be emphasized. Surgeons note that the opening of the peritoneal cavity frequently causes a drop in the blood pressure. This condition probably is closely related to what is termed primary shock in which there is "bleeding" into the capillaries themselves, resulting in a diminution in the circulating volume of blood. In view of the results that were obtained in the experiments in which fluids were injected intravenously, the question arises as to how a patient who has a low blood pressure should be treated. I think in the absence of the ability to obtain a donor that solutions of sodium chloride or dextrose should be introduced but that the injection should be terminated if there is not an early favorable response in the blood pressure. Otherwise, it is believed that the continued introduction of fluid will result in a great diminution in the amount of protein in the blood stream and that the chances of recovery will be lessened. Further work should be directed toward finding something that will decrease the permeability of the capillaries. Unless such attempts are productive there will continue to be many patients in shock who are unsuccessfully treated.

Undulant Fever in Children.—. . . The surprising thing, however, is that the incidence of undulant fever among people drinking infected milk is comparatively low. As investigation proceeds, it is becoming apparent *either that the* bovine strain of Brucella melitensis is of relatively low pathogenicity for human beings, or that there are other factors of immunity responsible for the low incidence of the disease among those exposed. It has been repeatedly stated by those who have described undulant fever, fostered undoubtedly by those who have previously described Malta fever of caprine origin, that the disease is of rare occurrence in childhood and therefore of little importance in this age group. While it is true that the majority of cases which have been reported have occurred in adults, one is hardly justified, in the present state of knowledge, in accepting this conclusion. Children are not immune, and the disease has been observed during the febrile stage even in infancy. We should like to add three cases occurring in children to those already on record. We do not, of course, presume to draw any conclusions concerning undulant fever from so small a series. There is much that is still unknown concerning the relation of infectious abortion in cattle to undulant fever in man. It is not impossible that unrecognized infections in childhood may be one factor in accounting for the relatively high immunity to the disease in adults.—Anderson, E. D., and Pohl, J. F.: Undulant Fever in Children, *Am. J. Dis. Child.* **42:**1103 (Nov.) 1931.

Clinical Notes, Suggestions, and New Instruments

AGE INCIDENCE OF CARCINOMA OF THE CERVIX

TWO THOUSAND, ONE HUNDRED AND EIGHTY-ONE CONSECUTIVE CASES AT THE HOWARD A. KELLY HOSPITAL

Edwin F. Daily, M.D., Baltimore

A question frequently asked in recent years has been "Is carcinoma of the cervix occurring in younger women more often than it did a few decades ago?"

A careful tabulation of 2,181 consecutive cases of squamous cell carcinoma has been made (table 1). The cases have been grouped into yearly divisions from 1913 to 1931, and the percentage of occurrence for each ten years of life and the average age of occurrence for the entire group have been computed. The ages given are the ones at the time the diagnosis was made. The onset of the first symptoms was computed to be on the average 9.3 months earlier. The average age of onset then would be 47.39 years, and the age at the time of diagnosis 48.16 years. The youngest patient in this series was 22 years, the oldest 83 years, of age.

For comparison, Pozzi's statistics as published in his "Treatise on Gynecology," 1891, are used (table 2). In a series of 3,471 cases the average age of onset for his patients was 48.2 years. This is practically the same as in our cases. The average age incidence of cases for each ten years span of life is also practically the same in his series as in ours.

Table 1.—*Age Incidence of Squamous Cell Carcinoma of the Cervix at the Howard A. Kelly Hospital*

			Age

1927	142	48.1	9	6.3	23	16.2	43	30.3	47	33.1	18	12.1	2	1.4	0	0.0
1928	130	49.3	4	3.8	19	14.6	45	34.6	36	27.7	24	18.5	2	1.5	0	0.0
1929	124	47.3	9	7.3	25	20.2	36	28.8	38	30.7	12	9.7	4	3.2	1	0.8
1930	132	47.8	6	4.5	25	18.9	41	31.0	44	33.3	12	9.1	2	1.5	2	1.5
1931	93	46.5	6	6.4	23	24.7	31	33.3	16	17.2	13	14.0	4	4.3	0	0.0

Of interest in table 1 is the fact that for the past seven years the average number of cases between the ages of 20 and 30 is above the average for the whole series at this age. We have no explanation to make for this, but it has been the impression of those seeing many of these cases each year that the disease is now occurring in younger women more often.

Table 2.—*Age at Which Cancerous Disease of the Cervix Begins**

Age	Number of Cases	Percentage
17 years	1	0.026
19 years	1	0.026
20 to 30 years	114	3.3
30 to 40 years	770	22.2
40 to 50 years	1,196	34.2
50 to 60 years	856	24.6
60 to 70 years	340	9.8
70 years	193	5.5
Total	3,471	

* Average age incidence equals 48.2 years.

CONCLUSIONS

The average age incidence of cancer of the cervix has not changed in the last fifty years.

At this clinic there has been a very slight increase in the incidence of occurrence between the ages of 20 and 30 during the last few years. Although cancer of the cervix is chiefly a condition of middle life, its occurrence in younger women must always be kept in mind, especially by the general practitioner when he faces a differential diagnosis of cervical disease.

1418 Eutaw Place.

Committee on Foods

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public. They will be included in the Book of Accepted Foods to be published by the American Medical Association.

Raymond Hertwig, Secretary.

OVALTINE NOT ACCEPTABLE

A Chocolate Flavored Dry Malt Extract Containing a Small Quantity of Dried Milk and Egg

Ovaltine, widely known throughout the world because of extensive advertising, is sold with two slogans: "A food beverage" and "A food concentrate." Because of its extensive exploitation, because it is stated to be widely recommended by physicians as a building and strengthening food in convalescent and other invalid conditions, because of the special stress placed on it as a means of inducing calm, natural sleep without the use of drugs, and because recent advertising has emphasized the alleged vitamin and diastase content, the Committee on Foods thought it desirable to consider the nature of the product and the claims made for it even though this preparation has not been voluntarily submitted to the committee.

Ovaltine as sold in the United States is manufactured by the Wander Company, Chicago. The Connecticut Experiment Station in 1917 reported its composition as follows:

Bulletin 200, Food Products and Drugs, 1917, page 154: "Ovaltine. Ovaltine, Tonic Foods Beverage. A. Wander, London, England. 'A concentrated extraction from malt, milk and eggs, flavored with cocoa.' 'Is rich in lecithin, the assimilable organic compound of phosphorus. It is thus a valuable article of food in cases of mental and nervous exhaustion.'

Water	1.03
Ash	3.52
Protein (N × 6.25)	12.75
Fat	5.58
Fiber	0.64
Nitrogen-free extract	76.48
Lecithin phosphoric acid	0.10
Reducing sugars (chiefly maltose, lactose, dextrose and dextrins)	70.01
Active amylase	present
Starch	trace
Calories per 100 grams	407

"The product appears to be composed of the foods claimed. The small amount of lecithin phosphoric acid present, 0.10 per cent, hardly seems to justify the claim that the food is 'rich in lecithin' or that it is 'a valuable article of food in cases of mental and nervous exhaustion.'"

In 1927 a supplementary statement said:

"32813. Ovaltine. The Wander Company, Chicago, Illinois.

"Analysis:	per cent
Moisture	1.65
Ash	3.80
Protein (N × 6.25)	13.44
Fiber	0.18
Starch	none
Sugars (as dextrose)	39.53
Undetermined carbohydrate (largely dextrin)	35.32
Fat	6.08

"A product of the same name was analyzed in this laboratory in 1917 in which an active amylase was present and a small amount of lecithin phosphoric acid was found. We have not examined the newer product for amylase or for lecithin phosphoric acid, but otherwise the composition is substantially the same as previously found. The label declaration implies a high vitamin content, but we have made no biological tests for vitamin. The original sample examined was an English product claimed to be made from malt, milk and eggs."

It seemed desirable to compare the diastatic value of Ovaltine to that of U. S. P. Malt Extract:

Diastatic Value.—The method described under "Extract of Malt," page 147 of the U. S. Pharmacopeia, was used to determine qualitatively the diastatic value of a sample of Ovaltine purchased in a drug store in Chicago. The test indicated that active diastase is present in Ovaltine in somewhat less quantity than that of an equal weight of U. S. P. Extract of Malt, which latter is sufficient to convert "five times its weight of starch into water soluble sugars." Therefore, Ovaltine is not equivalent to U. S. P. Malt Extract in its amylolytic properties.

Advertising Claims.—Ovaltine is exploited as a "Swiss food discovery" and "a scientific food concentrate; containing in highly concentrated form practically every single food element necessary to life." It is stated to be "recommended by 20000 physicians the world over . . . for many purposes, both in health and sickness . . . as a building and restorative food for convalescents and invalids; for stomach disorders and feeble digestion, for nervous and rundown conditions; as a means of inducing calm, natural sleep without the use of drugs; for growing children, particularly those under par or underweight; as a pick-up and restorative food drink for busy workers; a food for expectant and nursing mothers to maintain their strength and promote the flow of milk."

It is claimed that Ovaltine "actually makes children want to eat more—and increases the nourishment and digestibility of every bite they take; taken regularly, it usually adds a pound or more a week to a child's weight and has a noticeable effect in curbing nervousness; it (has) solved the problem of feeding invalids . . . and is also solving for modern mothers the problem of child feeding. It constitutes in itself a complete food . . . makes milk digest twice as easily . . . contains 'lecithin' which is a direct nerve food. A few days' use of Ovaltine usually curbs nervousness noticeably. Of greatest importance, Ovaltine contains in high proportion a remarkable food element 'diastase' (A substance which gives one food the power to digest the starch content of other foods in your stomach). It will digest four to five times its own weight of other foods."

DISCUSSION OF ADVERTISING CLAIMS

In advertising appearing in women's periodicals during September, 1931, much emphasis is placed on the Ovaltine oatmeal test. The reader is urged to add three teaspoonfuls of Ovaltine to a cereal dish of cooked warm oatmeal and to see how the Ovaltine digests the starch content, thereby speeding up the digestion and creating a sensation of hunger. Any physician will realize that the test is one of those pseudoscientific demonstrations calculated to confuse rather than to enlighten and leading thereby to unwarranted inferences. Although Ovaltine does contain some active diastase there is little reason to believe that the addition of Ovaltine as a beverage to the diet of a child will hasten the digestion of cereals or induce hunger. Ovaltine does not have the diastase content of U. S. P. malt extract and will not digest four to five times its weight of other foods. Such effect as it has concerns starch digestion only. There is no apparent reason why it should affect to an appreciable extent the digestion of a mixed meal. If there is any evidence that Ovaltine actually does speed up digestion and empty the stomach sooner than usually is the case, that evidence is not available in scientific literature.

The claim that lecithin, which may be considered one of the ingredients of Ovaltine since it is derived from the eggs, is a direct nerve food is about as preposterous as the old claim that fish is to be considered a brain food. The strange notion that any substance taken into the stomach will be selected by the blood and carried directly to the nerves and to the brain, thus giving them the physical properties that they possess, is not substantiated by any physiologic knowledge. True, nerve and brain tissue contain phosphorus, but the feeding of vast amounts of phosphorus will not enhance the functions or the qualities of these highly specialized tissues.

On a par with the claim for lecithin is the one on which so much emphasis is laid in both periodicals and radio advertising for Ovaltine. This drink is urged as a cure for insomnia, as a preparation which induces natural sleep in the most severe cases, as a method to induce restful instant sleep entirely without drugs. The claim is based quite obviously on the well established fact that any warm drink taken before going to bed is an aid to overcoming restlessness. No doubt much of the effect is physiologic, some of it perhaps the same type of physiologic reaction as the general relaxation that accompanies the application of warmth. There is not, however, in Ovaltine any specific sleep-producing principle. It is not to be considered a hypnotic, a narcotic or a sedative, and it will not accomplish for severe cases of nervous diseases or stubborn cases of insomnia what can be accomplished by proper psychologic study, suitable physical therapy, such as a warm bath, or the proper administration of selected medicinal preparations.

Ovaltine may be said to represent an example of the way in which well recognized foods are exploited like "patent medicines" to credulous and ignorant people. Here is the emphasis on impaired digestion, sleeplessness and nerves; here again the pseudoscientific claims; here again the exploitation of a foreign chemist and the mystery associated with the type of advertising that was used to build "Sanatogen," the glorified cottage cheese, into America's most popular nerve tonic more than a decade ago.

To this now is added the claim for vitamin content. The reader is told that Ovaltine has a high content of appetite-producing vitamin B. When another preparation was announced to be fortified with vitamin D, the promoters of Ovaltine immediately assured readers that it contained this interesting substance. Possibly the content of eggs, although low, does provide some vitamin D. Quite likely its content of malt does assure a possible content of vitamin B! But what assurance has the user that the vitamin B that it contains is preserved unchanged? What assurance does he have that the vitamin D that is present is there in such amount as to be of any service whatever?

Ovaltine is advertised as a "quick pick-up" and "for adding five pounds a month to your child's weight." Ovaltine has a food energy value of approximately 120 calories per ounce. The label directions call for the addition of from one to three heaping teaspoonfuls to one glass of milk, which addition is equivalent to from 100 to 150 calories to the 175 calories of the one glass of milk. The food energy value of one glass of Ovaltine in milk prepared according to directions is therefore approximately 1.7 times that of the milk itself. A one ounce slice of bread contains about 75 calories. Ovaltine is essentially a carbohydrate food, and its value in gaining weight is no more nor less than that of other similar carbohydrate mixtures.

There are now available in the open market for those who wish to purchase beverages of this character several products of known composition advertised honestly with claims based on their actual content. In contrast, Ovaltine is sold with grossly exaggerated claims; its composition is kept a mystery, and even if it did contain what the manufacturer says it does, it could not do the things the manufacturer says it will. The exploitation of Ovaltine represents a flagrant abuse of recognized principles in food advertising; it is in many respects not in accord with scientific fact and therefore misleading to the public. For these reasons the Committee on Foods makes available this statement and lists Ovaltine among the products not acceptable.

BLOOD DISTURBANCES AND THROMBOGENESIS FROM CLINICAL INTRAVENOUS INJECTIONS OF DEXTROSE SOLUTIONS

In intravenous medication, more attention is often devoted to the details of technic of the injection than to the changes that may occur in the blood and in important physiologic functions following such administration. Even the apparent benefits of such injections are sometimes attributed to some trivial modification of a technic or to some minor or inconsequential modification of a solution. More important than such technical accessories in the choice of intravenous medication is the fundamental fact that agents, drugs or solutions so injected act as foreign agents in the blood stream. The presence of foreign bodies in the normal circulation, the direct effects on the blood and the indirect or reflex effects on various functions are obviously significant. The fact that the disturbances might be greater and more serious in pathologic conditions, in which intravenous solutions may be indicated, has scarcely received the consideration it deserves. Hence the results with intravenous dextrose solutions on patients reported by Stuber and Lang [1] of the City Hospital in Kiel, Germany, are timely, and worthy of the attention of all physicians who practice such injections.

Using 20 cc. of 20 per cent dextrose solution, Stuber and Lang made observations of changes in the coagulation time, glycolysis, alkali reserve, p_H, and protein and chloride content of the blood of a large number of healthy individuals and of patients with cardiac decompensation. The most notable and constant change was an acceleration of blood coagulation, which was faster in patients with decompensation than in normal individuals. Other noteworthy changes in decompensation were increases in glycolysis and of lactic acid, also variations in mineral content, disturbed albumin-globulin ratio with increases in the globulin and fibrinogen fractions, increase in thrombocytes associated with a decrease in their electrical charges, and agglutination of platelets. All changes in blood chemistry were more extensive in patients with decompensation than in the normal. Collectively, the phenomena observed were characterized as profound physical-chemical changes in the blood, which would favor the formation of thrombi and emboli. The more definite changes in decompensation were attributed to blood stasis, a condition known to favor embolism or thrombosis, which may be directly initiated and thus rendered easier of formation by a foreign intravenous solution. The blood changes caused by the latter fulfil the requirements for thrombus formation, according to previous studies of the same authors.[2] These results of intravenous medication merit serious thought.

Intravenous injections in general should be appraised more carefully than is usually the case. The results reported by Stuber and Lang are convincing; in fact, they confirm experimental evidence previously emphasized by The Journal. Against a background of such correlated experimental and clinical evidence, much that has been claimed for intravenous medication appears doubtful.

The clinical significance of these phenomena cannot be overlooked in view of reported cases with disturbing symptoms and even of death following intravenous injections of dextrose. Such reports have been recently published by Askey and Hall,[3] Ylanan,[4] and Opitz.[5] The symptoms, which appear to be common to such injections, consist of flushing of the face, headache, marked rise of body temperature, severe chills, diuresis and sometimes collapse. Although death in Askey and Hall's case was attributed to the intravenous dextrose, caution should be exercised in the correct interpretation of clinical cases with severe disease. Yet it is under just such conditions that the results of Stuber and Lang enjoin great caution on the physician attempting treatment by the intravenous method. In this connection, the recent report by Helmholz [6] of the Mayo Clinic, on the effects of hypertonic sucrose solutions injected intravenously, should not be overlooked. This solution is reported to have caused renal tubular injury from which recovery appears to have occurred, although some chronic changes persisted.

In contrast to the experimental and clinical evidence here cited is the commercial propaganda disseminated through the organs of proprietary manufacturers who advocate and exploit all sorts of substances and solutions for intravenous injection. It is unfortunate that credulous and uncritical physicians accept these claims and thoughtlessly jeopardize the lives of their patients. Probably the height of absurdity, if not of recklessness, has been reached in the endorsement of orange juice intravenously. A physician of South Africa [7] has stated that he gave intravenous injections of raw, unneutralized orange juice (10 cc. in 150 cc. of physiologic solution of sodium chloride) at intervals to a patient and that this caused steady improvement and disappearance of all symptoms of scurvy and saved the man's life. Such a procedure could have amounted to nothing more than a spectacular test of the patient's heroic resistance to a foreign agent. Nevertheless the obvious reasoning of the physician—*post hoc ergo propter hoc*—and the single uncontrolled case did not prevent the report from becoming a "contribution" to medical literature and thus abetting the abuse of "intravenous therapy."

Nearly every physician has observed sudden and alarming symptoms accompanying intravenous injections. The practical difficulties are that the changes and symptoms are not exactly predictable, and the solution or drug, once it is in the circulation, is not retrievable. Before attempting such injections, the physician should keep in mind the physical-chemical changes which occur from the sudden introduction of foreign agents into the blood stream, and the necessity for great caution and restraint in the administration and choice of remedial agents for intravenous use.

THE GENEVA CONVENTION OF 1931

The international conference on the limitation of the manufacture of narcotic drugs, held in Geneva, Switzerland, during the past summer, was guided not only by altruistic motives but also by practical objectives. The treaty resulting from the conference should be a beneficial influence in helping to solve the medicosocial problem of drug addiction, in simplifying the administration of laws and regulations governing the distribution and uses of these drugs, and in reducing the quantity of contraband arriving at American ports. Approximately three and a half tons of contraband narcotic drugs was seized last year, all destined for illegitimate trade and originating outside the Western Hemisphere. The quantity of contraband confiscated indicates the extent of the illegitimate market for these substances. This factor is all the more important when it is appreciated that drug addiction becomes established at a much earlier age than is generally supposed; almost half, or 47 per cent, of addicts who come within the purview of observation have their habit established before reaching the age of 25 years, and two thirds, or 66 per cent, before age 30. Measures, therefore, that will tend to lessen the avalanche of contraband drugs reaching American shores are of great importance to this and the rising generation.

Drug addiction occurs in most unexpected places. No occupation possesses a monopoly of the practice. While it appears to be more common in the larger urban communities, where accessibility to the drug is probably greater, the geographic distribution of narcotic drug addiction is comparable to the distribution and concentration of the general population. Its geographic distribution may be compared to an endemic disease that is being engrafted on the people.

One problem of narcotic drug law enforcement in the United States is the prevention of the unlawful introduction of drugs from abroad. Domestic manufacture in the United States is limited so closely to the medical needs of the country that diversion of home-manufactured products is comparatively negligible. Foreign overproduction, however, in excess of the amounts needed for medical and scientific purposes supplies the international illegitimate trade. It is impossible, therefore, for the United States to set its house in order in this regard without the cooperation and assistance of other governments in limiting the manufacture of narcotic drugs to medicinal and scientific needs.

The Geneva convention of 1931 is designed to control further the international traffic and distribution of narcotic drugs and to limit the manufacture of all dangerous and potentially dangerous narcotic drugs to medicinal and scientific requirements. The medical, pharmaceutic, dental and veterinary professions continue as custodians of these narcotics which are so essential in the treatment of the sick. The conference recognized the impossibility of applying, effectively, any scheme for the limitation of manufacture without means of limiting the quantity of raw materials, which factories are permitted to transform into narcotic drugs. The scheme for limitation of manufacture involves the transmission by all countries of estimates of the quantities of narcotic drugs required for domestic consumption and the control of exports from manufacturing countries. The manufacture of narcotic drugs is indirectly limited in the United States already, and the convention does not effect any further limitation of manufacture in this country. Dangerous and potentially dangerous drugs, codeine being included in the latter since it is so easily transformed into dangerous substances, come within the purview of limitation. Annual estimates to be submitted by each government as to the needs for narcotic drugs are based solely on medicinal and scientific needs. Newly discovered products obtained from the dangerous alkaloids of opium or from the ecgonine alkaloids of the coca leaf are restricted to the use of import and export certificates in international traffic until their dangerous properties have been determined. The quantities to be manufactured in any country come within the limit of the annual estimates for medical purposes, thus fixing a definite quantity that may be manufactured. Stricter supervision is to be maintained over the amounts of raw material and manufactured drugs in possession of every manufacturer, including accountability for drugs produced and their disposal; quarterly reports are to be submitted to a central agency, thus setting up, in keeping with previous international agreements, a system or scheme for accounting for the manufacture of narcotic drugs and their distribution in the international trade. More stringent control is to be exercised over imports and exports, and diacetylmorphine (heroin) is to move but once in international traffic.

---

[7] Spencer, H. A.: South African M. Record 24: 386 (Sept. 11) 1926.

The Geneva convention of 1931, for limiting the manufacture of narcotic drugs, is of great potential value to the population of the United States. It embodies many features found in the legislation now in effect in the United States, constituting an additional reason for ratification by the Senate. Its ratification should have the support and endorsement of the medical profession.

FOOTBALL FATALITIES

A leading educator[1] remarked several years ago that nothing is more exasperating than to be compelled to witness a great tragedy which we know could be prevented if we could only do the right thing. He added that probably physicians in earlier times felt much the same way when they saw their patients die by the scores during some epidemic with which they were powerless to cope. Until the last half century, he continues, all who had to do with disease were so bound by the bonds of ignorance that they were well-nigh powerless. Meanwhile the progress of science and the unremitting efforts of its numerous devotees in the field of medicine have brought about extremely commendable changes resulting in a shift from the high mortality of an earlier period to the relatively low figures for the present generation. It has been a story of the routing of many scourges, the elimination of the terrors of wound infection, the conquest of yellow fever, the control of malaria, and varied similar experiences that have increased human happiness. Meanwhile great concern is obvious for less spectacular menaces—for the losses from lowered physical efficiency, preventable disorders and bodily injuries. Industrial hazards are attracting the attention of preventive medicine. Efforts are widespread to avert the growing number of accidents incident to the "speed" of present-day life.

Occasionally, disconcerting reports that cannot be lightly thrust aside arouse thoughtful persons to cynical reflections. There is, for example, the annual record of the toll of the firearm, the firecracker and similar "patriotic playthings" that tend to make Independence day recall unnecessary deaths and injuries. The Fourth of July fatalities seem to be confined for the most part to the less intelligent groups in our population. Another harrowing challenge, however, presents itself at the very gates of our most distinguished centers of learning, the American schools, colleges and universities. The now closing football season has taken a toll of thirty or more lives in addition to producing injuries the number and consequences of which cannot even be conjectured. Each new tragedy or distressing accident arouses nation-wide expressions of sympathy and protest only to be completely forgotten in the excitement of the next game.

Football is not a game for the untrained; it calls for strength and courage; its accidents and fatalities need not, however, be inevitable. Those who are devoting their energies to the conservation of life should not sit by listlessly and join in the coaches' lament of "a sad but inevitable death." We must not condone the reckless disregard of the limitations of human endurance and the return of injured players to the field, all for the glory of Alma Mater and the enjoyment of thousands of holiday seekers in the great stadiums.

Physical culture and athletic sports are not intended to develop supermen. At the recent White House Conference on Child Health and Protection, Secretary Ray Lyman Wilbur[2] remarked that we want to see our children develop into adult citizens with wholesome bodies and prepared minds, both under the control of the developed will operating in the atmosphere of what we call character. Does such a program call for a mortality record incident to the tasks? Surely not! The general objectives of a rational plan are to inculcate health habits; to develop the body harmoniously through systematic exercises; to correct physical defects; to form habits of exercise for use in after-school days; to provide situations which will arouse and increase the qualities of courage, fair play, self sacrifice and loyalty; and to give instructions in citizenship through leadership and response to commands.[2] We should be able to discover a way by which these aims can be attained without loss of life in our athletic ventures. Football has a greater incidence of fatalities and permanent injuries than any other sport. The rules committee may well consider carefully what it can do to lessen the hazards of this game.

PANACEAS FOR THE COMMON COLD

With the first blasts of wintry air a considerable number of our citizenry begin to develop the running of the nose, the lacrimation, the depression, the fever and the other symptoms commonly associated with the onset of a cold. No doubt, the vast majority of the practice of physicians is concerned with symptoms of this character. Probably no other disease is responsible for so much temporary disability. From the teachings of the hygienists, the sanitarians, the public health writers and physicians, most of the public have learned that the symptoms can be abated and the cold controlled in the majority of instances if the patient will go promptly to bed and stay there for at least three days. Actual observation indicates that less than one half of one per cent of people really follow this advice.

The promoters of various types of devices and foods associated with health maintenance have been prompt to take advantage of every possibility for exploiting their materials in connection with the universality of the common cold. Vitamin D has been vaunted for this purpose in the form of ultraviolet rays, cod liver oil, cod liver oil concentrates, irradiated foods and what-not, notwithstanding the fact that there is not the slightest scientific evidence to indicate that excess of vitamin D will prevent a cold or have any effect in curing it.

---

[2] White House Conference, New York, Century Company, 1930.

More recently evidence has been offered to indicate that in mice an excess of vitamin A favorably affects the tissue of the respiratory tract. Thus far, however, there is not sufficient actual evidence to warrant any claim at all for the use of vitamin A in preventing a cold. Nevertheless, the National Dairy Company, through one of its subsidiaries, presents the following statement in its advertising:

> "Dr. E. V. McCollum, world-known nutritionist from Johns Hopkins, in an address before the American College of Physicians, stated that lack of Vitamin A and common cold are linked together.
>
> "Think what this means! If your body contains plenty of Vitamin A, you are not so likely to get a 'cold.'
>
> "What common, economical food is the best source of Vitamin A? Milk! If you consume four glassfuls daily—either as a beverage, or in cream soups, creamed vegetables, custards, ice cream, etc.—you will have enough of this priceless vitamin to help guard you from 'colds.'"

For this statement again it may be said there is not adequate evidence.

An old English general practitioner, when asked what was the best thing to get for a cold, replied "Two dozen soft linen handkerchiefs." The tendency of the common cold is to be self-limited. At the end of three days the patient is generally better or beginning to get a more serious disease. The simple home remedies established by use in the last century will continue to be employed with considerable satisfaction by most people. They involve going to bed, indulging in perspiration by the use of hot water bottles and warm drinks slightly alkaline, the prescription of remedies somewhat antipyretic and analgesic, and watchful waiting for the onset of symptoms indicating any complication.

In the meantime, both the physician and the layman may well be advised to distrust conclusions as to the prophylactic value of any device or preparation for the common cold beyond the well established hygienic advice to stay out of crowds, to keep the head cool and the feet warm, and specifically to keep away from people who have colds. Our modern housing and transportation make the last mentioned measure almost an impossibility.

As concerns vitamin A particularly, it has been established that it has in mice the virtue of maintaining the integrity of the epithelial linings of the mucous tracts and the skin. Acceptable evidence in support of its specific virtues as related to the common cold is not available. Indeed, such evidence as is available tends to indicate that it has little if any important virtue in this regard.

Current Comment

THE TREND OF ADVERTISING

When any industry or profession begins to take stock of its own methods with a view toward reform, those methods have probably evolved to a point at which they are antisocial and opposed to the general good. Today, leaders in the advertising field are protesting in their own organizations against abuses to which THE JOURNAL has been referring for several years. In a recent address before the Advertising Council of Chicago, Mr. Ralph Starr Butler of the General Foods Corporation emphasized the fact that the public is not sufficiently educated to recognize exaggerated and untrue claims in most instances and that the continued use of such claims by many advertisers is likely to lead eventually to disappointment and to cause the public to indict the veracity of advertising as a whole. Mr. Butler was particularly concerned, however, with the type of advertising which discusses the competitor's product rather than the goods of the manufacturer who purchases the space. In good times, when conditions are generally satisfactory, most manufacturers and most salesmen find business so easy to secure that they concern themselves only with the sale of their own products. In times of economic stress, however, the average individual travels about with a chip on his shoulder, ready to attack his competitor for what may be merely the results of bad times or perhaps merely his own failure. Mr. Butler referred particularly to the type of advertising now employed by several manufacturers of cigarets. The claims made are mutually contradictory, and it seems reasonable to believe that sufficient emphasis on these points to the public will lead intelligent readers eventually to the opinion that neither of the products is good. In the thesis emphasized by Mr. Butler there is a lesson for the medical profession, the hospitals and all those associated in the practice of medicine today. Much is to be gained by mutual activity, by helpful cooperation and by education of the public in the service that medicine is able to render. In some communities, various medical groups associated with individual hospitals, with individual schools or in other ways have reflected unfavorably to the public on their presumably competitive neighbors. Such reflections will do little to aid those who make them; their ultimate result will probably be harm to the practice of medicine as a whole in that community.

INSULIN—A PROTEIN

In the latest edition of his well known book on the treatment of diabetes mellitus, Joslin[1] remarks that "diabetes is no longer fatal and the diabetic has ceased to die of his disease." One of the main factors, and probably the most important influence, in bringing about this beneficent result has been the discovery of insulin and the introduction of its use. The continued efficacy of the commercial preparations of the pancreatic hormone that are now everywhere available has brought much happiness. The duration of life for diabetic children, who seldom survived diabetes for more than two years in former days, has already been trebled. Joslin says, "The diabetic child of today is a living and not a dying diabetic." In view of these cheering statements it will readily be understood why scientists are at present so deeply concerned about the chemical nature and properties of insulin, the substance that possesses such remarkable physiologic potencies. Indeed, its uniqueness seems to be accentuated as the years pass by. The early investigations of insulin gave indications that it is either a protein or a protein-like substance or something closely associated with proteins in nature. Very active preparations give many of the familiar protein test reactions; they yield familiar amino-acids so characteristic as protein disintegration products; they are destroyed by digestion with proteolytic enzymes, namely, trypsin and pepsin. Then came the splendid contributions from the laboratory of Abel at Johns Hopkins University, resulting in the preparation of highly purified, optically active crystalline products. To the chemist the production of crystals out of amorphous residues always represents an apparent step in the direction of greater purity. Using crystalline insulin as a material for new studies, Sjögren and Svedberg[2] of the University of Uppsala have estimated its molecular weight by their ultracentrifugal methods. It approximates 35,100. Insulin is stable from a p_H of about 4.5 to about 7.0; at higher or lower hydrogen ion concentrations the molecule is broken into smaller units. The molecular weight, sedimentation constant, molar frictional constant and molecular radius of insulin are within the limits of error identical with the corresponding constants for egg albumin and Bence-Jones protein. This circumstance makes it extremely probable that insulin is a well defined protein and that the physiologic activity of this hormone is a property of the insulin molecule itself or of some special group within it. Recent months have witnessed the successful crystallization of several enzymes—urease, pepsin, trypsin and amylase—and the growth of new evidence that these, too, presumably belong to the category of proteins.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts at 11:15 a. m. on Saturday, over Station WBBM (770 kilocycles, or 389.4 meters).

The program for the week is as follows:

December 19. Diphtheria Prevention.

Five Minute Health Talks may be heard over Station WBBM of the Columbia Broadcasting System from 2:25 p. m. to 2:30 p. m. on Monday, Wednesday and Friday.

The program for the week is as follows:

December 14. Diphtheria Prevention.
December 16. Diphtheria Prevention.
December 18. Diphtheria Prevention.

The broadcast this week is in conjunction with the Chicago health department.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Personal.—Drs. William R. P. Clark and John H. Graves have been appointed members of the state board of health to succeed Drs. Adelaide Brown and Edward F. Glaser, resigned. ——Dr. Eli A. Kusel has been appointed city health officer of Oroville, and Dr. Edwin B. Godfrey, health officer of San Bernardino County to succeed Dr. Samuel B. Richards.——The city of Santa Paula health department has been taken over by the county health department.

Outbreak of Trichinosis.—Sixteen cases of trichinosis caused by the eating of jerked bear meat were recently reported in Vallejo, San Francisco and Oakdale. September 16, a Vallejo boy killed a bear in Trinity County. A number of persons ate steaks, roast and liver from the bear and the remainder was jerked and smoked. A San Francisco man took a portion of the jerked meat home and the remainder was brought to Vallejo. This meat was distributed among families in Vallejo, San Francisco and Oakdale, where cases from this source occurred. The boy who shot the bear died, October 13. According to the state department of health in its bulletin, November 14, it is possible that more fatalities will occur. A sample of the meat sent to the state laboratory was found positive for Trichinella spiralis.

COLORADO

License Reinstated.—At a meeting of the state board of medical examiners, October 6, the license of Dr. George D. Hoschouer, Denver, was reinstated. Dr. Hoschouer's license had been revoked, April 7, for unprofessional and dishonorable conduct in associating with an unlicensed man.

Society News.—Dr. Max M. Ginsburg addressed the Medical Society of the City and County of Denver, November 17, on "Septicemia in Children"; Dr. George M. Blickensderfer presented a case of psychoneurotic vomiting.——Dr. Marion D. Douglass, Jr., Cleveland, addressed a meeting at the University of Colorado School of Medicine, Denver, November 23, on "Tumors of the Urethra."

FLORIDA

Society News.—The Florida Public Health Association held its annual public health conference, December 7-10, in Jacksonville. The opening address was given by Governor Doyle E. Carlton on "The State in Public Health"; among others, Dr. John A. Ferrell of the Rockefeller Foundation, New York, spoke on "Education and Training of Public Health Personnel." ——Dr. William E. Ross, Jacksonville, addressed the Orange County Medical Society, Orlando, October 21, on "Milk, with Special Reference to the Value of Certified Milk to the Individual and a Certified Dairy to a Community," and Dr. Joseph H. Chiles, Orlando, gave a paper on "Infantile Impetigo Contagiosa."——The Central Florida Medical Society was addressed at its semiannual meeting in Ocala, October 15, by Drs. Gaston H. Edwards, Orlando, and James Ralston Wells, Daytona Beach, on "The County Society" and "The Public Relations Committee's Activities," respectively. Dr. Edwards also addressed the October 14 meeting of the Polk County Medical Society in Bartow on "Cooperation of Individuals and of County Societies as a Means of Benefit to Them and to the State Association," and Dr. Kenneth Phillips, Miami, spoke on "Essential Nature of Bronchial Asthma."——Dr. Robert A. Strong, New Orleans, addressed the Duval County Medical Society, Jacksonville, October 2, on "Our Newer Knowledge of Nutrition."

GEORGIA

Meningitis at Federal Penitentiary.—Four cases of spinal meningitis with two fatalities were reported between November 8 and November 19 at the federal penitentiary, Atlanta. Three new cases were reported, November 28. According to the newspapers, no new commitments will be sent to the penitentiary until the disease has subsided. Prisoners destined for the institution will be sent to Leavenworth and to the reformatory at Petersburg, Va. It was stated that the Atlanta penitentiary is overcrowded, the present population having been reported as about 3,800, nearly double the prison's capacity of 2,000. Members of the U. S. Public Health Service have been in constant attendance at the institution since the disease was reported, to prevent its further spread.

---

[2] Sjögren, B., and Svedberg, T.: The Molecular Weight of Insulin, J. Am. Chem. Soc. 53:2657 (July) 1931.

ILLINOIS

Society News.—Dr. Albert B. Yudelson, Chicago, addressed the Peoria City Medical Society, December 1, on "Relief of Symptoms of Tabes Dorsalis."——Dr. Charles Spencer Williamson, Chicago, addressed the DeWitt County Medical Society, Clinton, November 30, on pneumonia.——Dr. Chester H. Warfield, Chicago, addressed the Will-Grundy Counties Medical Society, December 2, on bone tumors.

Chicago

Personal.—Drs. Douglas Gordon Campbell and Margaret W. Gerard have been appointed heads of the psychiatric service in the University of Chicago's Student Health Service to succeed Dr. Stewart B. Sniffen, who resigned because of ill health. ——Dr. Herman N. Bundesen, health commissioner of Chicago, has resigned as coroner of Cook County.

Society News.—The Chicago Society of Internal Medicine will be addressed, December 14, among others, by Drs. William A. Brams and Louis N. Katz on "Nature of Fibrillation and Flutter of the Heart."——At the meeting of the Chicago Surgical Society, December 11, Dr. Samuel J. Fogelson, among others, spoke on "Treatment of Peptic Ulcer with Gastric Mucin."——A symposium will be held before the Chicago Medical Society, December 16, on the infantile cerebral palsies (The Spastic Child); the speakers will be Drs. H. Douglas Singer, Julius H. Hess, Henry B. Thomas, Abraham A. Low, and Miss Jane A. Neil, assistant superintendent of the public school system of Chicago.

City Council Approves Vivisection Ordinance.—At a meeting, December 1, the city council by an overwhelming majority approved an ordinance which permits the mayor to name a supervisor of the pound and release unclaimed dogs to medical schools and research laboratories approved by the city health commissioner and the chief of police for experimental work in medicine. This ordinance was a substitute for one submitted by antivivisectionists, which would prevent the medical schools and research institutions of Chicago from obtaining animals from the pound for experimental purposes. At a hearing of the judiciary committee of the city council, November 3, the speakers in opposition to the latter ordinance included Robert Maynard Hutchins, president, University of Chicago; Drs. Anton J. Carlson, professor of physiology, University of Chicago; Andrew C. Ivy, Nathan Smith Davis professor of physiology and professor of pharmacology, Northwestern University Medical School; David J. Davis, dean, University of Illinois College of Medicine; Louis D. Moorhead, dean, Loyola University School of Medicine, and Herman L. Kretschmer, president-elect, Chicago Medical Society.

LOUISIANA

Society News.—At the thirteenth annual fall meeting of the Sixth District Medical Society in Jackson, October 14, the speakers included Drs. Sidney C. Barrow, Shreveport, on "Economic Trend in Medicine"; Charles S. Miller, Jr., Jackson, "Psychiatry and the General Practitioner"; Lester J. Williams, Baton Rouge, "Roentgen Ray in Skin Diseases," and Lucius D. McGehee, Hammond, "General Practitioner and Specialist."

Recent Changes at Tulane University.—The following changes in the faculty, among others, at Tulane University of Louisiana School of Medicine, New Orleans, have recently been announced:

Dr. William Harvey Perkins, professor and head of the department of preventive medicine.
Dr. Bruce Peck Webster, assistant professor of medicine.
Dr. Kiyoshi Hosoi, Honolulu, Hawaii, instructor in surgery.
Dr. Howard Raymond Mahorner, instructor in surgery.
Dr. Ambrose Howell Storck, instructor in clinical surgery.
Dr. Durward Olera Wright, instructor in medicine.
Dr. Herbert John Schattenberg, instructor in pathology and bacteriology.

The following new appointments in the Graduate School of Medicine of Tulane were also announced:

Dr. Joseph Hume, director, division of urology.
Walter Clarence De Rouen, Jr., D.D.S., assistant professor of oral hygiene.
Dr. Frank James Kinberger, assistant professor of clinical pediatrics.
Dr. Eugene B. Vickery, assistant professor of urology.
Dr. Hymen Leon Cohen, clinical assistant in obstetrics.
Dr. John Ashby Colclough, clinical assistant in operative surgery.
Dr. Warren Leucht Rosen, clinical assistant in medicine.
Dr. Philip John Saleeby, clinical assistant in metabolism and dietetics.
Dr. Jack Ezell Strange, clinical assistant in pediatrics.

MARYLAND

Osler and Halsted Clinics Completed.—A medical and surgical building was completed at Johns Hopkins Hospital, November 6, giving the institution a capacity of about 1,000 beds. Half of the building, the Osler Clinic, was completed and occupied in January; the other half is the Halsted Clinic. These clinics are memorials to the late Dr. William S. Halsted, first professor of surgery, and the late Sir William Osler, first professor of medicine at the Johns Hopkins University School of Medicine. The addition, which provides about 300 beds, will house only ward patients. The building cost $1,740,000, provided by a gift of $500,000 from the General Education Board and an appropriation from an anonymous gift of $3,000,000. An additional endowment is being sought to meet the cost of maintenance of the annex recently completed.

Herter Lectures Given by Dr. Greenwood.—The annual Herter lectures were given, December 2-4, at the Johns Hopkins School of Hygiene and Public Health, Baltimore, by Dr. Major Greenwood, since 1926 professor of epidemiology and vital statistics, London School of Hygiene and Tropical Medicine. The lectures were devoted to a discussion of experiments in the prevention and control of epidemics, beginning with a review of the historical background of epidemiology. The Herter Foundation was established in 1902 by a gift of $25,000 from Dr. and Mrs. Christian A. Herter, New York, "for the formation of a memorial lectureship designed to promote a more intimate knowledge of the researches of foreign investigators in the realm of medical science."

MASSACHUSETTS

Society News.—The Boston Society of Psychiatry and Neurology was addressed, November 19, by Drs. Tracy J. Putnam on "Treatment of Dystonia Musculorum Deformans by Section of the Extrapyramidal Tracts"; Leon J. Saul and Hallowell Davis, "Action Currents in the Auditory Pathways," and Jacob Kasanin, "Pavlov's Theory of Schizophrenia."——The Cambridge Tuberculosis Association recently changed its name to the Cambridge Tuberculosis and Health Association; Dr. Hilbert F. Day is president.——Dr. Russell L. Haden, Cleveland, addressed the Harvard Medical Society, November 24, on "Development of Methods for the Determination of the Numbers, Size and Hemoglobin Content of the Red Blood Cell."——The New England Pediatric Society was addressed in Boston, November 19, by Dr. Homer F. Swift, New York, on "Rheumatic Fever."——Dr. Roderick Heffron, Boston, addressed the Hampden District Medical Society, Springfield, November 24, on "The Massachusetts Pneumonia Program"; Drs. Laurence D. Chapin and Ernest A. Gates discussed Addison's disease.——A symposium on gonorrheal vulvovaginitis featured the first annual meeting of the Neisserian Medical Society of Massachusetts, Boston, November 18.——Dr. Harold I. L. Loverud, Boston, among others, addressed the New England Roentgen Ray Society, Boston, November 20, on "Massive Collapse Complicating Pneumonia."——A program on congenital cardiovascular disease was held in Boston, December 2, by the New England Heart Association; this was the second meeting of the cardiac course for the season; the speakers included Drs. Arthur C. Ernstene, Howard B. Sprague, Hyman Green and Kenneth D. Blackfan.——A symposium on the surgical treatment of pulmonary tuberculosis featured the meeting in Waltham, December 10, of the Middlesex South District Medical Society.

MINNESOTA

Dr. Simons Honored.—Dr. Edwin J. Simons, Swanville, was awarded the 1931 prize of $250 by the Minnesota Society of Internal Medicine for his monograph on primary carcinoma of the lung. The prize is offered annually to the practitioner of medicine in the state, not a member of the society, who has made the most valuable contribution to medical knowledge.

Chiropractor Sentenced.—George F. Sjoden, licensed chiropractor of Kensington, was sentenced to six months at hard labor in the Douglas County jail, November 12, by Judge Roeser, for practicing medicine without a license. Sjoden has been prescribing medicine and attempting to remove tonsils. After having the medical practice act and the chiropractic law very carefully explained to Mr. Sjoden, the judge suspended the sentence on condition that he pay the costs of the prosecution, that he refrain from practicing medicine in the future and that he keep the peace and be on good behavior.

Society News.—Dr. Moses Barron, Minneapolis, spoke on "The Importance of Hepatomegaly and Splenomegaly in Differential Diagnosis" before the Minnesota Academy of Medicine, November 11; Dr. Archa E. Wilcox presented a case report on acute condition in the abdomen complicating pregnancy.——The Minneapolis Surgical Society was addressed, December 3, among others, by Dr. Daniel A. MacDonald on "Double Uterus and Vagina with Unilateral Atresia."——Dr. Alfred W. Adson, Rochester, among others, addressed the Minnesota Academy of Ophthalmology and Otolaryngology at a meeting in Rochester, November 13, on abscess of the brain.

MISSOURI

Society Celebrates Golden Jubilee.—The fiftieth anniversary of the St. Louis Medical Society was observed at a meeting, November 24. The program included addresses by Alphonse M. Schwitalla, S.J., Ph.D., dean, St. Louis University School of Medicine, on "Men in Medicine"; Dr. Robert J. Terry, professor of anatomy, Washington University School of Medicine, "Contributors to Medicine," and Dr. Amand N. Ravold, "Brief Sketches of a Few St. Louis Physicians." Special recognition was given to the fifty years or more spent in the practice of medicine by the following physicians: Drs. Ravold, Max C. Starkloff, Carl Barck, James A. Dickson, Willis Hall, Louis Hauck, Harvey G. Mudd and Henry L. Wolfner, St. Louis; Eugene F. Hauck, Clayton, and Henry J. Harnisch, Flagstaff, Ariz. With the exception of Dr. Starkloff, who was ill, all were present. Seven of the physicians are graduates of the St. Louis Medical College, now known as Washington University School of Medicine. Entertainment included an informal reception, bridge, refreshments and dancing.

Society News.—At a meeting of the St. Louis Medical Society, November 6, Dr. Francis L. Reder was elected president and Dr. Alvin H. Diehr, secretary. Dr. Amalie M. Napier was elected president and Dr. Emma Phelan, secretary of the Women Members of the St. Louis Medical Society at a meeting, November 3.——The Jackson County Medical Society, Kansas City, was addressed, November 24, by Drs. Samuel H. Snider on "Bronchial Function in Pulmonary Tuberculosis"; Ralph E. Emerson Duncan, "Use of Oxygen as a Therapeutic Agent," and Harvey P. Boughnou, "Atelectasis versus Pneumonia."——Dr. Russell M. Wilder, Rochester, Minn., addressed the Kansas City Academy of Medicine, November 20, on "Diseases of the Parathyroid."——A symposium on the diagnosis of diseases and abnormalities of the gastro-intestinal tract featured a joint meeting of the Radiological Society of North America and the St. Louis Medical Society, December 1; the speakers were Drs. Thomas A. Groover and Alexander B. Moore, Washington, D. C.; Henry K. Pancoast, Philadelphia; Byrl R. Kirklin and Harry M. Weber, Rochester, Minn.; John L. Kantor, New York, and Horace W. Soper and Evarts A. Graham, St. Louis. The two societies were guests of the St. Louis Roentgen Society at a luncheon.——Dr. Leo G. Rigler, Minneapolis, addressed the St. Louis Trudeau Club, December 3, on "Roentgen-Ray Observations on Free Pleural Effusion," and Dr. Louis H. Clerf, Philadelphia, "Bronchoscopic Observations in Tuberculosis."

MONTANA

Society News.—The Mount Powell Medical Society recently sponsored the first public meeting devoted to cancer that was ever held in Montana at Anaconda. More than 250 persons were in attendance. Dr. William F. Cogswell, secretary of the state board of health, spoke, and the Lewis cancer film was shown.

NEW YORK

Meeting of Laboratory Workers.—The New York State Association of Public Health Laboratories held its autumn meeting in Albany, November 6. Guest speakers were Philip B. Hadley, Ph.D., Ann Arbor, Mich., on "Microbic Dissociation in Relation to Medical Bacteriology"; Dr. Fred W. Stewart, New York, "Aspiration Diagnosis of Tumors," and Chester W. Emmons, Ph.D., New York, "Variations in the Ringworm Fungi." Round table discussions were held relating to regulation of human blood donors and to isolation and identification of meningococci in the spinal fluid from cases of meningitis. In this connection the state laboratory has asked physicians to send either transplants of cultures of meningococci or specimens of spinal fluid for use in studies now in progress on the production of antimeningococcus serum. Dr. George M. Mackenzie, Cooperstown, is president of the laboratory association.

New York City

Third Harvey Lecture.—William H. Taliaferro, Ph.D., professor of parasitology, University of Chicago, will deliver the third Harvey Society Lecture at the New York Academy of Medicine, December 17, on "Infection and Resistance to the Blood-Inhabiting Protozoa."

Society News.—Dr. Udo J. Wile, Ann Arbor, Mich., addressed the New York Academy of Medicine, December 3, on "Cutaneous Manifestations of Systemic Disease."——Dr. Harold E. B. Pardee addressed the Medical Society of the County of Queens, November 24, on "Diagnosis and Treatment of Coronary Arteriosclerosis." Dr. Frank C. Yeomans addressed the society, December 4, on diagnosis in proctology.——Drs. Norman E. Titus and George C. Andrews, Jr., addressed the Yorkville Medical Society, November 16, on "Medical Diathermy" and "Physical Therapy in Dermatology."

Exhibit on Pure Air and Clean Streets.—To impress on the public mind the menace to health of impure air and dusty, cluttered streets, the New York Academy of Medicine has arranged an exhibit to open January 12 and continue for eight days. It will consist of scientific instruments of precision in measuring contamination, models of modern street cleaning apparatus, stoking devices, ventilating machines and motion pictures depicting modern methods, in addition to charts, graphs and photographs. The exhibit is to be held under the auspices of the academy's committee of public health relations and the committee of twenty on outdoor cleanliness.

Hospital Opens Unit for Middle Man.—An experiment in the provision of hospital and nursing care for patients of moderate means was launched by Mount Sinai Hospital, November 18, with the opening of a new twelve-story building for this service. Three departures from the usual hospital practice will be instituted, the hospital has announced. These are innovations in the construction of the building, group nursing and voluntary action of the medical staff in setting a definite limitation on the fees to be charged by surgeons and attending physicians. The expense of the new service will include, for bed accommodations, $35 per week; special group or cooperative nursing, if desired, $45 per week and the fees of the medical staff restricted to a similar proportion. In the new hospital, which will accommodate 156 patients, rooms are arranged in units of two, each containing four beds in cubicles, with a nurse's substation between. Quiet rooms are provided for patients who are very ill. Lockers are used for individual patients and a built-in closet for nursing supplies. The new building is constructed of brick and limestone to harmonize with the other Mount Sinai buildings and occupies the entire Fifth Avenue frontage between One Hundred and First and One Hundred and Second streets. It cost approximately $1,250,000. One floor will house the newly organized consultation service for patients of moderate means (The Journal, July 25, p. 255).

OKLAHOMA

Personal.—Dr. Wann Langston, Oklahoma City, has resigned as superintendent of the University Hospital to become professor of clinical medicine in the University of Oklahoma Medical School.——Dr. Thomas W. Stallings, Tulsa, has been appointed health officer of Tulsa County, succeeding Dr. Bernard L. Branley.

Medical Films.—The Oklahoma State Medical Association has purchased two films, one on the application of forceps and one on eclampsia, for circulation among the county societies. The films are kept and serviced by the extension department of the University of Oklahoma, Norman. County societies are required to see that they are handled only by qualified operators and to pay the expenses of transportation to and from Norman.

Society News.—Drs. Leander A. Riely and John E. Heatley, Oklahoma City, addressed the Osage County Medical Society, recently, on "Clinical Aspects of Gallbladder Disease" and "X-Ray Diagnosis of Gallbladder Disease," respectively.——Among physicians who addressed the annual meeting of the Oklahoma State Hospital Association, Oklahoma City, December 2-3, were Drs. Talbert B. Hinson, Enid, "Hospital Rates"; Frank H. McGregor, Mangum, "Effects of the Present Economic Condition on Hospital Operation"; Berry H. Burnett, Duncan, "Hospital Relationship to Practitioners of Medicine," and D. B. Collins, Waurika, "The Problem of the Ever-Increasing Automobile Accidents."

PENNSYLVANIA

Society News.—Drs. John Sturgeon and Ralph P. Beatty discussed "Pyelitis in Infancy and Childhood" from the points of view of the pediatrician and urologist, respectively, before the Fayette County Medical Society, Uniontown, December 3.——Dr. Thomas A. Shallow, Philadelphia, addressed the Montgomery County Medical Society, Norristown, December 9, on intestinal obstruction.——Dr. Ludvig Hektoen, Chicago, delivered a lecture entitled "What About Scarlet Fever?" at the Western Pennsylvania Hospital, December 9.

Philadelphia

Society News.—Dr. Robert J. Hunter, among others, addressed the Philadelphia Neurological Society, November 27, on "Localization of Intracranial Tumors by the Bárány Method."——Drs. Robert J. Hunter and Henry Dintenfass addressed the Philadelphia Laryngological Society, December 1, on "Physiology of the Antrum" and "Catheterization of the Natural Ostium of the Maxillary Sinus versus Inferior Meatal Puncture," respectively.——Dr. Edwin Beer, New York, delivered the annual Mütter Lecture of the College of Physicians of Philadelphia, December 2, on "Diverticulosis of the Alimentary and Urinary Tracts."——Speakers at the meeting of the Philadelphia County Medical Society, December 9, were Dr. Herman O. Mosenthal, New York, on "Diet in Bright's Disease"; Dr. Carl F. Schmidt, "Respiratory Depressants and Respiratory Stimulants," and Charles H. LaWall, Pharm.D., "Cooperation Between Physician and Pharmacist."——Dr. Truman G. Schnabel delivered the postgraduate seminar, December 4, on "Anemias Simulating Pernicious Anemia."

TEXAS

Change in Subscription Representative.—Mr. William M. Dickinson, Dallas, is no longer acting as representative for publications of the American Medical Association. Mr. Fletcher Lane, Waco, has succeeded him.

Society News.—Drs. Louis Daily, Houston, and Horace S. Renshaw addressed the Tarrant County Medical Society, Fort Worth, November 3, on "Value of Bronchoscopy in Diagnosis and Treatment" and "Boehler Treatment of Fractures," respectively.

VIRGINIA

Health at Richmond.—Telegraphic reports to the U. S. Department of Commerce from eighty-two cities with a population of 36 million, for the week ended November 28, indicate that the highest mortality rate (17.8) appears for Richmond and the rate for the group of cities as a whole, 10.5. The mortality rate for Richmond for the corresponding period last year was 10.8 and for the group of cities, 10.7. The annual rate for eighty-two cities for the forty-eight weeks of 1931 was 11.8, as against a rate of 11.9 for the corresponding weeks of 1930. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have large Negro populations may tend to increase the death rate.

GENERAL

Society News.—Dr. Frank Smithies, Chicago, was elected president of the American Society of Tropical Medicine at its annual meeting in New Orleans, November 20, and Dr. Henry E. Meleney, Nashville, Tenn., secretary. The next annual session will be held with the Southern Medical Association in Birmingham, Nov. 18-20, 1932.——The annual conference of Eastern roentgenologists will be held, January 29-30, in New York. Societies that will participate include the New York Roentgen Society, New England Roentgen Society, Philadelphia Roentgen Ray Society, and the roentgenologists of Baltimore and Washington.

Unauthorized Salesman Preys on Physicians.—A man using the name G. A. Jennings is reported to be swindling physicians in several Southern states by posing as a representative of the Woolcraft Company, Grand Rapids, Mich., makers of men's clothing. The firm reports that he visits physicians exclusively and that the most recent complaints have come from Georgia. He carries expensive samples, and his story is that he is making a special introductory price to representative citizens to advertise the firm. He collects a deposit from the customer and disappears. The man is described as about 40 years old, slightly bald. He has red hair, a small red mustache and dark eyes and frequently wears dark rimmed glasses. His height is about 5 feet 8 inches and his weight between 150 and 160 pounds. Any physicians approached by G. A. Jennings are requested to wire the firm collect immediately. It is said that his operations have continued over a period of two years. The fact that he promises a future delivery of the goods gives him time to seek other fields before a complaint can be made.

Eyestrain Among School Children.—A comprehensive study of the strain on eyesight in school activities is being undertaken as a joint project of various departments of Columbia University and the National Society for the Prevention of Blindness. No time limit has been set for the completion of the work, nor is the scope of the problem being limited to fit a given group of workers, the report states. The plan is to carry the investigations over as long a period of time and into as many fields as is necessary. A study of the eyestrain of the school children from the ages of 5 to 10 years is now being carried on as the first step in the proposed work. The program of research will include the vision of the child, the lighting conditions under which he works, the materials he uses and the length of time he uses them. The announcement reports that plans have been completed for this research after a year of planning by Teachers College of Columbia University, staff members of the department of ophthalmology in the medical school, authorities in related fields within the university, and staff members of the National Society for the Prevention of Blindness.

Association for Advancement of Science.—Section N (the medical sciences) of the American Association for the Advancement of Science will meet, December 28-31, during the general meeting of the association at New Orleans. Subjects to be considered include "Parasitology of Medical Interest" at a joint meeting with the American Society of Parasitologists; "Effect of Drugs and Internal Conditions on Behavior"; symposiums on growth in joint sessions with the sections on anthropology and archaeology and on social and economic sciences; mental disorders, which will be discussed in two sessions, one with the section on psychology. Among numerous speakers announced are Dr. Abraham Myerson, Boston, on "Psychological Approach to Functional Nervous Conditions"; Dr. Gilbert J. Rich, New York, "Relationships Between Personality and Body Chemistry"; Richard E. Scammon, Ph.D., Minneapolis, growth of the individual; Dr. Frederick J. Cullen, U. S. Food and Drug Administration, "Fake Remedies Unearthed by the Pure Food and Drug Act." Dr. Howard T. Karsner, Cleveland, is vice president for the medical section.

Hospital Association Opposes Increase in Federal Hospitals.—A resolution opposing continuance or enlargement of the present legislative program of the federal government in the construction of veterans' hospitals has been sent to members of Congress by the American Protestant Hospital Association through its secretary, Frank C. English, D.D., Cincinnati. The protest points out that many general hospitals are burdened financially and need all local revenue. The association feels, therefore, that the plan to send veterans to distant cities and pay for their care, while their families are frequently thrown on local hospitals as charity patients, works a hardship on such hospitals, especially when half of their beds are often vacant. The trustees of the association believe that the government should provide hospitals for the permanently disabled and the tuberculous, cancerous and mental patients, but should consider carefully the question of having those who are temporarily sick and injured treated in civilian hospitals as more economical. It is believed that this can be done at a cost to the government less than what it costs to build and operate veterans' hospitals.

News of Epidemics.—Five thousand residents of Plattsburgh, N. Y., were vaccinated in November to check the spread of an epidemic of smallpox, which amounted to forty cases, November 13.——Whooping cough is reported to be widely prevalent in Illinois, with about 300 cases developing each week, more than twice the weekly average for 1930.——The county jail at Akron, Ohio, was quarantined in November after a prisoner became ill of diphtheria. Six other inmates were found to be carriers.——Public schools in Winchester, Ky., were closed when five cases of scarlet fever were found among the pupils, November 19.——An epidemic of typhoid in Buchanan County, Va., caused local authorities to appeal to the state board of health, November 28, for help in checking it. It was said that in some sections of the county there were families with from one to six members ill. Contamination of springs from which these people take their drinking water was thought to be the cause of the outbreak.——Several cases of typhoid in Wilmington, Del., were recently traced to the unauthorized collection of garbage by farmers who sold raw milk in the city. It was said that farmers removed garbage in violation of law from places where there were cases of typhoid and later dumped this contaminated material on their farms, where it was eaten by cattle or polluted the water they drank.

CORRECTION

"Focal Infection of Anal Origin."—In the article by Dr. Louis J. Hirschman in THE JOURNAL, November 28, page 1609, the strength of the nupercaine solution advised for infiltration anesthesia should be 0.05 per cent instead of 0.5 per cent. The strength of the procaine solution mentioned is correct.

Government Services

Army Personals

Major George E. Hesner, relieved at Alcatraz, Calif., and ordered to duty in the Philippine Department; Capt. John P. Russell, San Francisco, for the convenience of the government, proceeded to his home about October 31 to await retirement; Major John M. Hewitt, having attained the age of 64 years, September 25, his retirement from active service by direction of the President is announced; Major Max R. Stockton, on completion of present tour of foreign service, is assigned to duty at the Army Medical Center, Washington, D. C.; Major George W. Reyer, assigned at Fort Bragg, N. C., effective on completion of present tour of foreign service in China; Capt. George P. Chase, relieved at San Francisco and assigned to duty in the Hawaiian Department; Major Clarence M. Reddig, relieved at Washington, D. C., and ordered to duty in the Panama Canal Department; Major William M. White, relieved at Fort Sam Houston and ordered to duty in the Panama Canal Department; Major Oscar T. Kirksey, relieved at Fort Banks, Massachusetts, and ordered to duty in the Philippine Department; Major Meredith R. Johnston, relieved at Panama Canal, C. Z., and ordered to duty at Letterman General Hospital, San Francisco; Capt. James H. Turner, relieved at Fort Sam Houston and ordered to duty in the Panama Canal Department; Capt. Silas B. Hays, relieved at Letterman General Hospital, Presidio of San Francisco, and assigned to duty in Honolulu; Col. Frank W. Weed, relieved at Boston, and assigned to duty in the Philippine Department; Major Peter D. MacNaughton, having been found by an army retiring board incapacitated for active service on account of disability incident thereto, and such finding having been approved by the President, his retirement is announced; Capt. Paul Hayes, relieved at Fort Sheridan, Illinois, and ordered to duty in the Philippine Department.

Changes in Veterans' Administration

The November *Medical Bulletin* of the Veterans' Administration notes the following recent changes in medical personnel, among others:

HOSPITALS

Dr. Leonard M. Brown, from Bronx, N. Y., to St. Cloud, Minn.
Dr. James H. Chapple, from Sheridan, Wyo., to Hines, Ill.
Dr. Compton N. Crook, from Tucson, Ariz., to Outwood, Ky.
Dr. Sherwood Dix, from Bronx, N. Y., to Northport, L. I.
Dr. James H. Dyer, from Lake City, Fla., to Muskogee, Okla.
Dr. William A. Jones, appointed at Palo Alto, Calif.
Dr. Samuel Luber, resigned at Lexington, Ky.
Dr. Willis E. Manney, detailed to Gulfport, Miss.
Dr. Emanuel Messinger, from Northport to Lyons, N. J.
Dr. Asa L. Myers, from Chillicothe, Ohio, to Washington, D. C.
Dr. Luther E. Nichols, from Outwood, Ky., to Tucson, Ariz.
Dr. Tracy C. Owens, permanently assigned at Chillicothe, Ohio.
Dr. Spiro Sargentich, from American Lake, Wash., to central office.
Dr. Frank R. Sedgley, from Minneapolis to Hines, Ill.
Dr. Ashby Steele, from Bedford, Mass., to Lexington.
Dr. Miguel Steinberg, from Bronx, N. Y., to Augusta, Ga.
Dr. Claude A. Thompson, from Muskogee, Okla., to Kansas City.
Dr. John A. Thurston, Jr., from Kansas City to Lake City, Fla.
Dr. Antonino Triolo, from Bronx to Northport.
Dr. Frederick L. Wright, from Palo Alto to American Lake.

REGIONAL OFFICES

Dr. Harold T. Allison, resigned at Scranton, Pa.
Dr. William J. Burdashaw, resigned at New York.
Dr. Samuel C. Kahlstrom, appointed at Cincinnati.
Dr. Frank M. Shafer, from National Military Home, Dayton, Ohio, to National Military Home, Hampton, Va.
Dr. Dana P. Stearns, appointed at Richmond, Va.
Dr. Ralph E. Stevens, resigned at Jacksonville, Fla.

Change of Station in the Navy

Lieut. Comdr. William B. Hetfield from the U. S. S. *Medusa* to the marine corps base, San Diego, Calif.; Lieut. Cyrus C. Brown from the naval hospital, San Diego, to the U. S. S. *Rigel;* Lieut. Comdr. Herbert L. Shinn from the Garde de Haiti, Port au Prince, Haiti, to the navy yard, Washington, D. C.; Lieut. Walter G. Kilbury, from naval hospital, League Island, Philadelphia, to Nicaraguan National Guard Detachment; Lieut. George F. Blodgett from naval hospital, New York, to naval station, Tutuila, Samoa; Lieut. Walter L. Bach, from Guardia Nacional, Nicaragua, to recruiting ship, New York; the resignations of Lieuts. Eric D. Pearson and David M. Segrest have been accepted, effective November 5 and 21, respectively; Lieut. Clyde M. Longstreth's resignation has been accepted, effective February 28.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Nov. 14, 1931.

The Increasing Importance of Blood Transfusion

In view of the increasing importance of blood transfusion, the Medical Research Council and the British Red Cross Society have appointed Dr. H. F. Brewer, senior demonstrator of pathology, St. Bartholomew's Hospital, as medical officer to the Blood Transfusion Service organized by the Red Cross. He will supervise the examination of transfusion volunteers and the collation of information on the effect of blood transfusion on donors, and he will carry out research into blood groupings, so that the service can keep abreast of the latest developments in surgery and hematology. Laboratory facilities are being provided by St. Bartholomew's Hospital. Since it was begun in 1921, the Red Cross Blood Transfusion Service has grown steadily. Last year, 1,627 transfusions were carried out, as against 1,333 in 1929. For the first nine months of this year, the number was 1,502. This rise is all the more significant when it is remembered that the success of the liver treatment of pernicious anemia has often obviated the necessity for successive transfusions. The membership of the service is now over 1,100, of whom about a fifth are women. More than a third of the members belong to the Rover Scouts, but almost every social service organization is represented on the service's list of volunteers. It was originally anticipated that a few hundred donors would be ample to meet the needs of all the London hospitals, but it is now found that at least 2,000 are required. The operation is neither painful nor in the least harmful to the donor, who frequently benefits by it. In most cases, if called on in the daytime, he returns to work within an hour. All expenses, including fares, telephone calls and time lost from work, are immediately refunded.

Radium Treatment in the Municipal Hospitals

The importance and advancing standard of the London municipal hospitals, which are quite different from the voluntary hospitals, has been shown in previous letters to The Journal. The Central Public Health Committee of the London County Council, which now controls them all, has had under consideration the advisability of developing radium treatment. The conclusion reached is that it is now so available in the council's hospitals that no additional facilities are required for the present. The committee has decided that at the most important unit, the Lambeth Hospital, where the treatment of cancer by radium and low voltage roentgen rays is given, the medical officer should possess highly specialized knowledge and skill. His position will be designated "whole-time surgical specialist" and his salary will be $6,250, rising by increments to $7,500 a year.

Psychiatric Clinics at the Municipal Hospitals

Increased attention is being given in this country to functional nervous diseases. The Maudsley Hospital in southeast London was endowed by the well known psychiatrist of that name and was organized by the London County council on the lines of the combined neurologic and psychiatric clinics of the continent and of America. It represented the first provision of the kind by a public body in this country. To increase accessibility of psychiatric diagnosis and treatment, the council has now established psychiatric clinics at each of the three municipal general hospitals north of the Thames: Mile End Hospital, St. Mary's, Islington, and St. Charles's Hospital, Hammersmith. The Maudsley Hospital has a complete staff of eminent specialists in the various branches of medicine and surgery, and the three new clinics will be subordinate to it. The clinics will be supervised by the medical superintendent of the Maudsley Hospital, and the physicians in charge of them will be drawn from its staff. Patients can be referred to these clinics by their physicians. The condition of suitability is likelihood of fitness for further treatment at the Maudsley Hospital or elsewhere on a voluntary basis. Among suitable conditions are neurotic disturbances, such as neurasthenia, hysteria, obsessional and anxiety states, and mental or neurotic symptoms associated with physical disease. On the other hand, mentally defective patients, those clearly requiring certification and nonvolitional patients are excluded. After diagnosis at the clinics, patients will usually, owing to local exigencies of time and space, be referred for treatment at the Maudsley Hospital.

The Financing of Irish Hospitals by Means of Sweepstakes

The work of financing Irish hospitals by money mostly drawn from England by means of sweepstakes goes merrily on. The third sweepstake of this year is about to be held, and there is little doubt that the fund will reach $10,000,000, of which a third will go to the hospitals. The reason of the great success is that such sweepstakes are illegal in England, and the prospect of large prizes, beginning at $150,000, proves especially attractive. The channel boats from England are crowded with visitors who want to obtain tickets for themselves and their friends. The British government has made ineffectual efforts, by refusing the use of the mails, when possible, and by prosecutions, to stop its subjects from taking part. Journalists from all parts of the world are attending the draw, for which special machinery is installed. Extensive rebuilding of hospitals has already been carried out by means of the proceeds.

The Causes and Prevention of Suicide

At the meeting of the Medico-Legal Society, Dr. Dennis H. Geffen, health officer for Enfield, dealt with the problem of suicide. Its magnitude was shown by the fact that in England and Wales as many as 4,907 persons committed suicide in 1927 and 4,882 in 1928. In addition, probably twice the number attempted suicide but failed. These figures may be compared with the 3,000 women who lose their lives every year in childbirth. The usual verdict after an inquest in a case of suicide is "suicide during temporary insanity," but figures show that only one case in every five is due to definite insanity. What is the cause of the suicide in the 4,000 sane persons? Dr. Geffen finds that it is nearly always present trouble, not fear of the future. But he describes it as a "mentally infectious disease," because it is often due to following an example. The first signs of impending suicide are mental depression, and a threat of suicide should never be taken lightly. Availability of means is important, such as ease in obtaining firearms. The ready availability of coal gas is now a serious matter. Up to the age of 30 there is little difference in the suicide rates of men and of women, but later three times as many men as women commit suicide. The part played by the sex factor accounts for the equalization before 30. Race plays a part; in America the rate for the Negro population is lower than for the white. As to occupation, the highest rate is for those in the liquor trade, and then follow pharmacists, lawyers come third and physicians fourth. As stated by Hoffman in his book on the suicide problem, highly developed mentality and occupational strain may predispose to mental breakdown.

Dealing with prevention, Dr. Geffen could see no advantage in making suicide a criminal act. Our law should be amended in this respect, as has been done by the United States and by Italy. Returning to the power of suggestion, he thought that the press reports of cases of suicide and the methods had a bad effect on the minds of the mentally depressed. This was shown by fashions in suicide. Also, the theory that suicide is hereditary was attributed to the effects of suggestion caused by previous cases in the family. Recently a young lawyer seemed keenly interested in a discussion on methods of suicide. The Roman method of opening a vein in a hot bath was mentioned. A few days later he committed suicide in this manner. The difficulty of restoring to society a man who has attempted suicide is increased if his case has been broadcast in the press. He feels that he is a pariah, and he is ashamed to face the public. The ministry of health insists that notifications of infectious disease must be confidential. If suicide had been accepted as a public health problem, like infectious diseases, and treated in the same way, something would have been done for its prevention. A third method would be investigation of the mentality of those who attempt or commit suicide. Dr. Geffen finds that the former are only too anxious to talk to any one who interests himself in their problem. Cure of the would-be suicide depends on three factors: complete rest, suitable occupation, and reinstatement in his place in life. It would often be necessary to isolate him from his family and acquaintances. There should be a special court to investigate these cases, which should take the form of going into the patient's troubles in comfortable surroundings, and, if necessary, detention should follow in a special hospital, not in a prison.

Improvement in the Health of the School Child

In his annual report on the health of the school child, Sir George H. Newman, *principal medical officer to the ministry* of health, says that school medical officers should conceive the primary object of medical inspection to be the answer to the question "Is this child developing according to the plan which nature has mapped out for him?" This is a difficult question, for it does not depend on averages of height, weight, alertness or mental attainment but on an estimate of the whole individual, who may be naturally short or tall, fat or lean, lethargic or alert, bright or stupid, and never intended by nature to be otherwise. What has to be determined is not whether he is below the average in any respect but whether he is below the standard which nature has set for him. To answer this, the medical officer must be able to visualize each child in a state of normal health and to estimate in what respect he falls short. The defect most frequently encountered in medical examination is related to vision; next come enlarged tonsils and adenoids, skin diseases and malnutrition. Only 1 per cent of the children now suffer from malnutrition. A great improvement has taken place. The better dress of the children is both a cause and an effect. No self-respecting school girl would now accept an accusation of uncleanliness without shame. There has been a revolution in cleanliness and dress, which has been conducive to health. The improvement in nutrition has been brought about partly by supplementary school feeding and partly by general care of the child at home and at school. When the school medical service began in 1907 there was approximately 10 per cent of malnutrition in the London schools. During 1930 in London, excluding special schools, 4,760,004 milk meals and 776,192 cod liver oil meals were given on the advice of physicians, the cost being recovered from the parents in nonnecessitous cases.

MORE OPEN AIR AND SUNSHINE

The introduction of the open air school for debilitated children has been of great service but more sunlight and open air are required for every child, sick or well. The principles of the open air school must be applied to the normal child. Progress in this respect is shown by the fact that 80 per cent of the building plans submitted to the board of education include proposals for throwing open to the outside air whole portions of class rooms and for admission of more sunlight than was formerly deemed necessary.

PARIS

Nov. 4, 1931.

The Congress of Pediatricians

The seventh Congrès des pédiatres de langue française was held recently in Strasbourg, under the chairmanship of Professor Rohmer. The first topic on the program was "Alimentary Fevers in Infants." Professor Schaeffer considered the various theories advanced in explanation of these fevers. He regards as the true cause the increase of the metabolism of substances that fix water, and more particularly the proteins. He maintains that there is no alimentary fever without absolute or relative dehydration. It is possible that, as a result of dehydration, there develops an action of poisons affecting the regulatory nerve centers. With a diet rich in albuminoids, such as dry milk, the combustion of proteins liberates less water than the combustion of carbohydrates. The heat produced is greater and is eliminated through perspiration, which creates a need for water. At the same time, these proteins leave a large quantity of urea, which requires a heavy dilution for its renal elimination. Dried human milk produces less harmful effects than skimmed and dried cow's milk because it furnishes fewer proteins. During the discussion that followed, Coréan and Vallette of Strasbourg expressed the view that in the mechanism of alimentary fever not only the excess of proteins but also the excess of sodium chloride played a part.

René Mathieu and Jean Chabrun considered in turn the various foods that may provoke fever in the infant: dry milk, buttermilk, condensed milk, ordinary milk whey, and sweetened dry milk.

The second topic concerned cerebral tumors in children. In a comprehensive paper presented by Mr. Heuyer and Mlle. Voigt, the clinical signs of such tumors were considered in detail: eye disorders, symptoms of paralysis or convulsions, modifications of tonus, headache, and changes of the cerebrospinal fluid. For the diagnosis, two signs are essential: choked disk and positive roentgenographic observations. The next step is to locate the tumor, which is often difficult in children and requires the use of ventriculography. The surgical treatment of these tumors was discussed by Clovis Vincent, David and Puech, who described their operative technic and the results secured by the surgical treatment of craniopharyngiomas (tumors developing from the remnant tissues of Rathke's pouch). An attempt should be made to extirpate the cystic pocket in toto, although that is often impossible. The statistics of their personal cases reveal a mortality of 25 per cent for this delicate operation.

The third topic, "The Concealed and Latent Types of Avitaminoses in Infants and the Causes of Their Appearance," was presented by Mr. Bertoye of Lyons. Among the causes he mentioned were defective diet, favorable terrane, the early age of the patient, and the activity of growth. Scurvy, beriberi, xerophthalmia and rickets never appear suddenly but are preceded by unobtrusive prodromal symptoms, which the speaker described with the greatest detail. He then reviewed the modes of treatment and the foods that may have deficient vitamins; also the medicaments (viosterol) and the physical agents (ultraviolet rays).

An International Council of Scientific Societies

During the period immediately following the war, the scientists of the allied countries created an organization called Conseil international des recherches scientifiques, the seat of which was at Brussels. Under the chairmanship of Mr. Emile Picard, the council developed some activity, but, with the return of peace, it was impossible to maintain its exclusive character. It became transformed, and simultaneously with Mr. Picard's communication to the Academy of Sciences stating that fact, he resigned as the president. The new organization, which will be called "Conseil international des unions scientifiques," will constitute a federation of the numerous international societies that specialize in various researches. Its chief purpose will be to appoint joint commissions that will pave the way for understandings between the various countries with respect to researches of common interest. The president is Professor Hale, astronomer at the Mount Wilson observatory, California, and one of the two vice presidents is General Ferrié, member of the Academy of Sciences in Paris.

Tubercle Bacilli in Tuberculous Pleural Effusions

Search for tubercle bacilli in pleural effusions has given heretofore such uncertain results that most microbiologists have become discouraged and have finally been inclined to admit that the fluid of these effusions exerts a lysing action on the bacillus. Karwacki, using ordinary culture mediums, succeeded in finding tubercle bacilli only three times, although he examined 33 liters of fluid. Schlossmann succeeded a little better by using the Petron method. Professor Bezançon, in collaboration with his assistant Mr. E. Buc, has recently solved the problem. He observed that the pleural fluid immediately modified its hydrogen ion concentration through loss of carbon dioxide. It is therefore necessary to acidify slightly the culture medium. The medium he uses is composed of distilled water, to which are added 2 per cent of peptone, 5 per cent of glycerin, and 1 per cent of monobasic potassium phosphate and sodium phosphate. Several tubes are filled with from 2 to 3 cm. in height and a few filaments of cotton are added. The contents are sterilized at a temperature of from 110 to 115 C., and an equal quantity of pleural fluid is added. The tubes are well stoppered and are kept in a bath at an exact temperature (between 37 and 38 C.). The colonies appear in from three to four weeks, either on the threads of cotton, which were added to serve as their support, or at the bottom of the tube. They increase in volume in the form of arborescent prolongations, especially in the more aerated region of the surface. The bacilli appear in countless numbers, and presenting their usual characters as to form, acidoresistance and inoculability in the guinea-pig. The positive results are virtually constant, especially if one considers the pleural exudates of artificial pneumothorax.

Dr. Chompret Honored

The first university chair of stomatology was established in 1844, at the Faculty of Medicine in Budapest. In memory of Professor Arkovy, its most eminent occupant, from the scientific point of view, the Hungarian society of stomatology has created a gold medal to be awarded every three years, by an international committee, to the stomatologist adjudged the most eminent. The medal has just been awarded (for the first time) to Dr. Chompret, stomatologist to the Hôpitaux de Paris, at the Hôpital St. Louis, who will retire at the end of this year from active service. He was the founder and has remained the director of the principal dental school of Paris.

Creation of a Hematologic Society

A new scientific society has been created in Paris: the Société d'hématologie. It numbers 250 charter members—French and foreign. Professor Hayem was chosen honorary president. Professor Chauffard was elected president; Professors Vaquez, Achard and Jolly, vice presidents; Dr. Chevallier, general secretary. The society will meet once a month in a conference room at the Hôpital de l'Hôtel-Dieu and will publish regularly scientific articles submitted by its members.

The German Pediatric Society

At the congress of the Deutsche Gesellschaft für Kinderheilkunde, held recently in Dresden, the Bonn pediatrician Goett discussed "The Physiology and Pathology of Sexuality in the Child." He surveyed the origin and development of the sex impulse in the child. Even in childhood there may be erotic exhibitions that cannot be entirely separated from sex consciousness. In abnormal paths of development, associations with a given emotion or a certain situation frequently assume an etiologic rôle. In most cases the prognosis of sexual disturbances in children is good. Aberrations of the sex impulse are frequently replaced after puberty by normal trends. Matters pertaining to home training are of especial importance in that connection.

Friedjung of Vienna, who has made a special study of the sexuality of the child, considers the manifestations from the standpoint of a follower of Freud. It is difficult to distinguish sharply between the normal and the abnormal in the life of the child. In connection with manifestations of budding sex impulse in the child, great caution must be exercised in the matter of ethical control. Great tact and a clear understanding of the situation are required in order to know when to impart information and what information to impart.

The second topic, "Active Immunization Against Diphtheria," constituted the high level of the session. According to the hygienist Bürger of Königsberg, the morbidity can be reduced by active immunizing measures to one fourth and possibly even to one tenth of the previous status. The case mortality cannot be influenced to any marked extent by the methods that are available. The duration of the immunity secured and its protective value in times of severe epidemics need to be investigated further. Legislative regulation of vaccination against diphtheria is not to be considered under present German conditions, and in the light of our present knowledge would be premature. The proper time for vaccination appears to be during a lull between outbreaks, since it requires months to develop immunity. Vaccination should be confined to young children (without reference to their susceptibility to toxins), to the toxin-sensitive children of the primary class in school, and to the care-taking personnel of the departments for infectious diseases.

Schick of New York reported on the extensive trials of vaccination against diphtheria carried out in the United States. He advised that Germany should hold fast to thoroughly proved procedures, and warned against drawing far-reaching conclusions from small series of observations. His statistics of diphtheria cases in the United States reveal, in the regions with active immunization, a marked reduction of the morbidity, after giving due allowance to the tendency toward spontaneous decline, such as is observed in various regions. Loss of immunity occurs occasionally. Children under 6 years of age are more difficult to immunize than older children. In infants favorable results have been secured with the Ramon anatoxin (toxoid). For older children, subneutralized toxin is commonly used. He showed how it was possible through an extensive campaign of publicity to carry out immunization against diphtheria in practically all the children of New York City.

Goebel of Halle reported observations in a home for infants. When using the antitoxin remedy put out by the Behringwerke, a triple inoculation was necessary to secure adequate protection, a double inoculation proving ineffective.

The central idea of the paper presented by Hottinger of Düsseldorf was the question as to why some persons inoculated do not acquire adequate immunity and wherein the nature of malignant diphtheria lies, in which the antitoxin has no sure effect. No essential progress in the treatment of these cases has previously been achieved. He thinks that a familial predisposition, together with certain peculiarities of the diphtheria bacilli and the association with other pathologic agents, plays a part in the origin of malignant diphtheria. Schlossmann emphasizes the probability that a change in the epidemiologic properties of the causative agents has come about. That malignant diphtheria is more prevalent than formerly cannot be questioned. The fact that the researches of Kolle and at the Behringwerke have revealed no changes in the toxin formation of the strains shows that the degree of toxin formation alone does not cause the malignant condition. He is opposed to the idea that the observations made thus far furnish satisfactory evidence for the success of active immunization.

Several speakers emphasized the worthlessness of the Löwenstein ointment. Reserved statements were made with regard to the practical value of the Schick test, since in many cases a correct idea of the defense forces cannot be obtained. In addition to the official topics, many different fields of pediatrics were treated in numerous independent communications.

Care of Persons Who Are Hard of Hearing

In a time when the greatest economy must be exercised in all departments, it appears to be more important than usual to render needed aid to handicapped persons and to put them in such a condition that, in spite of their physical infirmities, they can support themselves. The welfare service for the benefit of deafmutes and persons hard of hearing has been gradually extended throughout the German *reich.* In 1871 there were 9.7 deafmutes for each 10,000 inhabitants; in 1900, 8.6, and in 1925-1926 there were 7.3. The last mentioned figure includes also those who are only deaf. The rural districts have the larger percentage of deafmutes. In about 10 per cent the disorder is congenital; in 21 per cent scarlet fever is the cause; in 10 per cent, spinal meningitis; in 19 per cent, suppurations of the middle ear, and in 11 per cent, accidents. The retrogression of deafmutism is doubtless to be sought in the energetic combating of infectious diseases and in the general progress of medicine. The welfare service in aid of deafmutes is based on the statistics concerning the deaf and dumb children who enter each year the group in which school attendance is compulsory. The school physicians examine every case that comes to their notice and make a report on a prescribed blank. The training and education of the deaf and dumb children who are found adapted to such instruction are given in the institutions for deafmutes, of which there are at present seventy-three in the German *reich.* These institutions belong to the various *länder* and the communes, or they are supported by societies or organizations, some connected with the churches and some of a lay character. The instruction, which is given by specially trained teachers, extends first to the spoken language, the articulate language replacing as far as possible the former sign language. The instruction includes all the branches that aid the pupil in becoming a useful citizen. In addition, the pupils receive a thorough industrial training in classes taught by specialists and artisans, who are given special awards in recognition of any marked skill shown by their pupils. At the present time, 20 per cent of the deafmutes in Germany and 7 per cent of those who are deprived of only their hearing are receiving institutional care. In addition to the private institutions for deafmutes, about forty German societies participate in the welfare work, which includes watching over the economic welfare of adult deafmutes. A self-help organization exists as the Reichsverband der Gehörlosen Deutschlands. The physical education of deafmutes is in the hands of the Reichsausschuss Deutscher Taubstummenverbände für Leibesübungen. Two thirds of the German deafmutes use the spoken language;

almost half of them use the written language, while less than one fourth make themselves understood with the aid of signs. The welfare service in aid of persons hard of hearing is of more recent origin. The state has established for their benefit several special schools and continuation schools. The instruction in these schools is given in accordance with the so-called *hörschmethode*, or a suitable combination of hearing and seeing. Recently a special service has been created with a view to protecting deafmutes and persons hard of hearing in court proceedings.

BUCHAREST

(From Our Regular Correspondent)

Oct. 17, 1931.

The New Law and the Adulteration of Food

Regulations in the new health law embrace all kinds of foodstuffs. The law forbids the sale or manufacture of decayed or harmful foods and beverages. Food articles must be named after the raw substance used in their manufacture, and this name must be used not only in advertisements, samples and invoices but also on the containers. It is strictly forbidden to use names which do not correspond with the true substance of the food or beverage.

Drinking water served in cafés and restaurants must be light, colorless, free from odor, and devoid of any by-taste. Its temperature must not exceed 15 C. (59 F.) in any part of the year. Besides this, it has to contain carbon dioxide. Soda water and lemonade factories can be established only with the authorization of the magistrate. Especial authorization is needed for making portable lemonade and other refreshing beverages. In the manufacture of lemonade, only well refined sugar may be used. Syrups made of sugar must consist of two parts of sugar and one part of boiled water.

Artificial mineral waters must contain the same constituents as the respective natural water: carbon dioxide may be added. Artificial mineral waters should be prepared only according to the formulas approved by the ministry of health. Only table mineral waters may be manufactured, while medicamentous, that is curative, waters must not be made artificially, excepting bitter waters.

For the cooling of foods and beverages, natural and artificial ice may be used. Artificial ice must be prepared from pure drinking water. Natural ice can be used for cooling only after a preliminary water analysis. Artificial ice may be in direct touch with the food articles, while, if natural ice is used, the articles have to be wrapped in some water-proof covering.

Milk can be sold only by licensed dealers. The license is issued by the veterinary section of the village magistrate's office to those who milk their own cows. Milk can be sold in aluminum or zinc containers.

As to yeast, only spirit or beer yeast can be sold to the public. The blending of the two kinds is prohibited. On the wrapper a label must be fixed, stating whether the product contains beer yeast or spirit yeast.

For preserving meat, the only method permissible is refrigeration. It is forbidden to sell the meat of sick animals or to use decayed vegetables for making preserves or for coloring them, or to use starch in their preparation. As to vinegar, the lowest acetic acid content allowed is 3, and the highest, 15 per cent. Vinegar essence must contain 80 per cent acetic acid.

Merchants unwittingly selling adulterated or impure foods or beverages are liable to a fine of from 1,000 to 3,000 lei, while those who sell such articles knowingly are fined from 2,000 to 10,000 lei. For a second offense the fine is doubled. If the adulteration was committed by one who brought the article into traffic, the fine is from 5,000 to 10,000 lei, and in case of a second offense it is double, with imprisonment from one to three months. In case adulterated or decayed or impure food articles cause death, a fine of from 10,000 to 50,000 lei is imposed, with imprisonment from one to three years, independently from the indemnity fixed by the civil court. Adulteration of milk involves a fine of from 2,000 to 5,000 lei.

According to the law, these regulations are enforced by the public health inspectors, the county physicians-in-chief, medical officers of cities and towns, and the chiefs of the state laboratories. The chiefs of custom houses are obliged to control all food articles imported from abroad and have to send samples for analysis to the laboratory of the ministry of health.

A special section of the law deals with the requirements in regard to cleanliness and hygiene in restaurants, cafés and all localities where foods are served. The agents of the public health office in towns and cities have to visit all such places twice a year. The new law is already in force.

Bachelor and Spinster Tax in Rumania

In view of the great infant mortality rate and the great spread of the so-called social diseases, the Rumanian government felt impelled to draft a bill taxing all bachelors and spinsters. According to the first chapter of the law, the taxes to be paid by bachelors and spinsters will be turned over for the subsidizing of hospitals, dispensaries and other social institutes. The second chapter asserts that the terms bachelor and spinster apply to all single men and women between the ages of 30 and 65. Exemption is made in the case of clergymen, monks and those who are not permitted by the civilian law to marry. The tax is fairly low: up to 35, the annual fine is 200 lei ($1.22) up to 50, it is 500 lei ($3.05) and beyond 50, the fee is 300 lei ($1.83). The last chapter of the law deals with the fines to be imposed on those who want to evade the payment of these taxes under some false pretexts. An interesting item of this law is that in factories, warehouses and other establishments the employer is responsible for the notification of his bachelor and spinster employees.

Trachoma in Rumania

In the prophylaxis and treatment of trachoma, the army did great service in prewar times. The examination of the eyes of recruits resulted in the discovery of trachoma cases. If a lad was found to have trachoma he was sent to a trachoma hospital, where he was kept as long as the condition was infectious. A physician experienced in the treatment of trachoma was sent to the district from which the lad came, and all the inhabitants there were examined. Those suffering from trachoma were sent to a hospital or, if this was impossible, put under treatment by the village doctor. If the number of trachoma patients in a district was too great, a trachoma specialist was entrusted with the treatment. The lads with trachoma were admitted into the army only after one year's absolute freedom from any symptoms of trachoma. In this manner, the number of trachoma cases was kept at a low level prior to the war. During war times, the invasion of foreign troops, the immigration of Russians, the annexation of Bessarabia, the return of war prisoners and the return of imperfectly healed soldiers from the field added much to the spread of trachoma.

In 1921, Dr. V. Cerkez examined all the children in an orphanage in Jassy and found that 47 per cent were trachomatous. In a school for girls in Jassy, 6 per cent of the children suffered from trachoma. In the outpatient department of the Jassy eye hospital, 580 trachoma patients were treated in 1928, 1929 and 1930, representing 3.5 per cent of all patients. Follicular conjunctivitis, though difficult to distinguish from trachoma, remains a well characterized and outlined pathologic entity; only 5 per cent of the follicular cases become in time trachomatous. In order to prevent relapses, complete cures must be insisted on: after an operation, the upper eyelid must not be turned up sooner than the eighth day. In respect to prophylaxis in Rumania, Cerkez urges the legislative carrying out of early diagnosis, regular eye examination of school children and workmen, the erection of special trachoma hospitals and dispensaries, migratory dispensaries for the village folk, compulsory notification and treatment, eye examination of all immigrants and, finally, the organization of propaganda work.

Prohibition of Advertising

The Medical Chamber of Rumania started activity some weeks ago, and its good work is already noticeable. While formerly the Bucharest daily papers were congested with the advertisements of venereal specialists, at present only some outsiders try to attract public attention by their obscene advertisements. The medical chamber is impotent, however, against the objectionable advertisements of some unscrupulous chemical manufacturers. These cause tremendous harm to the doctors because in the present critical financial circumstances even the intelligent classes are inclined toward self healing, evading consultation with the doctor and preferring to spend the money thus saved to buy an advertised cure. The medical association wants to appeal to the press syndicate, requesting nonprofessional papers to be more critical in accepting advertisements. At the same time the medical association will request its members who are in parliament to intercede in the chamber of deputies against the fraudulent advertising of worthless proprietary medicines.

ITALY

(From Our Regular Correspondent)

Sept. 15, 1931.

The Institute of Marine Biology

The Istituto italo-germanico di biologia marina was recently dedicated at Rovigno, Istria. The origin of the institute dates back to a zoological station established at Rovigno by Germany in 1891, and which, after the war, was turned over to the Comitato talassografico italiano. A recent agreement entered into by the governments of Italy and Germany provides that the institute shall be regarded as the joint property of the two countries, which will share equally the current expense of its administration and will have an equal number of persons on its staff. Professor Sella has been appointed codirector for Italy and Professor Stener for Germany. The institute has important collections of fish, mollusks and crustaceans, and there are rare specimens of Gambusia, starfish and polyps. Researches have been made on ocean depths, ocean currents and water pressure at various ocean depths.

Meetings of Societies

The Società medico-chirurgica of Pavia met recently under the chairmanship of Professor Ferrata. Professor Viola reported the results of his research on contractility of the spleen. The author, using three different stimuli (the action of cold, muscular work, the action of epinephrine), observed attacks of fever of a malarial type produced in man. He attributed the attacks to contraction of the spleen, the physiologic importance of which he emphasized. Callerio reported certain details regarding several clinical cases of tumor of the biliary passages diagnosed during anatomic studies on cadavers, and called attention to the importance in such cases of determining the percentage of fat substances in the feces, for the localization of the lesions along the biliary passages. Bianchi and Callerio spoke on the influence of the bacteriophage on the hemolytic action of the typhoid bacillus. From their studies on 166 typhoid strains isolated from the blood of patients, the authors reached the following conclusions: 1. There is a large percentage of typhoid strains (about 1.8 per cent) that, from the time of their isolation, possess in varying degree an evident hemolytic action for the red corpuscles of sheep. 2. With the bacteriophage one can show those strains to be hemolytic that do not appear spontaneously as such. 3. The phenomenon of hemolysis that is demonstrable with the typhoid bacillus by means of the bacteriophage appears closely associated with the development of the bacteriophagic action itself on the micro-organism. 4. It is not always possible to demonstrate the presence of a bacteriophage in strains possessing the hemolytic property from the time of their isolation from the patient. 5. Under the conditions of bacterial lysis produced by the bacteriophage in the typhoid bacillus, the authors did not succeed in demonstrating the production of soluble hemolysins. 6. Concerning the interpretation of the phenomenon, the authors are inclined to hold that the bacteriophage does not confer on the micro-organism a property previously nonexistent, but that it strengthens or enhances a capacity that the typhoid bacillus possesses normally, although in only a moderate degree.

Bignami spoke on extrabulbar ulcer of the duodenum, describing the radiologic manifestations on the basis of his records of seven personal cases and the few contributions on the subject contained in the literature. He remarked that, as is the case with ulcer of the stomach and of the bulb, the radiologic picture presented in extrabulbar ulcer is rather uncertain. He stated that, also in the diagnosis of extrabulbar ulcer of the duodenum, absolute reliance can be placed only in the niche sign, whereas it is not usually advisable to ascribe to other manifestations more than secondary diagnostic value and to consider them noteworthy only when complete and in harmony with clinical data.

Pellegrini discussed tuberculosis of the mediastinal glands in the adult, describing cases of tuberculous adenopathy of the mediastinum with many caseous glands of the infantile type, without tuberculous localizations in other organs.

At Brescia there was held also a meeting of the Società medico-chirurgica, under the chairmanship of Professor Baratozzi. Professor Mazzardi described a case of metastatic ophthalmia, with special involvement of the cornea, in a subject with acute osteomyelitis of the femur, together with empyema. Fifteen days after the appearance of the osteomyelitis there began disturbances affecting the left eye, which led to its enucleation owing to the presence of panophthalmia. The bacteriologic and cultural examination of the exudate taken from the empyema and from the cornea revealed the presence of Staphylococcus pyogenes with like morphologic, cultural and staining characteristics. The speaker excluded exogenic keratitis, toxic keratitis and internal ulcer, and decided in favor of metastatic origin.

Pellegrini spoke on the seroprophylaxis and the serotherapy of purulent peritonitis. For the past year he has applied this method systematically in peritonitis resulting from appendicitis and from perforation of the digestive tract, making use of anticolibacillary serums combined with antigangrene serums. He cannot as yet give a final opinion, but he thinks that serotherapy has a favorable effect. Even though such simple treatment should have to be regarded as supplementary to operative treatment, it would still mark a step in advance.

Pellegrini, in speaking on modifications in the technic of appendicectomy, considered the lumbar incision, the formation of the "tobacco bag" before resecting the appendix, and resection with the electric knife. Certain variations that are advantageous only in special cases cannot be recommended as normal methods.

Anophelism and Malaria in the Province of Novara

At a recent session of the Società di cultura medica novarese, Dr. Frongia spoke on the present status of anophelism and malaria in the province of Novara, describing the transformation of rice fields, the index of malaria, the density of anophelism and the classification of Anopheles, the resistance of Anopheles of the rice fields of Novara to malarial infection, and the transmission to Anopheles of malarial infection in man. The speaker concludes that the rice fields of the province of Novara have changed their character during the past twenty years, having been transformed by the rotation of crops and more intensive cultivation. Malarial infection has gradually diminished and conditions today are much improved. The improvement cannot be ascribed to a diminution in the number of Anopheles, as these are present in great numbers in the rice regions of Novara. Of 100 specimens, 94 are Anopheles claviger or Anopheles maculipennis, 4 are Anopheles superpictus, and 2 are Anopheles pseudopictus. No specimens of Anopheles bifurcatus were found. Anophelism sine malaria may be ascribed, in all probability, to the fact that Anopheles of the rice fields, owing to some organic transformation, has lost to a great extent its susceptibility to malarial infection on being exposed to the malarigenic hematozoon through biting a person harboring that organism. Experimentally, it proved impossible to infect the mosquitoes of the Novara rice fields with malaria through contact with a malarial patient.

A School for Ametropic Pupils

In Brescia there has been functioning for two years a special school for ametropic pupils, to which are admitted children, belonging to the second to fifth elementary grade, who are affected with serious myopia, hypermetropia, astigmatism, strabismus, or sequels of diseases of the anterior segment of the bulb or of the deep membranes, which reduce the vision to less than 3/10. The children supplied with glasses give immediate evidence of improved vision, applying themselves to their studies with less fatigue and greater profit, the vomiting spells, the headaches and the other disturbances produced by asthenopia being eliminated. On an average, visual acuity in the children supplied with lenses increased from 3/10 up to 7/10. Another advantage was the recovery from blepharoconjunctivitis due to defects of vision. A third advantage is the treatment of strabismus and of amblyopia ex anopsia by means of exercises. Increases of visual acuity amounting to 6/10 were observed.

Dangers of Malaria Treatment of Dementia Paralytica

Addressing the Accademia delle scienze medico-chirurgiche of Naples, Professor Romano described the possible dangers associated with the treatment of degeneration of the neuraxis. The untoward effects that may arise are not to be ascribed solely to the reduced organic resistance of the patient or to an error in the choice of the strain of malaria but chiefly to a third cause more important than the two preceding. This consists in the fact that, as a result of inoculation with asexual malaria micro-organisms, with an incomplete biologic cycle and with a tendency to die or to be destroyed, malaria is not produced in the organism but a status malaricus. The toxemia induces in the organism already weakened disease symptoms that are not always foreseeable or controllable. In concluding, Professor Romano expressed the view that in a patient treated by malarialization there may develop a true toxinfection with a special type of septicemia. And since it is held that the mechanism of this therapeutic process is based on the action of febrile heat and on the destruction of neurotropic organisms, the speaker suggests that physical means be adopted for that purpose, as, for example, diathermy.

In the discussion following Professor Romano's paper, Professor Colucci pointed out that by attenuating the attacks of malaria with small doses of quinine, the dangers of malariotherapy are much lessened. He considered the attitude of Professor Romano pessimistic and remarked that the beneficent effects of malariotherapy do not lie solely in the elevation of temperature. Castronuovo held that by choosing carefully the strain of malaria to be inoculated one can always regulate the course of the malaria and check it when it appears desirable. Malariotherapy exerts furthermore a genuine immunizing biologic stimulus of value for direct defense against syphilitic spirochetosis. Seiuti considered malarialization the best method for the treatment of dementia paralytica provided it is applied early. But there are other methods that may prove efficacious, such as sulphotherapy and a combination of arsphenaminotherapy and reinjection of the patient's own spinal fluid. It is indispensable that pyretotherapy be followed by an energetic specific antisyphilitic treatment.

Professor Romano in reply reaffirmed his view that inoculation with atypical malaria during the incompleted asexual cycle (which he terms "wagnerism") is different from true malarialization, which must be the result of biologically perfect malarial inoculation. He contends that in some cases wagnerism may be more harmful than malarialization itself.

Early References to the Circulation of the Blood

Dr. N. Mariscal recently lectured before the Academia Nacional de Medicina of Madrid on the history of medical discoveries, with especial reference to the share of the Spanish medical profession in the discovery of the circulation of the blood. The speaker made the following statements: In "De Trinitatis erroribus," the first book of Michael Servetus (Miguel Servede), which was published in Basel in 1531, there appears a description of the circulation. "Christianismi restitutio," written by the same author and published in 1553, is a compilation of his previous books. There is a popular belief that the books of Servetus were destroyed, only two copies of "Christianismi restitutio" being saved, one of which is in Vienna and the other, partly burned, in Paris. These are not the facts, however, since the Biblioteca Nacional of Madrid obtained from a Quaker several copies of his works, among which were two copies of "Christianismi restitutio" and one copy of "De Trinitatis erroribus." Matteo Realdo Colombo, Andrea Cesalpino, Carlo Ruini and Eustachius Rúdius probably obtained their ideas on the circulation from Servetus. Baron Leibnitz gave Servetus (whom he termed "the famous anti-Trinitarian heretic doomed by Calvin in Geneva") credit for having been the discoverer of circulation. Andrés Laguna, in 1535, published in Paris his so-called anatomic method in which, while speaking of the contractions of the heart, he said: "This is a movement which is a property of the heart without any connection with the nervous system, since, if the nerves and the arteries originating in the brain are ligated, the systole and the dyastole continue." In 1542, Luis Lobera de Avila wrote: "The heart has two ventricles, right and left. In the right ventricle there enters a large vein (the vena cava), which brings the blood to the heart and originates a large vessel (the pulmonary artery), which carries the blood from the heart to the lungs. In the left ventricle there enters a large vessel (the pulmonary vein), which brings blood to the heart and originates a large artery (the aorta), which carries the blood all over the body." Francisco Matías Marti of Valencia, in 1616, twelve years before Harvey's book appeared, wrote thus: "The heart seems as if it were divided into right and left halves, to each of which an auricle and a ventricle, with alternate movements, correspond. The first movement of the heart originates in the right auricle, which, by means of a contraction, expels the blood which it receives from the vena cava to the right ventricle. The contraction of the ventricle, in turn, forces the blood to the pulmonary artery, from which it goes to the lungs, where it is subject to a process of purification while in contact with the air which is there by inspiration; and, once arterialized, it returns through the pulmonary vein to the left auricle, whence, through the contractions, first of the left auricle and then of the left ventricle, it is forced to the aorta, from which all the parts of the body are supplied through many branches. Then the blood returns through the veins again to the vena cava and to the right auricle in a revolving uninterrupted movement of the blood."

The second part of Dr. Mariscal's lecture was a study of the life of Servetus, which was characteristic of the beginning of the Renaissance. In that time of fanaticism, Servetus's theological writings were condemned. He published his books either under his own name or under the pseudonyms of "Villanobus" or "Serveto de Reves."

In view of the data given by Dr. Mariscal, the Spanish Republic made the home village of Servetus a town.

Proposed Law for the Socialization of Medical Services

In several local political newspapers some of the most radical deputies have presented the following suggestion: "The undersigned deputies, having in mind the problems concerned with the high fees that are charged by physicians for attendance on the sick and for hospital attendance, in which problems are involved related to the conservation of the race, and having as grounds for their request article 42 of the Spanish constitution, suggest the following draft of a law: Article 1. All clinics, sanatoriums and hospitals should be socialized and considered as not having the right to charge any honorariums for attendance on the sick. While new laws for the national sanitation are being enacted, centers for the care of the sick, which at present are in active work, should continue under the regulations by which they have been functioning. Article 2. The practice of medicine and surgery and every one of its branches should be considered from a social point of view. Consequently, all physicians and surgeons should be considered as being public officers of the state. Their services, under proper regulations, should be regulated as follows: (*a*) In every city and town, a census of physicians and surgeons shall be made, noting their specialty if they specialize. The census will serve as a basis for a better distribution of social and public service from the medical profession. (*b*) Towns and cities, including their physicians and hospitals, will be divided into districts. Every physician should work in his district eight hours a day, during working days. Three hours of this time should be devoted to consultations in the physician's own office. The patients should be received in consecutive order. During the following five hours, physicians should attend patients unable to come to the office, who are either at home or in a hospital. Emergency calls should receive immediate attention, even if they are made outside working hours, and should be considered as of an extraordinary social value. Article 3. All physicians and surgeons will be paid by the government of the state. Their payment will represent a fixed amount equal to that given to state employees who receive the maximum payment in the town or city in which the physician lives and increased by a certain percentage for expenses of minors supported by him. Wives, who are considered equal to men and under their support, are not considered in that extra allowance. Article 4. Attendance given patients by physicians should be considered a service from state to community, the members of which, in order to pay for those services, should pay a double amount for their capitation fee. Article 5. On the date of publicity of this law, all obligations which hitherto were considered as imposing a duty on the patient to pay for medical or surgical attendance received, shall be abolished, and physicians shall be forbidden to receive any honorariums or charges representing a remuneration for services given to the patients. Article 6. In order to stimulate physicians to fulfil this social duty, every week the names of all physicians who during the week obtained a good record in their services will be read to the pupils in all the schools. Names of physicians who during the week gave extraordinary services will be placed on an honor roll list in the schools in order that their names may receive the homage of the social solidarity of their countrymen."

Marriages

Michael J. Lorenzo, Bridgeport, Conn., to Miss Elenora Martha Brownell of Northville, N. Y., August 8.

Florentine Peter Herman to Miss Lucille S. Williams, both of West Palm Beach, Fla., September 25.

Clarence C. Holcomb, Troy, N. Y., to Miss Marie V. Rogers of Washington, D. C., November 10.

Roland E. Kalmbach, Lansing, Mich., to Dr. Lydia L. Lightring of East Lansing, September 12.

Donald S. Fraser of Panama City, Fla., to Miss Margaret Van Cleve of Lynn Haven, October 8.

Kenneth J. Kemp, Columbus, Ohio, to Miss Katherine C. Daniels of New York, November 27.

Harry A. Schwartz, Long Island, N. Y., to Miss Sylvia Marcus of Brooklyn, November 1.

James F. Curry, Dunnellon, Fla., to Miss Neva Williams at Inverness, August 1.

Bernard Frazin to Miss Beatrice Minnie Hurwich, both of Chicago, October 1.

Luther H. Kelley, Atlanta, Ga., to Miss Louise Curtis, November 13.

Deaths

Walter Henry Robilliard, Faribault, Minn.; Hahnemann Medical College and Hospital, Chicago, 1884; an affiliate Fellow of the American Medical Association; member of the Radiological Society of North America; past president of the Rice County Medical Society; for ten years member of the board of education; on the staffs of the State School for the Deaf and St. Lucas Deaconess Hospital; aged 70; died, November 1, of pneumonia.

William F. Mitchell, Shelby, N. C.; University of Maryland School of Medicine, Baltimore, 1889; member of the Medical Society of the State of North Carolina; past president and secretary of the Cleveland County Medical Society; formerly member of the county board of health; on the staff of the Shelby Hospital; aged 63; died, October 27, of cerebral hemorrhage.

Joseph Clark Stephenson ⊕ New Orleans; Rush Medical College, Chicago, 1925; member of the Oklahoma State Medical Association; professor of anatomy, Louisiana State University Medical Center; formerly professor of anatomy, University of Oklahoma School of Medicine; aged 45; died, November 10, of spinal meningitis.

Benjamin B. Wheeler ⊕ Charleston, W. Va.; Louisville (Ky.) Medical College, 1904; member of the American College of Surgeons; formerly superintendent of the McKendree (W. Va.) Hospital and on the staff of King's Daughters General Hospital, Beckley; aged 55; died, November 3, of carcinoma of the stomach.

Charles Vincent Hart ⊕ Major, M.C., U. S. Army; Jefferson Medical College of Philadelphia, 1903; served during the World War; entered the Medical Corps of the U. S. Army in 1920 as a first lieutenant and was made a major in 1930; aged 54; was killed, July 16, in an airplane accident.

Roland H. Stubbs, Waterford, N. Y.; Medical Department of the University of the City of New York, 1877; member of the Medical Society of the State of New York; for many years health officer of Waterford; aged 76; died, November 17, in the Leonard Hospital, Troy, of arteriosclerosis.

Charles Henry Harvey, Philadelphia; Hahnemann Medical College and Hospital of Philadelphia, 1893; member of the American College of Surgeons; formerly surgeon to the West Philadelphia Homeopathic and Belmont hospitals; aged 63; died, November 12, of bronchopneumonia.

Sidney Stewart Pugh, Mobile, Ala.; Tulane University of Louisiana School of Medicine, New Orleans, 1889; member of the Medical Association of the State of Alabama; veteran of the Spanish-American War; aged 68; died, October 12, in New Orleans, of cerebral hemorrhage.

Charles Andrew Graham ⊕ Denver; University of Pennsylvania School of Medicine, Philadelphia, 1898; formerly associate professor of medicine, Denver and Gross College of Medicine; aged 60; died, October 22, in St. Luke's Hospital, of acute hemorrhagic nephritis.

Leonard Johnathan Hensler, Carrollton, Ill.; Vanderbilt University School of Medicine, Nashville, Tenn., 1908; member of the Illinois State Medical Society; served during the World War; aged 46; died, November 7, in St. Anthony's Hospital, St. Louis, of agranulocytosis.

Benjamin C. Logan ⊕ Morrilton, Ark.; Louisville (Ky.) Medical College, 1902; past president and secretary of the Logan County Medical Society; formerly county and city health officer; on the staff of St. Anthony's Hospital; aged 56; died, October 31, of heart block.

Reuben Nathaniel Palmer ⊕ Kenyon, Minn.; University of Minnesota Medical School, Minneapolis, 1926; formerly secretary of the Houston-Fillmore Counties Medical Society; served during the World War; aged 38; died, November 3, of heart disease.

James P. Tucker, Galveston, Texas; Texas Medical College and Hospital, Galveston, 1878; University of Louisville (Ky.) School of Medicine, 1885; aged 78; died, October 25, in the John Sealy Hospital, of acute pyelonephritis, cystitis and arteriosclerosis.

Cornelius H. Myers, South Bend, Ind.; Hahnemann Medical College and Hospital, Chicago, 1877; member of the Indiana State Medical Association; aged 79; died, October 31, in the Epworth Hospital, of injuries received when he was struck by an automobile.

John Newton Killough, Birmingham, Ala.; Kentucky School of Medicine, Louisville, 1887; member of the Medical Association of the State of Alabama; visiting physician to the Alabama Boys' Industrial School; aged 66; died, November 2, of carcinoma.

George W. Steward, Jerusalem, Ohio (licensed, Ohio, 1896); president of the Monroe County Medical Society; formerly member of the state legislature and member of the county board of health; aged 83; died, in November, of cerebral hemorrhage.

Robert Adoniram Segrest, Port Gibson, Miss.; Memphis (Tenn.) Hospital Medical College, 1903; member of the Mississippi State Medical Association; aged 51; died, October 31, in the Jackson (Miss.) Hospital, of carcinoma of the right lung.

William Albert Galloway, Xenia, Ohio; Medical College of Ohio, Cincinnati, 1890; member of the Ohio State Medical Association; on the staff of the Ohio Soldiers and Sailors Orphans Home; aged 71; died, November 7, of heart disease.

Columbus C. Black, Austin, Texas; Missouri Medical College, St. Louis, 1882; member of the State Medical Association of Texas; aged 75; died, August 28, in a local hospital, of hypostatic pneumonia, arteriosclerosis and chronic myocarditis.

John Emison Pack, Georgetown, Ky.; Bellevue Hospital Medical College, New York, 1873; formerly mayor of Georgetown, member of the state legislature, and the county board of health; aged 82; died, October 30, of cerebral hemorrhage.

Thomas Nathaniel Jackson, Jr., Athens, Ga.; Boston University School of Medicine, 1924; on the staffs of the Athens General Hospital and St. Mary's Hospital; aged 34; died, November 8, of myocarditis and pulmonary tuberculosis.

Harry Allan Spangler ⊕ Carlisle, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1892; served during the World War; aged 65; on the staff of the Carlisle Hospital, where he died, November 5, of cerebral hemorrhage.

Samuel L. Rucker, Moneta, Va.; University College of Medicine, Richmond, 1897; member of the Medical Society of Virginia; aged 60; died, October 4, in the Jefferson Hospital, Roanoke, of perforated gastric ileus and peritonitis.

Robert James Gillespie, Salyersville, Ky.; University of Louisville School of Medicine, 1912; director of the health department of Magoffin County; aged 43; died, November 2, in the Paintsville (Ky.) Hospital, of pneumonia.

George Wesley Kester ⊕ Grand Junction, Iowa; Drake University Medical Department, Des Moines, 1895; past president of the Greene County Medical Society; member of the school board; aged 62; died, November 4.

Charles Westlake Hoare, Windsor, Ont., Canada; McGill University Faculty of Medicine, Montreal, Que., 1888; formerly mayor of Walkerville and member of the board of education; aged 68; died, November 10.

Peter Harry Harmann, St. Louis; St. Louis College of Physicians and Surgeons, 1898; Barnes Medical College, St. Louis, 1900; aged 55; died, November 8, in the Missouri Baptist Hospital, of carcinoma of the liver.

Philip R. Cleaver ⊕ Johnstown, Pa.; Medico-Chirurgical College of Philadelphia, 1890; aged 64; on the staff of the Mercy Hospital, where he died, November 5, of embolism, following an operation for gallstones.

Amos F. Hamman ⊕ Long Beach, Calif.; Rush Medical College, Chicago, 1903; served during the World War; on the staff of the Seaside Hospital; aged 57; died, October 28, in Chattanooga, Tenn., of heart disease.

Charles Levin ⊕ New York; Columbia University College of Physicians and Surgeons, New York, 1905; on the staff of the Beth David Hospital; aged 53; died, November 8, of chronic valvular heart disease.

David Young, Winnipeg, Manit., Canada; Queen's University Faculty of Medicine, Kingston, Ont., 1871; superintendent of the Manitoba Mental Hospital, Selkirk, 1886-1912; aged 84; died, October 16.

John T. Davis, Zanesville, Ohio; Medical College of Ohio, Cincinnati, 1872; member of the Ohio State Medical Association; aged 83; died, November 10, in the Bethesda Hospital, of edema of the lungs.

William George Edward Flanders, Burlington, Vt.; University of Vermont College of Medicine, Burlington, 1888; aged 65; died, November 4, of arteriosclerosis, chronic nephritis and diabetes mellitus.

William D. Wheless, San Antonio, Texas; Tulane University of Louisiana School of Medicine, New Orleans, 1900; on the staff of the San Antonio State Hospital; aged 58; died, November 1.

Timothy O'Brien, Wahpeton, N. D.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1884; member of the North Dakota State Medical Association; aged 69; died, November 7.

Anthony J. Berresheim, Louisville, Ky.; Kentucky School of Medicine, Louisville, 1906; member of the Kentucky State Medical Association; aged 50; died, November 19, of encephalitis.

Daniel D. Murray ⊕ Duluth, Minn.; Albany (N. Y.) Medical College, 1881; formerly city health commissioner; aged 72; died, November 6, of coronary thrombosis and arteriosclerosis.

George Frederic Hunter Bartlett, Buffalo; University of Buffalo School of Medicine, 1883; aged 75; died, November 8, of carcinoma of the esophagus, arteriosclerosis and arthritis deformans.

John S. Bentley, St. John, N. B., Canada; McGill University Faculty of Medicine, Montreal, Que., 1904; for many years on the staff of St. John General Hospital; aged 53; died recently.

Edwin Putnam Gleason, Brockton, Mass.; Harvard University Medical School, Boston, 1892; aged 65; died, November 9, in the Brockton Hospital, of hypertension and heart disease.

James D. Scott, Holdenville, Okla.; Missouri Medical College, St. Louis, 1897; member of the Oklahoma State Medical Association; aged 59; died, October 31, of diabetes mellitus.

Frederick Roberts, Lake City, Ark.; University of Tennessee Medical Department, Nashville, 1907; aged 6[illegible]; died, October 17, in Brookland, of chronic nephritis and paralysis.

Max Mayo Miller ⊕ Arkansas City, Kan.; Northwestern University Medical School, Chicago, 1918; on the staff of the Mercy Hospital; aged 41; died, November 6, of heart disease.

George Neves, Colony, Okla.; Tulane University of Louisiana Medical Department, New Orleans, 1912; aged 49; died, July 16, in Thibodaux, La., of a self-inflicted bullet wound.

Allen Judd Nossaman ⊕ Pagosa Springs, Colo.; Keokuk (Iowa) Medical College, 1892; aged 64; died, October 9, in the Colorado General Hospital, Denver, of lymphosarcoma.

Benjamin William Dudley, Short Hills, N. J.; Columbia University College of Physicians and Surgeons, New York, 1904; aged 53; died, October 26, of cirrhosis of the liver.

Gilbert James White, Evanston, Ill.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1886; aged 74; died, November 12, in Picton, Ont., Canada, of myocarditis.

Terence Edward Darnelle, Detroit; Medical College of Indiana, Indianapolis, 1892; served during the World War; aged 62; died, November 4, in the Receiving Hospital.

Duncan A. Macdonald, Winnipeg, Manit., Canada; Manitoba Medical College, Winnipeg, 1907; on the staff of the Deer Lodge Hospital, St. James; aged 50; died, October 6.

Edwin Fancher, Middletown, N. Y.; Boston University School of Medicine, 1883; member of the Medical Society of the State of New York; aged 71; died, November 22.

Samson George Goode, Sidney, Ohio; Medical Department of the University of the City of New York, 1887; formerly justice of the peace; aged 86; died, October 23.

Maurice Mitchell Hallum, Carrollton, Ga.; Atlanta Medical College, 1898; for ten years member of the school board; aged 63; died, October 19, of cerebral hemorrhage.

William Stanton Winter, Port Arthur, Texas; Kansas Medical College, Topeka, 1898; member of the State Medical Association of Texas; aged 70; died, September 2.

Walter Ralph Stovall, Dallas, Texas; University of Louisiana Medical Department, New Orleans, 1878; aged 78; died, November 8, of carbuncle and heart disease.

Calvin M. Arnold, Harrisburg, Pa.; Homeopathic Medical College of the State of New York, 1867; also a druggist; aged 88; died, November 12, of cerebral hemorrhage.

Mary M. Kroetz, San Francisco; Hahnemann Hospital College of San Francisco, 1894; aged 74; died suddenly, October 28, of angina pectoris and arteriosclerosis.

George Washington Koenig ⊕ St. Louis; Washington University School of Medicine, St. Louis, 1904; aged 59; died, November 7, of a self-inflicted bullet wound.

George William Wood ⊕ Rockledge, Fla.; Georgetown University School of Medicine, Washington, D. C., 1894; aged 68; died, November 9, of morphine poisoning.

Daniel Shelley Solliday, Hillsboro, Va.; Medical College of Virginia, Richmond, 1900; member of the Medical Society of Virginia; aged 68; died, November 4.

Maxwell S. Simpson, Titusville, N. J.; Jefferson Medical College of Philadelphia, 1883; aged 75; died, November 12, in the Mercer Hospital, of heart disease.

L. Guy Ramaley, Oklahoma City, Okla.; Joplin College of Physicians and Surgeons, Joplin, Mo., 1882; aged 74; died, October 20, of carcinoma of the liver.

Amos Sheldon Edwards ⊕ Syracuse, N. Y.; Syracuse University College of Physicians and Surgeons, 1874; aged 89; died, November 6, of heart disease.

Herman C. Vetterling, San Jose, Calif.; Hahnemann Medical College and Hospital, Chicago, 1883; aged 83; died, September 5, of chronic myocarditis.

Lewis Edward Pearce, Houston, Texas; Marion-Sims College of Medicine, St. Louis, 1896; aged 76; died, October 10, of bacteremia and septicemia.

Albert E. Kumpf, Hot Springs, S. D.; University of Minnesota Medical School, Minneapolis, 1928; aged 30; died, in October, of cerebral hemorrhage.

Joseph Xavier Ryan, Chicago; Loyola University School of Medicine, Chicago, 1924; aged 31; died, November 23, at the Mercy Hospital, of tetanus.

Fletcher Marcellus Barnes ⊕ El Paso, Texas; Southwestern University Medical College, Dallas, 1911; aged 54; died, August 19, of pneumonia.

Henry Stine Weigle, Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1908; aged 45; died, October 4, of diabetes mellitis.

Louis A. Russlow, Randolph, Vt.; Baltimore Medical College, 1894; member of the Vermont State Medical Society; aged 65; died, September 21.

Rosa Douglas Wiss, Meridian, Miss.; Woman's Medical College of Pennsylvania, Philadelphia, 1895; aged 63; died, September 14, of myxedema.

Clarence Hudson Richardson, Brooklyn; Harvard University Medical School, Boston, 1912; aged 53; died, November 11, of lobar pneumonia.

George Henry Litsinger ⊕ Topeka, Kan.; University Medical College of Kansas City, 1900; aged 61; died, November 3, of agranulocytosis.

Herman A. Burkhart, Bethlehem, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1893; aged 69; died, July 27, of pneumonia.

Isaac Newton Devine, Groveton, Texas; Atlanta Medical College, 1880; aged 78; died, October 20, in Houston, of carcinoma of the rectum.

Fredric W. Haudenschield, Stewart, Ohio; Louisville (Ky.) Medical College, 1891; aged 73; died, November 12, in a hospital at Marietta.

Marion S. McCormick, Martinsville, Ind.; Medical College of Ohio, Cincinnati, 1882; aged 72; died, November 6, of cerebral hemorrhage.

John Selden Brandt, Ontario Center, N. Y.; Bellevue Hospital Medical College, New York, 1878; aged 76; died, September 20.

Harvey H. Bellwood, Long Beach, Calif.; Rush Medical College, Chicago, 1887; aged 83; died, October 23, of cerebral hemorrhage.

Bureau of Investigation

THE VON WALDENS

The Interesting Professional History of Rudolph von Walden and Some of His Family

"Professor" Rudolph von Walden is distinctly up-stage. He has presence; he has poise; he has a distinguished appearance even when he is photographed ("mugged") by the police. His sartorial elegance befits the millionaire that he is reported to be. His gray and luxuriant whiskers, parted meticulously in the median line, must in themselves be an asset of no mean worth. "Professor" von Walden is not and never has been a professor in any reputable institution of learning; he is not a physician; he is not licensed to practice medicine in any state in the Union. He has not, apparently, even the dubious honor of belonging to the chiropractic, osteopathic, naturopathic, seventh-son-of-seventh-son, or any of the other fifty-seven varieties of cults, that infest the American scene. Yet, newspapers have reported that it has been estimated that in his business of treating human ailments, he takes in between $6,000 and $10,000 weekly and has a personal fortune of between $500,000 and $1,000,000!

Rudolph von Walden is reported to have been born in Germany nearly 70 years ago and to have come to the United States in 1884. For some years he played up the "von" part of his patronymic. Then, the late unpleasantness made "vons" an advertising liability rather than an asset and Rudolph von Walden became R. V. Walden. He dubs himself a "scientist"; he used to admit that he was a "German scientist." There have been a number of "Walden Institutes" in different parts of the country. One of the first—if not the first—was the "R. von Walden Institute" of Cincinnati, said to be "Devoted to Diseases of the Heart, Angina Pectoris, Dropsy, Etc." Since that time, there have been Walden Institutes operated from New Haven and Hartford, Conn., New York City (various addresses), Atlanta, Ga., and St. Albans, Long Island.

HEART TROUBLE often results in Premature Death, unless the causes are removed. Through the famous Walden Method thousands of chronic cases of Heart Trouble, Dropsy, Short Breath, Angina Pectoris, High Blood Pressure, Hardened Arteries, Bronchial Asthma and Kidney Complaints, have been permanently relieved. Write explaining your troubles, and send 10c for descriptive literature [illegible]

O. C. WALDER, [illegible] ST. ALBANS, NEW YORK

PERSONAL

HOW TO RELIEVE
High Blood Pressure

Business with the von Waldens is not what it used to be. A few years ago Rudolph was carrying full-page advertisements in metropolitan dailies; today the small display and even the classified advertisement columns must perforce suffice.

Rudolph von Walden has an interesting family. The newspaper files prove it. There is, for example, Gerald Walden, who for a time conducted a Walden Institute at Hartford, Conn., in connection with his father. Then, the papers reported that Gerald had sued his own father for alienating the affections of his (Gerald's) wife. Another son is Sherman von Walden, chiropractor. He, apparently, is in his father's good graces and conducts an "institute" at Atlanta, Ga. When Sherman was studying (!) chiropractic at Davenport, Iowa, he too figured in the press reports—and law courts—in a disgraceful case that, because it has no medical significance, need not be detailed here. A third son, Edward, variously described by the newspapers as the "Metropole Bandit" and the "Flappers' Friend," has distinguished himself in other fields of human activity, that of ordinary robbery.

Other members of von Walden's family that have figured in the newspapers are his wife and two daughters. All three are reported, at different times, as having been arrested for breaches of the peace, while, according to the daily press, Mrs. von Walden has, in addition, been sentenced to jail (execution suspended) for contempt of court. In March of this year (1931), it was reported that Mrs. von Walden, in her suit against Rudolph for alleged failure to pay $12,000 in back alimony, had charged that her husband had transferred some valuable property by warranty deed to two individuals who, in turn, executed a mortgage on the property to one "Charles F. Roberts." Mrs. von Walden is said to have declared that "Charles F. Roberts" is merely an alias adopted by Rudolph von Walden for the purpose of removing the mortgage from the possibility of attachment. In June, 1931, the papers reported that von Walden had entered into a stipulation to pay his former wife $10,500.

"PROFESSOR" RUDOLPH VON WALDEN

So much for the satellites in the von Walden group. The first newspaper record that we have of the elder von Walden's quackery was published in May, 1916. From it one learns that Rudolph was found guilty of practicing medicine without a license at Portsmouth, Ohio, fined $300 and costs, and given a suspended sentence of a year. According to an article that was published in the *Ohio State Medical Journal,* it seems that in December, 1916, Rudolph von Walden went to Portsmouth to attend one Charles Fenstermaker, whose condition Portsmouth physicians had pronounced hopeless. Mr. Fenstermaker died shortly after von Walden had collected $250 from his family. The same medical journal also reported that some time following this episode, full-page advertisements appeared in the *Cosmopolitan* and the *Woman's Home Companion* and a number of southern newspapers, announcing the alleged therapeutic miracles that von Walden's "system" would accomplish.

DR SHERMAN VON WALDEN
SPECIALIST
ATLANTA GEORGIA

November 7th, 1928.

Some von Walden letterheads (greatly reduced). At the top as used in 1914 in Cincinnati; the New Haven, Conn., letterhead, vintage of 1922; the Newark, N. J., office in 1928 and Sherman's letterhead also in 1928.

In January, 1917, Alabama papers reported that Rudolph von Walden had been arrested in Mobile on the charge of practicing medicine without a license. We have no record of the outcome of this case.

Von Walden's activities were given some further publicity in the October, 1917, issue of the *Journal of the Tennessee State Medical Association,* which published a letter from two reputable physicians recording the case of a Mr. J. W. Kerr, a brother-in-law of one of the physicians. The letter stated that Mr. Kerr, who had had organic heart disease for many years, fell into the hands of Rudolph von Walden, at the time this quack was operating his Cincinnati "institute." Von Walden charged Mr. Kerr $500 in advance and kept him in Cincinnati long enough for the check to go through the clearing house. What von Walden did to Mr. Kerr is not known, but when he sent Mr. Kerr home, he telegraphed to Mrs. Kerr to meet her husband at the train, as he was "not very well." When Mr. Kerr was met at the train by Mrs. Kerr and his family physician, he was unconscious and died three hours later. The physician who was brother-in-law to Mr. Kerr threatened von Walden with legal action if the $500 was not returned to Mrs. Kerr. It was returned.

In March, 1921, Florida papers reported that Rudolph von Walden had been arrested in St. Petersburg. Here, again, von Walden apparently escaped fine or imprisonment, as we find no record of it. In January, 1924, newspapers reported that Rudolph von Walden had been arrested by the Richmond (Va.) police on the charge of practicing medicine without a license. At the same time, the police department of Richmond wrote to the Bureau of Investigation of the American Medical Association for such data as the Bureau had on von Walden. These, of course, were sent. Von Walden was reported held on two charges—that of practicing medicine without a license and that of having illegally in his possession three quarts of whiskey. The Richmond police are reported to have said, at the time, that von Walden evidently had some "influence behind him in the state of Georgia as while in jail [in Richmond] he called some town in Georgia and asked his bankers there to wire to a bank in Richmond, asking them to honor his check for $1,000, which was given to some local attorneys" and that "the Georgia bank immediately wired this information and the check was honored." When von Walden's case was called, the quack was dismissed! According to the newspaper reports, no evidence was produced to show that he practiced medicine and—most delicious of all—the "professor" was able to convince the court that the three quarts of whiskey found in his possession were "being used in connection with his professional work."

In 1930, Rudolph von Walden made a tactical error. He went to Hartford, Conn., to ply his trade, and Hartford has a Better Business Bureau with a live personnel. After prescribing a course of medical treatment for an investigator for the Hartford Better Business Bureau, Rudolph von Walden was arrested on a charge of violating the state healing arts law. On June 3, 1930, von Walden was fined $200 and costs for violation of the state medical practice act. While von Walden gave notice of appeal it was a bluff. He paid the fine and costs.

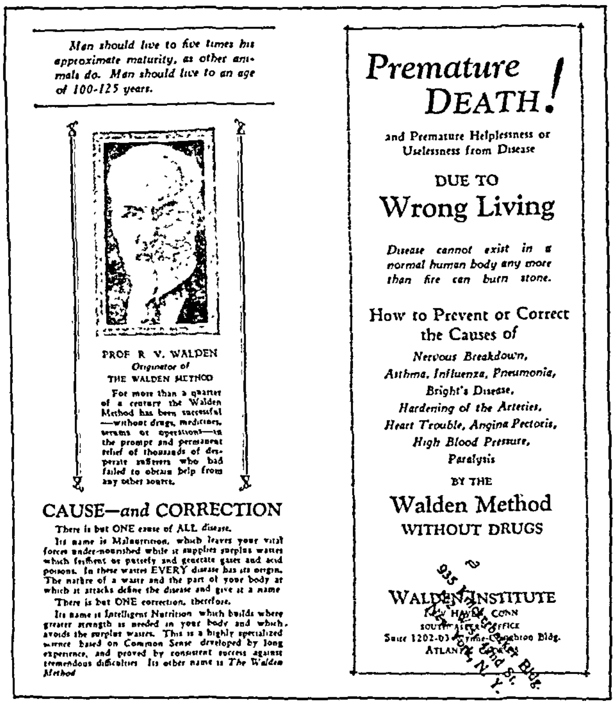
HOW RUDOLPH WORKS

Von Walden's *modus operandi* has been, in the past, to publish expensive advertisements, many of them occupying full pages of such newspapers as cater to such sources of advertising revenue. Those who wrote to von Walden in answer to the advertisements, received plausible come-on letters with "consultation blanks" common to mail-order quackery. The prospective victim was urged to fill out the blank and return it to von Walden, who would, upon its receipt, send "a written analysis of your symptoms" free of all expense. Von Walden's diagnoses, or as he would call them "analyses," were surprisingly uniform. They smelled of the rubber-stamp. Practically all those that we have seen read:

> "I find upon examination that the origin of your symptoms is in your abdominal organs; your stomach, your liver, your intestines, and also your abdominal circulation. These must be corrected first, before you can get rid of your symptoms."

Curiously enough, this same stock diagnosis—*verbatim et literatim*—is also used by Sherman von Walden. Sherman, it will be remembered, is operating at present from Atlanta, Ga. In 1927, the Atlanta concern was known as the "Walden Institute of Vital Dietetics" with R. von Walden, "Director," and "Dr. Sherman von Walden, Consultee." Later, stationery carried the name "Dr. Sherman von Walden, Specialist in Heart and Arterial Diseases, Suite 310 Mortgage Guaranty Building, Atlanta, Ga."

Rudolph von Walden has, at least on one occasion, used the stool-pigeon method of advertising. Sufferers from "heart trouble, dropsy, high blood pressure, paralysis," etc., were urged to write to Mrs. A. Spence at Gadsden, Ala., who offered to tell those who wrote her how her "dear mother was cured without drugs and her life saved." Mrs. Spence added that she felt that this was her "duty to humanity." Those who wrote to Mrs. Spence received a letter on the stationery of the Globe Realty and Auction Company, who were described on the same stationery as "Rental and Insurance Agents, Farm and Mineral Lands, Large Tracts for Subdivision, Water Power and Manufacturing Sites." This was said to be located in "Rooms Over the Cross Drug Store" on Broad Street. Investigation brought the report that no such company existed or ever had existed, except on paper. Furthermore, Mr. Cross, who operated the drug store and owned the building in which it was located, wrote that he had no knowledge of the Globe Realty and Auction Company, and that the company did not occupy any room above his store, nor had he ever rented a room to it. When Mrs. Spence's attention was called to the use of the stationery, she is said to have replied that she was only using it to economize, as they had it on hand and it was not being used. As different specimens that we have in our files show that the stationery of the nonexistent Globe Realty and Auction Company had been printed at least two different times and with two different styles of type, the "economy" is not obvious.



Man should live to five times his approximate maturity, as other animals do. Man should live to an age of 100-125 years.

PROF R. V. WALDEN
Originator of
THE WALDEN METHOD

For more than a quarter of a century the Walden Method has been successful—without drugs, medicines, serums or operations—in the prompt and permanent relief of thousands of desperate sufferers who had failed to obtain help from any other source.

CAUSE—*and* CORRECTION

There is but ONE cause of ALL *disease.*

Its name is Malnutrition, which leaves your vital forces under-nourished while it supplies surplus wastes which ferment or putrefy and generate gases and acid poisons. In these wastes EVERY disease has its origin. The nature of a waste and the part of your body at which it attacks define the disease and give it a name

There is but ONE correction, therefore.

Its name is Intelligent Nutrition which builds where greater strength is needed in your body and which avoids the surplus wastes. This is a highly specialized science based on Common Sense developed by long experience, and proved by consistent success against tremendous difficulties Its other name is *The Walden Method*

935 Knickerbocker Bldg.
42nd St.
New York, N. Y.

Greatly reduced reproduction of part of a piece of von Walden ballyhoo which in the original measured about 15 inches by 17 inches. Note that, according to von Walden, all disease is caused by malnutrition.

THE FEDERAL TRADE COMMISSION TAKES A HAND

Quackery of the von Walden type is hard to reach under any but state law, and the lukewarm attitude of state prosecuting attorneys in cases involving fakers who liberally patronize local newspapers is notorious. Von Walden and his ilk cannot be reached under the postal fraud order, because the mails are used only in making the "contact," the remainder of the transaction, together with the payment of money, being personal. The national Food and Drugs Act cannot be invoked, as von Walden sells no drugs in interstate commerce. The prohibition laws seem equally helpless, when a man without medical training or license can claim to use whiskey for "professional" purposes—and get away with it. The only federal agency left is the Federal Trade Commission that has done so much good work in throwing the fear of the law into medical fakers who have otherwise considered themselves above the law.

Early this year, the Federal Trade Commission served a complaint on Sherman von Walden, in connection with his exploitation of the so-called Walden Method evolved by Sherman von Walden's father, Rudolph. After stating that Sherman van Walden was selling the alleged von Walden Method "at prices ranging from $65 to $500, payable in advance," the Commission brings out the fact that the diagnoses made by Walden and the diets and exercises prescribed by him were made, in the majority of instances, without Walden's ever seeing the patient. The Commission then lists the following "false, misleading and exaggerated statements and representations" made by Sherman von Walden in the advertising matter and literature that he sent to customers and prospective customers:

"Paragraph Two: (A) That the Walden Method is a proper and successful method of treating the diseases and ailments known as

High blood pressure
Angina pectoris
Heart attacks
Hardening of arteries
Paralysis
Threatened fatal paralysis
Arteriosclerosis
Enlargement of heart
Valvular heart trouble
Asthmatic heart
Fatty heart
Symptoms of high blood pressure
Heart symptoms
Pains in heart
Heart pounding
Dizziness
Pains in head
Shortness of breath
Smothering spells
Bright's disease
Kidney trouble
Kidney stones
Inflammation of kidneys
Bronchial asthma
Bronchitis
Cardiac asthma
Asthma
Catarrh
Pains in chest
Nerve exhaustion
Symptoms which lead to pneumonia
Influenza
Fainting spells
Falling spells
Choking spells
Uremic poisoning
Colic

"(B)—(1) That respondent is a doctor of medicine; (2) That respondent is a 'specialist' in the treatment of diseases; (3) That respondent is a 'specialist' in the treatment of heart and arterial diseases; (4) That the Walden Method will cure diseases heretofore regarded by the medical profession as incurable; (5) That respondent makes a thorough, efficient and correct diagnosis of diseases without personal, or any, examination; (6) That proper treatment can be and is prescribed for all diseases, under the Walden Method; (7) That the Walden Method is scientific and was discovered by the great German scientist, Prof. R. von Walden; (8) That the Walden Method cures through modern scientific methods; (9) That The Walden Method is and was promulgated by the greatest living authority; (10) That nothing else equals the Walden Method; (11) That the Walden Method is the one sure method in existence for treating diseases; (12) That the Walden Method has relieved thousands of patients in the last 35 years; (13) That 95 per cent of the fatal heart diseases can be cured by the Walden Method; (14) That respondent maintains an Institute of Dietetics in connection with his said business, at said City of Atlanta.

"(C) Purports to reproduce testimonials from various persons who claim to have been cured of diseases or ailments by the Walden Method, from some of which alleged testimonials the following excerpts are quoted: (1) 'Suffered for years. Relieved in 72 hours. (Angina Pectoris.)' (2) 'Relief only through hypodermic; now restored without drugs. (Angina Pectoris.)' (3) 'Had only one year to live, relieved in 24 hours. (Angina Pectoris.)' (4) 'A remarkable restoration of a case of paralysis, without drugs and medicines, caused by High Blood Pressure.' (5) 'Physician relieved of facial paralysis, high blood pressure, Bright's disease, Within Sixty Days, Without Drugs.' "

The Commission's complaint then continues:

> "1.—In truth and in fact, R. von Walden . . . has never taken a prescribed course in medicine, nor has he received a diploma from a medical school, nor has he been licensed to practice medicine in any State of the Union, nor is he a scientific man in any respect, nor has he ever been a professor of a college or other institution of learning.
>
> "2.—The respondent, Sherman von Walden, has never been a physician or surgeon, nor has he ever received a college degree or any degree except as a chiropractor. He is not a specialist in dietary, he is in no sense a scientific man, and is not qualified to properly treat by diet, exercises, and rest routine, or either, any of the diseases or ailments mentioned in Paragraph Two hereof.
>
> "3.—The Walden Method will not cure nor will it aid in the cure of the diseases and ailments mentioned in Paragraph Two hereof.
>
> "4.—The Walden Method is unscientific and does not cure diseases or human ailments through modern scientific methods, nor does it cure or aid in the cure thereof at all.
>
> "5.—The Walden Method was not promulgated by the greatest living authority, or by any authority, living or dead.

"6.—The Walden Method is not a proper or sure method of treating the diseases and ailments mentioned in Paragraph Two hereof, or any other diseases or ailments.

"7.—The Walden Method has not relieved thousands, or any, patients of their ailments or diseases.

"8.—Ninety-five per cent, or any per cent of fatal heart disease has not been cured or relieved by the Walden Method.

"9.—The Walden Method is not the only sure method of curing or aiding in the cure of the diseases or ailments mentioned in Paragraph Two hereof, nor is it a sure method at all.

"10.—Correct and accurate diagnoses of said ailments or diseases of the human body cannot be made by the methods employed by respondent.

"11.—Many of the purported testimonials referred to in subdivision (c) of Paragraph Two hereof are false and misleading, many were never given and many were induced by purchase and such purchase not disclosed to persons reading the same.

"12.—The diagnoses attempted by the respondent are not within the range of this respondent's methods, skill or information.

"13.—The use of the abbreviation for 'Doctor,' 'Dr.,' as applied to the name of the respondent in the advertising and sale of the 'Walden Method,' as aforesaid, holds out to the public that respondent is a doctor of medicine, when such is not the fact."

Hearings have not yet been held on this case. They will be awaited with interest by those who seek to protect the public from quackery.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be *omitted, on request.*

DIFFERENTIAL DIAGNOSIS OF INTESTINAL WORMS

To the Editor:—I should be pleased to have your assistance in identifying an intestinal worm discovered in the stool of a girl, aged 18 months. The previous history is negative. The child is greatly emaciated, feeble and fretful; the appetite is fair; the digestion, except during brief dentition, has been good. The present illness began nearly three months ago, the chief symptoms being progressive loss of weight and strength, increasing anemia, constant fretting and crying for hours and hours. Slight fever is present most of the time. Urinalysis gives negative results; the hemoglobin is 60 per cent, the stool is well digested but contains many small islands of mucus. The first microscopic examination disclosed ova comparable to hookworm. The first dose of castor oil given after a course of chenopodium oil caused disappearance of these ova. None have *appeared since. In the first specimen and in all subsequent stools* examined, numerous worms have been seen which when magnified 70 diameters appear much like the male hookworm by naked eye; that is, straight or slightly curved, sharp at one end but clubbed at the other. The worms are striated transversely (ringed) for their entire length. They are not visible to the naked eye. Motion has not been observed. The food has been milk, eggs and cereal. No fruit substances such as peach fuzz have been ingested. Slight improvement in the child's condition followed an anthelmintic, but the stool still teems with these apparent worms. Please omit name.

M.D., Oklahoma.

Answer.—There is a question here as to a parasite really being present. It is difficult to diagnose the genera of worms by a written report. The problem of recognition of the parasite (?) present here would be simplified if one knew the residence of this child and also had available a differential blood count, showing the eosinophil percentage. Pathologic intestinal parasites, which by excretion of toxin (?) or by tissue invasion are producing lesions, commonly cause alterations from the normal differential leukocyte formula; the anomaly usually is eosinophilia. With 60 per cent hemoglobin, this child's red cells might be expected to present abnormalities.

Many of the signs and symptoms presented clinically by this child could be ascribed to a dietetic deficiency. Certainly, for an 18 month old girl a diet comprised wholly of milk, eggs and cereal is unbalanced in vitamins. It would be of importance to know what has been the diet prior to the one named. In a previous diet, the "ova" and "worms" described might well be vegetable hairs, fruit fibers or molds. It is difficult to recognize ova or worms accurately after the administration of castor oil; a saline cathartic delivers stools which may be readily examined both macroscopically and microscopically.

If the offending parasite here were hookworm, it is difficult to explain how ova were seen but once, whereas, on all occasions, the stool was rich in "worms." Hookworm-filled stools usually exhibit ova and worms simultaneously, at least at some examinations. Also, it is rare to find stools "teeming with hookworms" without observing mobility in many, especially if warm freshly passed stools are studied on a warmed microscope stage. The inquirer is ambiguous: are the worms invisible to the unaided eye, or is it the striations? Since hookworms vary in length from one-third to one-half inch, it is possible, if the stool is stirred on a black surface, to see them with the unaided eye. Ancylostoma is even longer than hookworm (Necator americanus). Striation is not seen microscopically. The pointed part of the female and the umbrella-like copulatory bursa of the male are characteristics readily identified under the medium powered lens.

The pinworm (Enterobius vermicularis) may be confused with hookworm. It can be seen macroscopically, squirming on fecal masses, since it is approximately half an inch long. Since eggs are deposited as the worm wanders, anal and perineal anal irritation is common and should be looked for, particularly at night. Scratching infects the fingers, produces surface body lesions, and spreads the infestation. The worm is actively motile and not transversely striated.

The roundworm (Ascaris lumbricoides), from one-half to one-fourth inch long and slightly pinkish, is transversely striated but has not a clubbed end as described by the correspondent. Infestation may occur through hogs or through those who come into contact with them and carry the slowly maturing eggs. Constitutional upsets may be severe, because the worm migrates extensively (through the liver, lungs, trachea or appendix). The knobbed ovoid eggs should not readily be confused with the rounded, four-segmented eggs of hookworm. The parasite is motile.

From the foregoing summary it would seem that, of the common worms infesting the alimentary tract of human beings, the correspondent is dealing with a roundworm (Ascaris lumbricoides) or an artefact.

In the circumstances, further observations should be made on foreign substance present in the stool.

Treatment should include a vitamin balanced, adequate ration. "On suspicion," a course or two of thymol may be tried after the patient has been on a fat-free diet for three days.

PREGNANCY IN DOUBLE UTERUS

To the Editor:—Please advise the wisest course to pursue in the following case: One of my patients, a primipara, who is three months pregnant, has a "uterus duplex." The vagina is also divided by a septum. The uterus on the right side is the one pregnant. Shall I let her go to term? Will there not be too much interference at term by the other uterus and the vaginal septum? The husband and wife do not want a cesarean operation performed. The pelvic measurements are normal. The literature available regarding this seems to be scarce. Please omit name.

M.D., Ohio.

Answer.—Uterus didelphys, or double uterus, consists of two distinct uteri, usually of different sizes, each with a separate cervix which communicates with the vagina. In most instances, as in the case cited, the vagina is also double. A review of the literature reveals that, in more than a fourth of all the cases, pregnancy is interrupted before the child is viable. The cause of this may be abnormal implantation of the ovum due to the uterine malformation or the malformation itself. In addition to the abortions that occur, labor takes place prematurely in an additional 10 per cent of the cases. Only about 60 per cent of all the patients with uterus didelphys carry their pregnancies to term. Of those who go to term, about 70 per cent are delivered normally, whereas the remainder have complications. This means that only about 40 per cent of all women with a pregnancy in a double uterus have normal deliveries. The most common factors that produce dystocia are the enlarged, nonpregnant half of the uterus, the vaginal septum when present, uterine inertia, tetanic contraction of the uterus, and retention of the placenta in the uterus. Breech presentation is frequently observed. Complications such as postpartum hemorrhage, hematometra and subinvolution occur more frequently in the presence of these malformations than in normal cases.

Since the majority of patients who go to term deliver spontaneously, the treatment of a case of pregnancy in a uterus didelphys should be conservative. An effort should be made to prevent abortion or premature labor. Repeated examinations should be made from time to time, but with great gentleness, to detect a beginning incarceration of the nonpregnant uterus. If symptoms of incarceration arise, treatment should be instituted early. When the patient goes into labor, she should be watched closely. Operative intervention is necessary only when abnormal symptoms present themselves. Even if the patient delivers spontaneously she must be carefully guarded during the puerperium. Excellent articles on this subject are those by N. F. Miller (*Am. J. Obst. & Gynec.* **4**:398 [Oct.] 1922) and Palmer Findley (*Am. J. Obst. & Gynec.* **12**:318 [Sept.] 1926).

USE OF IRON CITRATES IN SECONDARY ANEMIA

To the Editor:—What are the relative merits of ferric citrate and of iron and ammonium citrate in secondary anemia? What is the maximum dosage of each preparation? What is the extent of solubility in water or in other solvents? Please indicate method of prescribing these preparations. What is the toxicity, if any?

A. M. Loes, M.D., Dubuque, Iowa.

Answer.—Ferric citrate is not as soluble as iron and ammonium citrate, but it is more permanent in the air. Hence, the former would be more suitable for prescribing in powder form and the latter for solution. A dose of 1 Gm. is ordinarily not exceeded. Toxicity is slight. Extremely large doses might produce local irritation.

Iron and ammonium citrate is soluble in less than its own weight of water. It is insoluble in alcohol. The following prescription might be suggested:

	Gm. or Cc.
Iron and ammonium citrate........................	10
Syrup of orange..............................	60
Chloroform water..........................to make	120

M. Label: Teaspoonful in water three times daily after meals.

A tablespoonful dose of this preparation should not be excessive.

FRÖHLICH'S SYNDROME OR DYSTROPHIA ADIPOSOGENITALIS

To the Editor:—Mrs. M. G., aged 28, whose family history is irrelevant, has been married five years and has not become pregnant. Menstruation began at the age of 13 and there were only one or two menstrual flows each year up to the age of 20. From then until the present time there have been three or four menstrual flows each year, lasting from one to three weeks, occasionally accompanied by griping pains in the uterus. Sometimes the flow is light or bright red; again it is dark. At times there are clots of various sizes; again there are no clots. The last menstrual flow began June 15 and lasted periodically until August 1. The flow returned from two to five days in a gush, which the napkin could not contain. During this period the whole abdomen was sore and tender from a misstep or from an automobile ride. Between periods the abdomen is full and distended; this condition is relieved by the flow. The patient is 5 feet 4 inches (162.6 cm.) in height and weighs 160 pounds (72.6 Kg.), with some tendency to obesity. The patient desires to correct the condition and become pregnant, if possible. With many consultations there has been no satisfactory result. About one year ago a small polypus was removed, without results. Please omit name. M.D., Indiana.

Answer.—The history suggests a case of Fröhlich's syndrome, dystrophia adiposogenitalis, although an obstruction of the cervical canal is a possibility, and a dilator should be passed to rule out this complication. Fröhlich's syndrome is characterized by scanty and irregular menstruation, dysmenorrhea, and a tendency to adiposity with atypical deposition of masses of fat. Troubles of this nature are due to disturbed function of the endocrine system, notably the pituitary gland. The patient should have a determination of the basal metabolic rate. Roentgen examination of the sella turcica and a blood calcium determination might also be helpful. The treatment is unsatisfactory, although rapid strides are being made in the therapy of such conditions. An adiposity diet, outdoor life, and the administration of thyroid extract or pituitary gland substance, or the more recently advocated specific hormones may be helpful.

COMPARATIVE CALCIUM AND PHOSPHORUS VALUES OF FOODS

To the Editor:—Knowing the discriminating care that is employed in the acceptance of advertisements for The Journal, I was somewhat surprised to find the comparison that was published on the outside advertising page (page 62) of the issue for October 17. This contains a comparison of a proprietary cereal product with other cereals, and likewise with whole milk and eggs. A casual inspection of the figures might lead one to assume that milk (notably an excellent source of calcium and phosphorus) is comparatively deficient in these elements, when contrasted with the new proprietary product. Is this not misleading and likely to tend to curtail the use of milk, which has begun to play a large rôle in all the programs for child welfare? M.D., Connecticut.

Answer.—Our correspondent points out several features of the comparison that might easily be misleading. For example, the cereal referred to is recorded as having calcium, 0.78 per cent, in contrast with milk, 0.12 per cent; similarly the cereal phosphorus is given as 0.62 per cent, in contrast with 0.09 per cent in milk. The fallacy in this comparison lies in the fact that, whereas milk contains 87 per cent of water, the cereal in question has only 7 per cent of moisture. If the solids of the cereal and those of whole milk were compared, the relative value of milk would at once become conspicuous.

A quart of milk contains approximately 1.2 Gm. of calcium and 0.9 Gm. of phosphorus. It would require more than 150 Gm. (5 ounces) of the cereal in question to supply the equivalent of that amount of milk in the two elements referred to. The same comment may be made with reference to the comparison of the cereal with milk, in respect to the relative content of vitamin G. Obviously milk is normally consumed in far larger quantities than is the case for any cereal. The advertising comparison also contrasts the proprietary cereal, yielding 109 calories per ounce, with milk yielding 20 calories per ounce. In practice, however, a quart of milk will yield more than 600 calories, the equivalent of at least 6 ounces of the cereal.

SURGICAL DRAINAGE OF FELON

To the Editor:—Is it now good surgical practice merely to lance a felon of four or five days' standing with one short incision, one-fourth or three-eighths inch long, as though it were a boil? Please omit name.

M.D., Michigan.

Answer.—Because of the peculiar attachment of the skin on the tips of the fingers to the periosteum, spreading infection from a felon will extend downward and not laterally. This explains why there is no fluctuation until late, although the entire finger tip is usually swollen.

The old practice of an incision over the abscess, similar to that of lancing a felon, is to be condemned. This is not good surgical practice, because it may produce an incision which is longer than necessary for superficial abscesses; because a short incision will not drain and because any incision will leave a bad scar over the most important tactile area of the body.

The treatment for all felons is immediate drainage, preferably under regional anesthesia at the base of the finger with procaine. If the abscess is superficial and the area can be localized, it is good practice to place a sharp knife almost flat against the abscess area and cut off the top of the rounded swelling, thus opening up the abscess cavity. The removal of a certain amount of skin from around the cavity by this method will prevent its closing too soon, and will drain it better than a vertical incision.

In the felons which have gone on to deeper involvement, as evidenced by general swelling of the fingertip and severe pain, one must drain a wider area. Unless the felon is located directly at the tip of the finger beneath the nail, one should always preserve this area and not cut through it with the knife. If it must be cut, it should be cut parallel to the nail and circularly around the finger in the shape of a horseshoe.

In the ordinary felon near the middle of the tip, one should make two incisions—one along either side—and then undercut, parallel to the bone, across the abscess cavity. If necessary, the whole pad of the finger except the tip near the nail may be separated for adequate drainage. A soft rubber tissue drain is pulled through from one incision to the other and left in until the drainage has lessened.

HYPERSENSITIVENESS TO DIPHTHERIA TOXOID

To the Editor:—Having read the answer to the question concerning hypersensitiveness to toxoid in Queries and Minor Notes (The Journal, October 10, p. 1095), I would take the liberty of raising a question regarding the impression which the average reader may receive. The answer to Dr. Robbins' question states that "the control test, as carried out in the Schick procedure, serves as an indication of susceptibility to proteins in the toxin solution and may be used as a substitute for the injection of dilute toxoid solution in determining susceptibility of individuals to protein in the toxoid solution." As the reply to the question states, "Diphtheria toxin and toxoid are not the same substance and individuals do not react to the two in the same manner." Therefore, I believe that advice conveying the impression that Schick test control material may be used as a substitute for the dilute toxoid is true only to a limited extent and that this statement should be corrected. Diphtheria toxoid, representing the detoxified diphtheria toxin, is diluted 1:20 when prepared as reaction test material. Schick test control material is diluted the same as Schick test toxin of any given lot, which is approximately a 1:300 dilution. Walter E. King, M.D., Detroit.

Answer.—It is true that the Schick test control material is not identical with that of the diluted diphtheria toxoid used as a test for protein susceptibility. The impression intended to be conveyed was that the Schick test control serves as a guide to susceptibility to the proteins in the toxin solution and so, to a certain extent, may also be used as a guide to susceptibility to the proteins in the diphtheria toxoid solution.

ELECTROCARDIOGRAPHIC TRACINGS WITH PATIENT UNDER ANESTHESIA

To the Editor:—I should appreciate any information you may have available concerning the danger or safety of the taking of electrocardiographic tracings while the patient is under anesthesia, especially ethylene and oxygen.

James F. Alison, M.D., Selma, Ala.

Answer.—It is inconceivable that any dangerous situation might arise from taking an electrocardiographic tracing while the patient is under anesthesia, whether with nitrous oxide-oxygen, ether, or ethylene-oxygen. Even if a small portable electrocardiograph were taken into the room itself, there would be no danger. Some of the older types of machines throw a spark when the circuit is closed. In that case, of course, the machine is to be left in the hall, only the leads being allowed in the room.

OXYGEN TENTS

To the Editor:—Will you please give your impression as to the type of oxygen tent which is giving the best results in the market today? We anticipate the purchase of a tent in the near future and want advice.

M.D., Wisconsin

Answer.—There are several makes of oxygen tents that are sufficiently satisfactory for use under most conditions. The main requirements of an oxygen tent are that it should be large enough, at least 3 feet in each direction, that it should hold oxygen well enough so that from 50 to 60 per cent of oxygen can be maintained in it, and that the cooling device and circulation of the atmosphere of the tent should be adequate to keep the temperature at 70 F. Most of the tents that can be purchased will satisfy all these requirements in the winter time, but on hot summer days the temperature and humidity inside the tent cannot be properly controlled except with a few makes of oxygen tents. The patient's comfort, well being and progress toward recovery are dependent not only on the maintenance of a sufficient amount of oxygen in the tent but also on the control of the temperature and humidity in the tent. The temperature and humidity control has not been recognized sufficiently by most manufacturers. The following are well known tents: Barach-Davidson; Cecil-Plummer; Oxygenaire; Barach-Roth.

DIFFERENTIATING WHITE AND COLORED CHILD

To the Editor:—I have had an unusual case of a white girl giving birth to a male child which is apparently a Negro. I wish you would give me all the information you can in regard to differentiating between a white and a colored child born of a white mother. Kindly list the characteristics from a physical examination and also whatever laboratory means I can use to form a definite conclusion.

J. Marsh Frere, M.D., Chattanooga, Tenn.

Answer.—For the purpose of differentiating between a white and a Negro child, skin color is the only reliable guide. Furthermore, in a Negro child the hair will be dark and may be woolly but need not be so in white-Negro crosses. The eyes will be dark brown. The shape of the head is entirely unreliable, since both long and short heads occur in a white and a (mixed) Negro population. Laboratory tests will not be of much assistance when nothing is known regarding the paternity.

Heredity studies have revealed the fact that dark skin color is generally dominant over light color, although exceptions have been observed (but not for crosses between Negroes and whites). There are cases known in the literature in which two individuals with light coloring had dark-skinned offspring.

When the father is suspected to be either one of, say, two or three individuals, anthropologic measurements and an examination of the blood groups of all concerned may lead to a definite conclusion.

GANGLION OF WRIST

To the Editor:—I request some information in reference to the treatment of the so-called ganglions that occur frequently about the wrist. In cases which have not subsided with firm bandaging, it has been my custom to perform excision. I have had very good results from this treatment. However, there seem to persist rumors of the method of hitting these swellings with a heavy book to cause bursting of them subcutaneously. I have been unable to find this treatment recommended in any authoritative textbook, or to find any surgeon of standing who would admit using it. Will you inform me whether this method of treatment is really standard and satisfactory?

E. C. McCulloch, M.D., Staten Island, N. Y.

Answer.—So-called ganglions may disappear following a severe blow, but this form of treatment is not good practice. The subsidence following a blow probably results from the rupture of the wall, with absorption. Since a certain number may absorb following this procedure, it would be preferable to introduce a small knife at a distance subcutaneously, and cut the wall.

The best surgical practice is to excise the mass. However, this leaves a scar and, furthermore, because of the rather poor circulation, there is often a failure of healing by primary intention. This necessitates the utmost care in operation, which should always be done with the greatest aseptic precautions, in the hospital.

"ACCOMMODATIVE PHOSPHENE"

To the Editor:—Can you tell me where I can find an account of the "accommodative phosphene" of Czermak and how to elicit it? I can see a luminous ring at a distance in the dark, and on accommodation this becomes smaller, presumably from contraction of the pupil. Tscherning says that the experiment did not succeed with him. I am not satisfied that the ring is due to accommodation. It seems to appear anyway in a dark room. It is extremely vague, but my accommodation is only about 2 D.

Reginald A. Yeld, M.D., Edgewood, B. C.

Answer.—Details regarding accommodative phosphene can be found in the following articles:

Purkinje, J. E.: Beobachtungen und Versuche zur Physiologie der Sinne, Prague, J. G. Calve **1:** 126; **2:** 115, 1823.

Czermak, J. M.: Sitsungsb. d. k. Akad. d. Wissensch. **27:** 78.

Helmholtz, H.: Helmholtz's Treatise on Physiological Optics, translated from the Third German Edition, Ithaca, N. Y., the Optical Society of America **2:** 9, 1924.

Helmholtz gives a somewhat detailed discussion and covers the points in question.

USE OF OVARIAN EXTRACT AND SEX HORMONES

To the Editor:—In The Journal, October 3, there appeared an inquiry on the treatment of menopausal symptoms. I was expecting to find a suggestion as to the use of theelin or amniotin. You mention hypodermic injections of ovarian extract, which are not the same as the aforementioned products. Do you not consider their use and value as yet proved? I have treated several cases, with a substantial percentage of good results, in one case cutting down the heat flashes in two weeks from twenty a day to five a day by the use of 8 cc. of the product. What about these new extracts?

M. M. Hart, M.D., New Wilmington, Pa.

Answer.—The new preparations of ovarian hormone, such as Theelin and Amniotin, have been used in a large number of cases of troublesome menopausal symptoms, but the results obtained are by no means uniform. Neither Amniotin nor Theelin has been accepted for inclusion in New and Nonofficial Remedies. In many cases, no relief at all is obtained whereas in others, just as in the case cited, the benefit derived is excellent. In some cases in which good results are observed, part of the success may be attributed to the psychologic effect of the injections. In patients who have severe menopausal symptoms, these preparations may be employed but, in addition, it is important to prescribe sedatives and a proper diet and mode of living.

LEFT-HANDEDNESS AND BRAIN CENTERS

To the Editor:—I read an article on "The Left-Handed Child," by Arthur Dean, a newspaper syndicate writer. I beg you to give me your opinion as to the correctness of his statement. Mr. Dean seems to assume that, when the manual center is in the right side of the brain, other important centers which normally, or rather usually, belong on the left side are also in the right hemisphere.

Robert W. Gibbes, M.D., Columbia, S. C.

Answer.—This statement may be accepted as substantially correct. The "other important centers" referred to are chiefly those concerned with the speech mechanisms, both motor and sensory, and the eupraxis mechanisms. The leading hemisphere in these functions seems to be usually the left in right-handed persons and the right in left-handed persons, though it is possible that this is not always true. Clinical experience also has shown that in some cases there does seem to be a causal relationship between the compulsory use of the right hand by a left-handed person, and neurotic or other disordered behavior.

HEREDITARY CANCER IN MAN

To the Editor:—A mother was found to have cancer of the uterus within a few months after the birth of a male infant. Is this boy more liable to a future development of cancer than if the mother had not had the cancer?

J. Dale Graham, M.D., Columbus, Kan.

Answer.—In spite of the fact that in certain animals there is a distinct hereditary tendency to cancer, this has not been established as a factor susceptible of determination in human beings. The child in the case cited does not run a greater risk of the development of cancer than does any other child. This statement applies even if the cancer was present before the child was born.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALABAMA: Montgomery, Jan. 11. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: *Clinical.* Chicago, Dec. 29. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

AMERICAN BOARD FOR OPHTHALMIC EXAMINATIONS: Boston, Dec. 21. Sec., Dr. Wm. H. Wilder, 122 S. Michigan Blvd., Chicago.

ARIZONA: Phoenix, Jan. 5-6. Sec., Dr. B. M. Berger, 12 North Central Ave., Phoenix.

COLORADO: Denver, Jan. 5. Sec., Dr. Wm. Whitridge Williams, 422 State Office Bldg., Denver.

DISTRICT OF COLUMBIA: *Basic Science.* Washington, Dec. 29-30. *Regular.* Washington, Jan. 11. Sec., Dr. W. C. Fowler, District Bldg., Washington.

HAWAII: Honolulu, Jan. 11-14. Sec., Dr. James A. Morgan, Room 48, Young Bldg., Honolulu.

MARYLAND: *Homeopathic.* Dec. 17-18. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

MINNESOTA: *Basic Science.* Minneapolis, Jan. 5-6. Sec., Dr. J. C. McKinley, 126 Millard Hall, University of Minnesota, Minneapolis. *Regular.* Minneapolis, Jan. 19-21. Sec., Dr. E. J. Engberg, 524 Lowry Medical Arts Bldg., St. Paul.

NEBRASKA: *Basic Science.* Lincoln, Jan. 12-13. Act. Sec., Mr. P. H. Bartholomew, Lincoln.

NORTH DAKOTA: Grand Forks, Jan. 5-8. Sec., Dr. G. M. Williamson, Grand Forks.

OREGON: Portland, Jan. 5-7. Sec., Dr. C. J. McCusker, 1014 Medical Dental Bldg., Portland.

PENNSYLVANIA: Philadelphia, Jan. 5-9. Sec., Mr. Charles D. Koch, Harrisburg.

RHODE ISLAND: Providence, Jan. 7-8. Dir., Dr. Lester A. Round, 319 State Office Bldg., Providence.

SOUTH DAKOTA: The St. Charles Hotel, Pierre, Jan. 19-20. Dir., Dr. H. R. Kenaston, Bonesteel.

TENNESSEE: Memphis, Dec. 18-19. Sec., Dr. Alfred B. DeLoach, Medical Arts Bldg., Memphis.

WASHINGTON: *Basic Science.* Seattle, Jan. 14-15. *Regular.* Seattle, Jan. 18-19. Dir., Mr. Charles Maybury, Olympia.

WISCONSIN: *Basic Science.* Milwaukee, Dec. 19. Sec., Prof. Robert N. Bauer, 3414 West Wisconsin Ave., Milwaukee. *Regular.* Madison, Jan. 12-14. Sec., Dr. Robert E. Flynn, 315 State Bank Bldg., LaCrosse.

Utah June-July Report

Mr. S. W. Golding, director, Utah Department of Registration, reports the written examination held at Salt Lake City, June 30-July 1, 1931. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Three candidates were examined, all of whom passed. Five physicians were licensed by reciprocity with other states, and 3 physicians were licensed by the endorsement of credentials, July 14, 1931. The following colleges were represented:

College PASSED	Year Grad.	Per Cent
State University of Iowa College of Medicine	(1930)	82.3
University of Louisville School of Medicine	(1930)	82
Royal University of Bologna Faculty of Med. and Surg.	(1930)*	78

College LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Northwestern University Medical School	(1931)	Idaho
Indiana University School of Medicine	(1917)	Louisiana
State University of Iowa College of Medicine	(1930)	Iowa
University of Louisville School of Medicine	(1930)	Kentucky
University of Pennsylvania School of Medicine	(1928)	Penna.

College LICENSED BY ENDORSEMENT	Year Grad.	Endorsement of
Washington University School of Medicine	(1930)	N. B. M. Ex.
University of Pennsylvania School of Med.	(1929), (1930)	N. B. M. Ex.

* Verification of graduation in process.

California July Report

Dr. Charles B. Pinkham, secretary, California Board of Medical Examiners, reports the written examinations held at San Francisco, July 6-9, 1931, and Los Angeles, July 21-23, 1931. The examinations covered 9 subjects and included 90 questions. An average of 75 per cent was required to pass. Two hundred and eighteen candidates were examined, 206 of whom passed and 12 failed. The following colleges were represented:

College PASSED	Year Grad.	Number Passed
College of Medical Evangelists	(1930, 3), (1931, 41)	44
Stanford University School of Medicine	(1930, 2), (1931, 43)	45
University of California Medical School	(1931, 54)	54
University of Colorado School of Med.	(1930, 2), (1931, 2)	4
Loyola University School of Medicine	(1930), (1931, 3)	4
Northwestern University Med. School	(1930, 3), (1931, 11)*	14
Rush Medical College	(1921), (1931, 2)	3
University of Illinois College of Medicine	(1929), (1931, 4)	5
State University of Iowa College of Medicine	(1930)	1
University of Kansas School of Medicine	(1930)	1
Tulane University of Louisiana School of Medicine	(1931)	1
University of Michigan Medical School	(1931)	1
Harvard University Medical School	(1930)	1
Tufts College Medical School	(1930)	1
University of Minnesota Medical School	(1928), (1931)	2
Creighton University School of Medicine	(1931, 9)	9
Syracuse University College of Medicine	(1930)	1
University of Rochester School of Medicine	(1929), (1930)	2
University of Oregon Medical School	(1931)	1
Jefferson Medical College of Philadelphia	(1929), (1930)	2
University of Pennsylvania School of Medicine	(1929)	1
University of Manitoba Faculty of Medicine	(1925)	1
University of Toronto Faculty of Medicine	(1918)	1
McGill University Faculty of Medicine	(1930, 4), (1931)	5
University of Vienna Faculty of Medicine	(1930)†	1
Royal Univ. of Naples Faculty of Med. and Surg.	(1916)†	1

College FAILED	Year Grad.	Number Failed
University of Illinois College of Medicine	(1931, 2)	2
Creighton University School of Med.	(1930, 3), (1931)	4
University of Oregon Medical School	(1930)	1
Medical Faculty of Trinity University, Toronto	(1904)	1
University of Vienna Faculty of Medicine	(1930)†	1
University of Bordeaux Faculty of Med. and Pharm.	(1930)†	1
University of Amsterdam Medical Faculty	(1901)†	1
University of Tomsk Faculty of Medicine, U. S. S. R.	(1913)†	1

Dr. Pinkham also reports 6 physicians licensed by endorsement of credentials from April 23 to Aug. 6, 1931. The following colleges were represented:

College LICENSED BY ENDORSEMENT	Year Grad.	Endorsement of
Rush Medical College	(1906)	U. S. Army
Indiana University School of Medicine	(1929)	U.S.P.H.S.
State University of Iowa College of Medicine	(1889)	U. S. Army
St. Louis University School of Medicine	(1917)	U. S. Navy
Medical College of the State of South Carolina	(1916)	U. S. Navy
Baylor University College of Medicine	(1930)	U. S. Navy

* The M.D. degree of two of these applicants is being withheld pending completion of internship.

† Verification of graduation in process.

Michigan June Examination

Dr. F. C. Warnshuis, former secretary, Michigan Board of Registration in Medicine, reports the written examination held at Ann Arbor and Detroit, June 15-17, 1931. The examination covered 14 subjects and included 100 questions. An average of 75 per cent was required to pass. Two hundred and fifty-four candidates were examined, all of whom passed. The following colleges were represented:

College PASSED	Year Grad.	Per Cent
College of Medical Evangelists	(1931)	84.5
Hahnemann Medical College and Hospital, Chicago	(1918)	80.2
Loyola University School of Medicine	(1931)	78.7, 81.3
Northwestern University Medical School	(1931)	84.6, 84.7
Rush Medical College	(1927) 84.1, (1931)	82.8,* 85.8
University of Illinois College of Medicine	(1931)	85.3†
Johns Hopkins University School of Medicine	(1928)	85.9

Book Notices

Detachment of the Retina: A Contribution to the Study of Its Causation and Treatment. By J. Ringland Anderson, M.C., M.B., B.S., Ophthalmic Surgeon to the Alfred Hospital, Melbourne. With a foreword by Sir John Herbert Parsons, C.B.E., D.Sc., F.R.C.S. Published for the British Journal of Ophthalmology. Cloth. Price, $6.50. Pp. 207, with 9 illustrations. London: Cambridge University Press; New York: Macmillan Company, 1931.

This is a comprehensive review of the present knowledge of detachment of the retina. The material is divided into chapters, beginning with a presentation of the older ideas concerning the disease, the present ideas about its etiology, and the subjective symptoms and objective observations. Next are described the anatomy and physiology of the retina, the choroid, the circulation of the blood and the aqueous, and the ocular reactions to injuries. The chapter on pathogenesis gives the various theories as to the cause, the history of the origin of these theories, and the associated pathologic changes seen with detachment of the retina. The chapter on diagnosis considers in detail the methods of differentiating this condition from detachments due to sarcoma and gives the field changes as well as tension changes. The chapter on treatment considers the nonoperative method. The main portion of the work deals with the localization of tears or holes in the retina and their treatment by cautery after Gonin, giving in detail the technic for both and the operative results. The section on prognosis discusses the untreated cases and compares these with the cases treated with cautery. The bibliography is complete and conveniently divided into subtitles at the end of each chapter. The work offers nothing original but it does provide for the busy practitioner a compact and satisfactory summary of the present knowledge of the subject and should meet with the widespread approval of ophthalmologists at large.

Cantidad de hemoglobina de la sangre humana en la República Argentina. Tesis. Por el Dr. Oscar Orias. Trabajo del Instituto de Fisiología de la facultad de ciencias médicas de Buenos Aires. Paper. Pp. 116. Buenos Aires: Frascoli y Bindi, 1930.

The Newcomer colorimetric technic for the determination of hemoglobin is considered the most practical, exact method, and is the procedure of choice. The bloods of many people of the Argentine Republic have been examined by the author, who concludes that his values for the hemoglobin of this group of people are similar to those obtained in other parts of the world. Hemoglobin values are greater in males than in females, and greater in the new-born than in the adult; the hemoglobin value drops during pregnancy but rapidly returns to normal after the puerperium. At altitudes of 1,200 meters or more, an appreciable increase in hemoglobin occurs. University students and officials show greater hemoglobin values than do soldiers and sailors. It is thought that this apparent discrepancy is due to differences in nutrition, clothing and conditions of work in these classes of people. The variations encountered in different social groups merit further investigation.

Physiopathologie de la thyroïde: Diagnostic et traitement des goitres. Par Lucien Dautrebande, de la Foundation Reine-Elisabeth. (Avec la collaboration du Dr. A. Lemort.) Paper. Price, 40 francs. Pp. 326, with 36 illustrations. Paris: Masson & Cie, 1931.

In the first part of the book the author discusses the normal and the pathologic physiology of the thyroid gland in their relations to the chemical composition of the gland, its histology, general metabolism, and the special histology of various nutritional elements. The geographic distribution of goiters throughout the world and their relation to lack of iodine in water and in agricultural products are studied. Original ideas as well as a criticism of former conceptions of hyperthyroidism are presented. The second part of the book is devoted to clinical considerations, and the author presents a physiopathologic classification of thyroid disorders, in which the presence or absence of hyperthyroidism is considered the essential point of differentiation and the determination of the basal metabolic rate is emphasized as being the most important piece of evidence in the differentiation of hypothyroid, normal and hyperthyroid states as well as in the estimation of the gravity of a given case of hyperthyroidism. This point is debatable and would probably be considered by most clinicians as of importance secondary to the clinical observation of the patient. Several chapters are devoted to the exposition of the author's main thesis; i. e., the major importance of prolonged iodine therapy in the successful treatment of hyperthyroidism. The surgical treatment of this condition, which in America at least is generally considered the treatment of choice, is relegated by the author to a place of secondary importance. In an appendix, certain neurotic conditions simulating hyperthyroidism are briefly discussed, together with the differential diagnosis by means of the basal metabolic rate. The book is well arranged throughout and, while little fundamentally new knowledge is presented, many of the apparently minor details give food for thought. A bibliography of several hundred titles completes the work.

Steps in the Dark. By Milton Mayer and John Howe. Cloth. Price, $2.50. Pp. 227. Chicago: Thomas S. Rockwell Company, 1931.

This volume includes a series of sketches for the popularizing of knowledge concerning science. Among the subjects of medical interest are the researches of Falk on influenza, of Luckhardt on ethylene, of Maud Slye on cancer, of Carlson on hunger and of Jacobson on relaxation. The first and the last of these are hardly sufficiently established or sufficiently significant to warrant the type of consideration that is given them. The interest of the other essays given in the book is of general scientific rather than of medical importance.

Die vierfache Muskelinnervation einschliesslich der Pathogenese und Therapie der progressiven Muskeldystrophie. Von Ken Kuré, Professor an der Universität Tokyo. Paper. Price, 20 marks. Pp. 320, with 137 illustrations. Berlin: Urban & Schwarzenberg, 1931.

This is an account of a large amount of research work on the cerebrospinal, sympathetic and autonomic innervation of muscle, all correlated with the investigations of other workers, which are subjected to a critical review. Chemical and pharmacologic investigations are reported as well as histologic studies and physiologic experiments. The chief practical application of interest to practicing physicians relates to the muscular atrophies. In a general way, so-called spinal muscular atrophy, including amyotrophic lateral sclerosis and neuritic muscular atrophy (Charcot-Marie type) are related to the cerebrospinal motor system, while it is claimed that in muscular dystrophy the sympathetic and autonomic innervation is at fault. The author has found that benefit has been obtained from treatment with atropine and pilocarpine, provided the motor nerve endings have remained intact.

The Cardiac Cycle. By Harrington Sainsbury, O.B.E., M.D., F.R.C.P., Consulting Physician to the Royal Free Hospital, Ventnor. Cloth. Price, $1.75. Pp. 79. New York: William Wood & Company, 1931.

Theories as to the phenomena of the cardiac cycle must, the author says, tally not alone with the facts of physiology but with the laws of physics and chemistry that operate as well in the living body as in the outer so-called inorganic world. When physiologic views are at variance with these laws, such views must yield; physics and chemistry are fundamentals. He makes the flow of the lymph a part of the circulatory act, a part of "one general, associated, liquid movement which obtains throughout the body—a movement essential to its corporate life." He stresses the pulse wave as an important pressor factor in the lymph circulation. The monograph is scholarly and well written. It will interest especially the student of cardiac physiology.

Arzneiverordnungsbuch der Deutschen Arzneimittelkommission. Fourth edition. Paper. Pp. 201. Leipzig: Verlag der Buchhandlung des Verbandes der Ärzte Deutschlands, 1930.

This collection of brief descriptions of remedies "that might be recommended to physicians" is edited by a committee somewhat analogous to the Council on Pharmacy and Chemistry of the American Medical Association, which was originated in 1911 by the Deutsche Gesellschaft für innere Medicin. The booklet itself differs from New and Nonofficial Remedies in that it gives information on official remedies also. It is, indeed, intended as a physician's handbook. Systematic attention is given to the cost of remedies and even of finished prescriptions, which seems to be demanded by the prevailing financial condition of the country, and most especially of the *krankenkassen.*

Medicolegal

When Disease Is Not an Accident

(Jackson v. Employers' Liability Assurance Corp. (N. Y.), 248 N. Y. S. 207)

The defendant insured the plaintiff, Jackson, as the owner of an apartment house, against loss from "bodily injuries, including death at any time resulting therefrom, accidently sustained by any person or persons while within or upon the premises." In one of the plaintiff's apartments, a 3 months' old infant, Cochenour, died from what the attending physician said was a general catarrhal condition, bronchitis and gastro-enteritis, "a toxic state of the general system as the result of exposure and chilling of the body surfaces." The administrator of the estate of the deceased infant sued Jackson, who he alleged had failed and neglected to heat, as required by law and under the terms of the lease, the apartment in which the infant lived. Jackson, he contended, had permitted the apartment to continue unheated, cold, damp, unsafe, and unhealthful, and was therefore liable for damages for the death. Judgment was rendered against Jackson, which he paid. He thereafter brought the present suit under his insurance policy to be reimbursed for the loss thus sustained.

The decision in the case turned on the answer to the question: Was or was not the death of a tenant from acute bronchitis and gastro-enteritis that were caused by the negligent and the unlawfully defective heating of an apartment over a considerable period of time an injury due to an accident, within the meaning of the insurance policy? The word "accident," said the supreme court, special term, King's County, from the point of view of the average man connotes an event of the moment rather than a condition which develops, progresses, and changes through a period of time. It means a happening, not only unexpected and unusual, but one referable to a definite and fixed time. Where disease was contracted from inhaling fumes gradually and over an extended period, the court could find nothing catastrophic or extraordinary in the happening, could not "fix time or place when a disease was contracted," and therefore held that a finding that disability was caused by accidental injury was not justified. *Rosenthal v. National Aniline & Chemical Co.,* 216 App. Div. 588, 215 N. Y. S. 621. In the present case illness was not occasioned by a definite or specific occurrence of a sudden and catastrophic nature and could not be regarded as the result of an accident.

Not only was the death in this case not the result of an accident, within the meaning of the policy, but it did not result from bodily injuries. The infant sustained no cut, abrasion, nor other traumatic injury, whereby poisonous substances or germs entered the system. Admittedly, a bodily injury may result from causes other than physical force, but in such cases it will usually be found that there has been an occurrence associated in the average mind with a known result, which follows as a natural and usually inevitable consequence. Such, for instance, are cases of typhoid fever caused by drinking water containing typhoid germs and cases of glanders caused by direct contact with infectious matter. These have been held to constitute bodily injuries accidentally suffered within the meaning of insurance policies. The circumstances of the death in the present case, however, were not similar. Insufficiency of the heating continued in varying degrees for nearly two months before death. The onset of the fatal illness could not be attributed to inadequate heating at any particular time. The extent to which other causes contributed to the death was conjectural. The lack of a cause relatively definite in point of time, catastrophic in character, and followed by a usual, if not inevitable, result distinguishes the present case from cases in which typhoid fever has followed drinking of contaminated water, tuberculosis has followed sudden inhalation of fumes, and glanders has followed direct contact with infectious substances.

Illness and death in this case were held, therefore, not to have resulted from a bodily injury accidentally sustained, and judgment was rendered in favor of the defendant insurance company.

License Revoked for Criminal Abortion

(Tapley v. State Board of Medical Examiners (Calif.), 295 P. 911)

Complaint was filed with the state board of medical examiners of California, charging that Tapley attempted to procure and did procure two criminal abortions, death resulting in each instance. In the course of the hearing, however, the complaint was amended so as to charge also that he "agreed and/or offered to" procure those abortions. The statute defines "the procuring or aiding or abetting or attempting or agreeing or offering to procure a criminal abortion" as unprofessional conduct. The board found Tapley guilty and revoked his license. He appealed to the superior court, city and county of San Francisco, which affirmed the order of the board, and thereupon he carried the case by a writ of certiorari to the district court of appeal, first district, division 2.

Tapley contended that the complaint was fatally defective because it did not state facts to show that he had procured or aided or abetted or attempted or agreed or offered to procure a criminal abortion, and that the words "criminal abortion" in the complaint as it then read represented nothing more than a legal conclusion based on undisclosed facts. All the facts necessary to the validity of a criminal complaint for criminal abortion, he contended, should be alleged in the complaint against him. The court of appeal pointed out, however, that both the district court of appeal and the Supreme Court of California had held contrary to Tapley's contention. To charge a physician in the language of the act with committing a criminal abortion is sufficient, without stating the facts enumerated in the penal code, because the language of the statute is sufficiently explicit to advise a person so charged of the particular kind of unprofessional conduct with which he is accused. Tapley contended further that the board had denied him "due process of law," by rejecting his defense that he had been acquitted by the superior court of Yuba County of one of the charges specified in the complaint. But the district court of appeal held that the state board of medical examiners was not bound by the acquittal of Tapley in the superior court and that evidence of that acquittal was properly rejected, quoting in support of its opinion 15 Calif. Jur. 114:

> Judgments in criminal proceedings are generally not competent or conclusive in civil proceedings, and vice versa, not only because ordinarily there is not the necessary identity of parties, but also because the same rules of evidence and degree of proof do not prevail in the two classes of proceedings.

Moreover, even if evidence of the judgment of acquittal had been admitted, it would have exculpated Tapley of only one of the offenses charged against him. In discussing Tapley's contention that the state board of medical examiners was without authority to allow the complaint against him to be amended by the insertion of new unsworn charges, without affording him an opportunity to plead to or put those charges in issue, the court pointed out that while such amendments were not commonly allowed in criminal actions, it was common practice to allow them in civil cases. Proceedings before the state board of medical examiners are more closely akin to civil than to criminal proceedings. The proceedings of the board, moreover, are not governed by the technical rules of pleading and practice and the analogies of criminal law may not be invoked. The provisions of the criminal code were not made applicable by the fact that the offense was described as "criminal abortion." Furthermore, the added charges of agreeing to perform criminal abortions were not so entirely foreign to the charges of actually performing them as to take Tapley by surprise or to jeopardize his right of defense.

The judgment of the court below affirming the order of the state board of medical examiners revoking Tapley's license was affirmed, and a rehearing was denied.

Trauma: Sarcoma of Bone Attributed to.—In February, 1926, the plaintiff, 17 years old and in good health, slipped and fell while descending a flight of stairs in the defendant's building, the accident being attributed to the condition of the steps and the lack of light in the stairway. Her left knee struck the concrete floor violently and stung and pained her. In the following few months the knee became swollen and continued to be painful. About a month after the accident she consulted a physician, but treatment failed to relieve the pain and swelling. The knee grew steadily worse. In September or October, 1926, an operation was performed and the plaintiff was shown "to have an infection of the bone called 'sarcoma' which had resulted from the injury." "Sarcoma," said the Supreme Court of Missouri, Division No. 2, before which the appeal was heard, "is a condition resulting from infection sometimes caused by traumatic injury." At the time of the trial, November, 1927, the plaintiff was not able to walk without the aid of a cane or somebody to lean on. The testimony of medical experts indicated that it was highly probable that an amputation would be necessary. There was substantial evidence, said the Supreme Court, tending to show that the tumor from which the plaintiff suffered was of a malignant type, likely to get into the blood stream, if it had not already done so, and carry "the infection" to other parts of the body, threatening not only the patient's health but her life. Under such circumstances the judgment for $25,000 awarded by the trial court was not unreasonable.—*Capstick v. T. M. Sayman Products Co. (Mo.), 34 S. W. (2d) 480.*

Hospitals: Liability of Superintendent of Insane Asylum for Crime Committed by Released Inmate.—Smith, an inmate of the Central Louisiana Hospital for the Insane, was released by its superintendent, the defendant in this case. On the day Smith was released, he killed the plaintiff's husband. A lunacy commission found that Smith was insane at the time of the homicide. The widow of Smith's victim, in suing the superintendent of the asylum, alleged that he deliberately and maliciously permitted Smith to have his liberty "when he knew that Smith was suffering from paranoia, which is recognized as an incurable disease, causing the sufferer to be extremely dangerous, with a persistent desire to take human life." The trial court gave judgment in favor of the defendant, which judgment the court of appeals of Louisiana, second circuit, affirmed. Through the board of administrators of the hospital, said the appellate court, the superintendent of the hospital was the representative of the state in conducting a state institution. In releasing inmates, he was vested with discretionary authority, in the exercise of which he released Smith. His good faith, therefore, cannot be questioned in a suit for damages resulting from an act of a discharged inmate, even though it be charged that in releasing that inmate he acted maliciously and without regard to the rights and safety of the public. Moreover, even though it were admitted that the superintendent was guilty of negligence, it could not be said that that negligence or the fact that Smith was released was the proximate cause of the death of the plaintiff's husband.—*Cappel v. Pierson (La.), 132 So. 391.*

Evidence: Scope of Expert's Opinion.—In a trial under an indictment charging murder by shooting, it was shown that the body of the victim was found on the railroad track, between the rails, while the head, which had been severed from the body, was lying about two feet from one of the rails. There was a gunshot wound in the left breast and another in one of the arms. The spinal column protruded from the body about 3 inches. The bone was not crushed, nor were the tissues bruised or mangled. The Court of Appeals of Kentucky held that it was not improper for a physician who had had considerable experience in cases of persons who had been run over by trains and who was testifying as an expert, to testify that he did not believe that "the railroad wheel cut this man's head off."—*Spencer v. Commonwealth (Ky.), 35 S. W. (2d) 319.*

Hospitals: Liability for Injury to a Special Nurse.—The plaintiff, a nurse, was caring for a patient in one of the rooms of the defendant hospital. She was not in the employ of the hospital but in the employ of the patient who occupied the room. According to her testimony, when she went on duty she told the head nurse on the floor that the floor of the room was slippery. On the following day she slipped, fell, and was injured. From a judgment in her favor, the hospital appealed to the Supreme Court of California. In her brief, the nurse claimed "a status enabling her to claim the same degree of protection as an employee in her place of employment" and that "the employer is bound to provide a reasonable safe place for his employee to work in." It clearly appears, however, said the court, that her status was that of an invitee and that she was in no sense an employee of the hospital. She had full knowledge of the condition of the floor during the afternoon of the first day of her employment in the hospital and for two hours in the forenoon of the next day. The hospital had no knowledge of the fact superior to that possessed by the nurse. If it was negligence for the hospital to maintain the floor in the slippery condition described by the nurse, there appears to be no escape from the conclusion that it was negligence for the nurse, with full knowledge of such condition, to continue in the use thereof. It was not necessary for the hospital to plead the contributory negligence of the nurse when that negligence was disclosed by her own testimony.—*Mautino v. Sutter Hospital Association (Calif.), 296 P. 76.*

Evidence: Qualifications of Physicians to Testify as to Firearms.—In a prosecution for murder, two physicians who examined the body of the deceased swore that from that examination they concluded that he had been shot through the head with a small bullet, either a 0.30 or 0.32 caliber. One of these physicians testified that the pistol submitted to him in the course of the trial was a 0.38 caliber pistol and in his judgment that was not the size of the bullet that made the wound in the head of the deceased. He testified further: "The shell you hand me now, is a 32, and looks like the bullet that made the wound." Concerning his qualifications to give such testimony, one physician said:

> To some extent I am familiar with the various sizes and calibers of pistols. In my practice I have had some experience in observing and treating gunshot wounds, but not a great deal of experience along that line. From my experience and observation of various caliber of guns and pistols, I think I can tell about what size caliber bullet that made the wound I saw there on Stegall's head.

The other physician testified:

> I have had quite a little experience in examining wounds of that character, and am familiar with the various sizes and calibers of guns and pistols. From the examination I made of the wound found on the deceased, in my judgment it was made with a 30 or 32 caliber bullet.

Objection was made to the testimony of these physicians on the ground that they were not shown to be sufficiently qualified to give their opinions. But, said the court of criminal appeals of Texas, we think the objections to the testimony of neither witness were tenable.—*Landry v. State (Texas), 35 S. W. (2d) 433.*

Evidence: Expert Opinion as to Causal Relation Between Disability and Accident.—If there is no dispute concerning the manner and cause of an injury or that an injury was sustained, a physician may directly testify that in his opinion a condition found later was caused by that injury. In this case there was no dispute that the plaintiff came in contact with a live wire and was severely injured. There was no error, said the Supreme Court of Illinois, in permitting a medical witness to state as his opinion that in all cases of severe electric shock a dilatation of the heart results, and to testify that he had found, both by clinical examination and by roentgenograms, that the plaintiff at the time of the trial was so affected.—*Wolczek v. Public Service Co. of Northern Illinois (Ill.), 174 N. E. 577.*

Insanity: Effect on Competence of Witness.—The fact that a person has been adjudged insane and confined in a state institution does not necessarily render him incompetent as a witness. Insane persons may have lucid intervals, and it is for the jury to determine whether the occurrence to which the witness testified occurred during a lucid interval and whether the witness is sane when he testifies.—*Conoway v. State (Ga.), 156 S. E. 664.*

Society Proceedings

COMING MEETINGS

Philippine Islands Medical Association, Manila, December 15-18. Dr. A. S. Fernando, 817 Taft Avenue, Manila, Secretary.

Society of American Bacteriologists, Baltimore, December 28-31. Dr. James M. Sherman, Cornell University, Ithaca, N. Y., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Alabama Medical Association Journal, Montgomery

1: 45-88 (Aug.) 1931

*Menstrual Disorders of Interest to General Practitioner. L. E. Burch, Nashville, Tenn.—p. 45.
*Differential Diagnosis of Certain Fevers. E. M. Mason, Birmingham. —p. 50.
A Neglected Boil. G. E. Blue, Montgomery.—p. 53.
What the Young Doctor Should Know. W. M. Cunningham, Corona. —p. 57.

1: 89-136 (Sept.) 1931

Ear, Nose and Throat in Relation to General Diseases. J. B. Greene, Asheville, N. C.—p. 89.
Mechanism of Production and Treatment of Shock. A. Blalock, Nashville, Tenn.—p. 94.
Heart in Toxic Goiter. H. P. Shugerman, Birmingham.—p. 99.
Diagnosis and Treatment of Common Dermatoses. R. P. Lester, Mobile. —p. 104.

Menstrual Disorders.—Burch emphasizes the following facts: 1. Abnormal uterine bleeding is due to three conditions; namely, hyperplasia, ulcerative lesions (cancer is the most common example of these) and the accidents of either uterine or extra-uterine pregnancy. 2. All cases of abnormal uterine bleeding call for a complete physical examination of the patient, which must include a careful pelvic examination (both digital and with the speculum). 3. A confirmation of the diagnosis can be obtained from the laboratory in each of the three etiologic factors.

Differential Diagnosis of Certain Fevers.—Mason calls attention to the fact that typhus fever, tularemia and undulant fever must be classed with malaria, typhoid and tuberculosis as among the commoner causes of continued fever. All these maladies have certain symptoms and signs in common. Therapeutic efforts in these diseases should be symptomatic only until exact diagnosis is determined. History and physical examination retain their importance in differential diagnosis, but final diagnostic conclusions are dependent on certain laboratory tests that are available to every physician, wherever located. Discriminating use of these tests must be made at an early stage in fevers, in order that appropriate therapy may be instituted without delay.

American Journal of Diseases of Children, Chicago

42: 735-966 (Oct.) 1931. Part I

*Prognosis of Acute Endocarditis in Childhood: Analysis of One Hundred Cases. J. L. Morse, Boston.—p. 735.
*Significance of Retention Ratio of Calcium: Phosphorus in Infants and in Children. Genevieve Stearns, Iowa City.—p. 749.
*Basal Metabolism in Diabetic Children. Anne Topper, New York.—p. 760.
Anorexia, Loss of Weight and Capricious Appetite. Maud Loeber and H. L. Weinberger, New Orleans.—p. 767.
Growth in Height and Weight, and Retention of Nitrogen, Calcium and Phosphorus During Recovery from Severe Malnutrition. Genevieve Stearns and Dorothy L. R. Moore, Iowa City.—p. 774.
*Treatment of Toxicosis with Aid of Continuous Intravenous Drip of Dextrose Solution. S. Karelitz, New York.—p. 781.
Epidemic of Measles: Attempted Prophylaxis with Whole Blood. S. A. Blauner and H. Goldstein, New York.—p. 803.
Electrocardiographic Studies in Infectious Diseases: III. Diphtheria. C. Shookhoff and L. M. Taran, Brooklyn.—p. 811.
*Oxycephaly as Pathogenic Entity. A. N. Bronfenbrenner, Thiells, N. Y. —p. 837.
Xanthomatosis. H. B. Mettel, Indianapolis.—p. 858.
Lupus Erythematosus Disseminatus Acutus in Juvenile. C. C. Stewart and W. H. Goeckerman, Rochester, Minn.—p. 864.
Miliary Tuberculosis with Purpura in Infancy. M. S. Gaede and J. O. Vaughn, Los Angeles.—p. 869.
American Academy of Pediatrics. I. A. Abt, Chicago.—p. 874.
William Moss, ?-1802. J. Ruhrāh, Baltimore.—p. 886.

Acute Endocarditis.—Morse reports that of 100 children seen during the first attack of acute endocarditis, from ten to thirty years before his article was written, 36 are dead, 3 are cardiac invalids and 61 are alive and well. Thirty-seven of those who are alive and well have normal hearts, eighteen have slightly damaged hearts, and the hearts of six were not examined. The age at the time of the onset of the disease and the intervals elapsing between the onset and the time when the patients were first seen had no apparent influence on the prognosis. In the cases in which rheumatism seemed to be the cause, the results were not so good as in those in which the apparent cause was an infection of the upper respiratory tract. Myocarditis and pericarditis were unfavorable signs. In a large proportion of the fatal cases, death occurred early. Recurrences of the rheumatic infections were not as common as is usually believed, and repeated attacks did not always prevent recovery. Only one of the patients who are alive and well has a diastolic mitral murmur. The results apparently depended more on the care that the children received than on any other single factor.

Retention Ratio of Calcium: Phosphorus.—Stearns considers that a retention ratio of calcium: phosphorus of between 1.5:1 and 2:1 is normal for an infant. A retention ratio lower than 1.5:1 indicates a more rapid growth of soft tissue than of bone. A ratio of 2.1:1 or over is considered as probably indicative that a calcium shortage in the body is being corrected. From the reported retentions of calcium and phosphorus in artificially fed infants, a retention of at least 40 mg. of calcium and from 20 to 25 mg. of phosphorus per kilogram of body weight daily is considered desirable for artificially fed infants. The ratio of retained calcium to phosphorus will be somewhat lower in older children than in infants because of the great increase in the relative amount of muscular tissue during childhood. In a normal child, it is considered that the retention ratio will probably be lower than that observed in infants, but it should be greater than 1:1. In older children, the absolute retention of calcium and phosphorus per kilogram of body weight may be expected to decrease with the age of the child. A daily retention of at least 10 mg. of phosphorus per kilogram of weight is desirable even in older children. The retention of calcium should be at least equal to the retention of phosphorus. Retentions of calcium and phosphorus of less than 10 mg. per kilogram of body weight are probably not optimal in very young children.

Basal Metabolism in Diabetes.—Topper made 100 determinations of basal metabolism on 27 diabetic children at intervals of six months over a period of from one to four years. The average rate of basal metabolism obtained in twenty-eight tests made on patients between the ages of 5 to 10 years was plus 3 per cent; in twenty-one tests made on patients between the ages of 10 and 12, plus 4 per cent; in thirty-one tests made on patients between the ages of 12 and 15, plus 5 per cent; in eighteen tests made on patients between 15 and 17 years, plus 21 per cent, and in two tests made on patients over 17 years of age, plus 7 per cent. On the basis of her observations the author concludes that the rate of basal metabolism in treated diabetic children is essentially normal. There is an increase in the basal metabolic rate between the ages of 15 to 17 years, which is probably a manifestation of puberty. This increase occurs normally between the ages of 11 to 14 years, but as puberty seems to be somewhat delayed in diabetic children, as evidenced by the late appearance of the catamenia, the prepuberty rise in basal metabolism also occurs later than in normal children. With proper care, the condition of nutrition in diabetic children is normal. Sexual maturity, however, seems to be somewhat delayed. The internal secretory glands are so closely interrelated that a defect in one probably somewhat checks the action of the others.

Dextrose Solution in Toxicosis.—Karelitz emphasizes the fact that certain facts previously known and borne out by experience must constantly be kept in mind if good results are to be obtained in the treatment of toxicosis. He recapitulates these factors thus: 1. Treatment must be radical and prompt as soon as the diagnosis of toxicosis is made. If too much time is lost, treatment may be of no avail. (Supportive therapy, such as the administration of epinephrine and caffeine, should be given as may be indicated.) 2. All cases of toxicosis should be considered severe. The intravenous administration of dextrose and transfusion should be employed promptly, and the minimum period during which milk is withheld should be from twenty-four to thirty-six hours, or until the detoxification is complete. 3. Once the feeding of milk is started it should be given in small quantities of from 5 to 10 cc., and increased slowly, the limited tolerance for food during this period of adjustment always being respected. 4. When there is a relapse, treatment should be started again from the beginning with the intravenous administration of dextrose, transfusion of blood and withholding of milk. 5. Patients with intercurrent infections, especially otitis media and abdominal distention, should be treated actively. 6. Special nursing care is of the greatest importance. The intelligent nurse often sees the child in a truer light than the physician who calls only two or three times daily. Her observations are most important in deciding when to start to give the patient milk, when to increase the amount and when to discontinue the use of it. The author believes that the routine he outlines, especially the continuous intravenous administration of dextrose solution by the drip method, can be applied to almost all intoxications of early childhood, especially those associated with gastro-intestinal disturbances. This method can be employed for such conditions as severe acidosis originating in diabetic or in cyclic vomiting. In the former, a steady supply of dextrose with or without insulin may be administered; in the latter, dextrose could be given as needed. Some cases of peritonitis, bacteremia, dysentery, icterus, tetanus, bulbar poliomyelitis, postdiphtheritic paralysis of the palate and shock—surgical, traumatic or due to burns—also suggest themselves for this treatment.

Oxycephaly.—In the study of a series of clinical cases of oxycephaly as well as the data reported in the literature, Bronfenbrenner noted certain characteristics of a compensatory adjustment mechanism: When a premature closure of the coronary skull suture occurs, it impairs the normal adaptability of the skull to the growing brain of a child, and an effort to meet the demands of the growing brain brings about the oxycephalic deformity. Factors of the premature synosteosis and the subsequent compensatory struggle may naturally damage the brain and its adjacent parts. Most frequently the optic nerve undergoes severe atrophic changes. The degree of the damage sustained by the entire brain bears a direct relation to the efficiency of the compensatory process: the less effective has been the compensatory mechanism and, thus, the less outspoken are the morphologic features of oxycephaly, the greater the brain damage to be expected. Hence, a marked mental defect is found in rather mild, atypical instances of oxycephaly (and allied deformities of the skull), while in cases with outspoken oxycephalic features a mental defect might not enter into the clinical picture at all. Various intracranial infectious processes appear to be the main etiologic factors in the premature skull synosteosis of oxycephaly and allied deformities of the skull. The cases reported by the author emphasize the importance of tuberculosis and especially syphilis as probable etiologic factors of oxycephalic deformity.

Am. J. Roent. & Rad. Therapy, Springfield, Ill.

26: 511-638 (Oct.) 1931

Contribution of Roentgenology to Medicine and Surgery in Last Twenty-Five Years. J. T. Case, Chicago.—p. 511.
Progress in Development of Roentgen-Ray Apparatus. H. M. Imboden, New York.—p. 517.
Relation of American Journal of Roentgenology and Radium Therapy to Development of Radiology. A. C. Christie, Washington, D. C.—p. 523.
Contributions of a Quarter Century of Electron Physics to Roentgen-Ray Science. G. L. Clark, Urbana, Ill.—p. 528.
Historical Evolution of Roentgen-Ray Plates and Films. F. C. Martin and A. W. Fuchs, Rochester, N. Y.—p. 540.
Early American Roentgeniana. E. H. Skinner, Kansas City, Mo.—p. 549.
*Review of Pneumonoconiosis: Further Roentgenologic and Pathologic Studies. H. K. Pancoast and E. P. Pendergrass, Philadelphia.—p. 556.

Review of Pneumonoconiosis.—Pancoast and Pendergrass review the subject of pneumonoconiosis from the standpoint of its etiology, its pathology and its roentgenographic appearances. Pneumonoconiosis is a more or less necessary risk of commercial development in the progress of civilization, but its progress and serious aspects may be lessened by certain preventive measures in most instances. Its incidence in many industries apparently cannot be altogether eliminated. It has aroused widespread interest and has received a great amount of study during the past few years. The roentgenologic examination is the most important and accurate means of detecting its presence, especially in early cases, of studying its progress and of determining its extent and severity. Rapidity of progression is easily determined by serial study. The authors believe that roentgenology will be employed more and more extensively as the necessity of study of workers in hazardous industries becomes realized and regulations for protection and compensation laws are adopted in this country. The roentgenologist must be experienced in his work and honest in the expression of his opinions. It behooves the roentgenologist to become thoroughly familiar with the subject from every angle. The particular hazards of certain industries must be understood and the roentgenographic appearances more or less characteristic of some of them must be learned. Roentgenographic appearances are the expressions of pathologic changes, and to interpret them properly requires an intimate knowledge of the pathology of the condition. A summary is given of the present exact knowledge of the pathology of pneumonoconiosis based on necropsy study and animal experimentation. Various theories advanced in explanation of some uncertain points are given brief consideration. Various classifications of the degrees of progress of the condition are in use in different countries. Most of these have a clinical basis with which roentgenographic appearances must be made to conform. No one of them seems adequate or entirely satisfactory in its application to every dusty industry, especially from the standpoint of the roentgenologist. The authors propose a new pathologic-roentgenologic classification.

Archives of Ophthalmology, Chicago

6: 489-646 (Oct.) 1931

Holth's Iridencleisis Antiglaucomatosa: Follow-Up Examination of One Hundred and Twenty-Two Eyes from Six to One Hundred and Fifty-Nine Months After Operation. H. G. A. Gjessing, Drammen, Norway.—p. 489.

*Conjunctivitis and Blepharitis Due to Yellow Mercuric Oxide. Beatrice M. Kesten, New York.—p. 582.
Tumors in Pituitary Area: Neurologic Symptoms. T. H. Weisenburg, Philadelphia.—p. 589.

Retinal Changes in Heart Disease.—Horine and Weiss believe that retinal changes must be correlated with the modern knowledge of heart disease. The failure of the authors of ophthalmologic textbooks to realize that arteriosclerotic heart disease and essential hypertension are distinctly different entities has caused much confusion. The blood pressure is elevated in essential hypertension but not in arteriosclerotic heart disease. Retinal changes in essential hypertension are quite different from those of simple arteriosclerosis. The terms albuminuric and nephritic retinitis are etiologically inaccurate and should be discarded. When referring to a patient with essential hypertension, one should use the term arteriolar sclerotic retinitis in place of arteriosclerotic retinitis. Retinal arteriolar sclerosis is usually progressive and, once developed, is permanent. The persistence of retinal arteriolar sclerosis permits of a diagnosis of essential hypertension even if the blood pressure is normal. Prognostically, changes in the fundus are of definite value.

Conjunctivitis and Blepharitis Due to Yellow Mercuric Oxide.—Kesten reports a case of conjunctival and skin sensitivity to yellow mercuric oxide. This sensitivity was confirmed by a disappearance of the inflammation when mercury ointment was discontinued, by a reappearance of the eruption following its application, and by positive patch tests.

Archives of Otolaryngology, Chicago

14: 413-550 (Oct.) 1931

*Production of Voice and Speech Following Total Laryngectomy. W. W. Morrison, New York.—p. 413.
*Rôle of Chronic and of Subacute Infections in Diabetic Children. D. M. Lierle and J. J. Potter, Iowa City.—p. 432.

Myringitis Bullosa: Two Cases. E. F. Ziegelman, San Francisco.—p. 472.

Production of Voice and Speech Following Total Laryngectomy.—Morrison calls attention to the fact that with the increasing number of persons rendered voiceless by total laryngectomy for laryngeal cancer there is a growing need for a therapy of pseudovoice production without the larynx. Patients with a complete, chronic, air-tight stenosis of the larynx from any cause are similarly in need of a pseudovoice. Laryngeal prostheses, or artificial larynges, have so many disadvantages that their use should be restricted to the patient who cannot learn to produce any type of pseudovoice. There are several types of mechanism of the production of a pseudovoice. One is the true buccal or pseudowhispered voice. Almost every laryngectomized patient learns it without difficulty; it is so faulty and imperfect that it should be employed only when a more satisfactory type cannot be produced. The pharyngeal pseudovoice is usually fairly satisfactory. It is produced with the aid of a pseudoglottis formed at the back of the mouth or in the hypopharynx, where air that has been aspirated or swallowed into a vicarious air chamber in the lowest hypopharynx or the esophagus and expelled again is set into audible vibrations; such sounds are modified into the vowels and consonants of the pseudovoice. One of the most perfect forms of the pseudovoice is the esophageal type, in which the vicarious glottis lies at the esophageal mouth of Killian, and the vicarious air chamber is formed within the lumen of the esophagus, particularly in its cervical and upper thoracic portions. Here the mechanism of pseudovoice production is strikingly like that of normal speech. In some cases the cardiac end of the stomach, with the stomach air bubble, may be the vicarious air chamber, which furnishes a stream of air for a pseudoglottis at one of the sites mentioned. A fairly definite system of therapy directed toward teaching the patient to produce one or another of the types of pseudovoice has been elaborated. It seems essential that all surgeons who perform total laryngectomy or who have patients with complete, chronic laryngeal stenosis should be aware of the facts given and should attempt to aid these voiceless persons in securing a useful pseudovoice; such patients will not be cut off in their social intercourse, nor will they be unable to earn a living because of their lack of intelligible speech. Having in view the fact that almost all laryngectomized patients can learn a pseudovoice, the laryngeal surgeon should, if it is possible, so conduct the operation as to favor the production of the pseudovoice, at least, on anatomic and physiologic grounds.

Chronic and Subacute Infections in Diabetic Children.—According to Lierle and Potter, chronic and subacute infections of the upper respiratory tract are common among diabetic children. Operative procedure on the diabetic patient is no more hazardous than on the nondiabetic patient, if proper preoperative treatment is observed. In the cases studied by the authors, frequent improvement in the general health as well as in the tolerance for carbohydrates was seen following treatment for chronic infection. Chronic and subacute infections are much more frequently diagnosed in children when a thorough and complete otolaryngologic study is made. A child with diabetes should receive the same careful study for foci that would be given an arthritic or nephritic patient.

Plastic Surgery of the Nose.—Peer divides nasal deformities into two main classes: those in which all the normal nasal elements are present and those in which there is a loss of some of the elements. A high deviation in the cartilaginous septum will prevent straightening of the bony bridge. In lateral displacements of the lower part of the nose, the cartilage causing this displacement must be removed. A submucous resection and rhinoplasty are never combined at the same operation. When a submucous resection is performed first, an autoimmunity probably develops. This apparently protects the patient against infection during the second operation. Depressions are filled with lower lateral cartilage, ear cartilage or rib cartilage, depending on their depth. A tube flap from the arm is best suited for the repair of partial loss of the external nose.

Art of Medicine Versus Drugs. N. L. Beebe, Fort Collins.—p. 453.

Nephritis.—Yegge calls attention to the fact that no satisfactory classification of nephritis acceptable to both clinician and pathologist has yet been perfected. Despite the recent advances in tests for renal impairment, the most practical renal function test for the average clinician is the water concentration and dilution test of Volhard. One must have knowledge of the character of edema formation and salt retention before he proceeds with the treatment of the various forms of nephritis. The reason for the formation of the different abnormal urinary constituents must be understood before one can intelligently treat nephritis. The method to adopt in the treatment of the different forms of nephritis depends to a large extent on the concentrating power of the kidneys, the percentage of nonprotein nitrogen in the blood, the amount of fluid retention, and the general condition of the patient.

*Important Reflex Relationships Between Lungs and Other Viscera. F. M. Pottenger, Monrovia, Calif.—p. 75.

Collateral Respiration.—Van Allen and Jung describe experiments on dogs in which they found that collateral respiration was surprisingly efficient. A very small section of lung lobe proved to be sufficient for aeration of the whole. Continuation of aeration of the ligated division when the bronchi of the free section were flooded with viscid fluid (blood) can be explained only by supposing that the fluid was soon absorbed or disseminated to a large degree. Nevertheless, judging from the diffuse red color and distinct swelling of the injected lobule, it was evident that much of the fluid still remained in the peripheral airways. The normal capacity of even this small section of the lobe seems, therefore, to have been superabundant for maintaining the inflation. Also, a wide margin of safety was present as regards the amplitude of respiratory movements, since very shallow breathing afforded significant collateral exchange. The most effective obstacle to the function was inflammatory consolidation of the tissues at the border between the obstructed and free sections of the lobe, although here, too, there was remarkable tolerance. The tissues had to be almost completely consolidated before this factor alone eliminated interlobular exchange altogether. On the basis of their observation the authors conclude that interference with collateral respiration constitutes a necessary link in the sequence of events in the development of most instances of postoperative atelectasis. It is probable that every patient who develops severe bronchorrhea acquires bronchiolar obstruction of some degree and of significant duration, but atelectasis forms only when the collateral respiration is interfered with, as may well happen under the special circumstances attending convalescence from abdominal operations.

Mortality of Operation for Acute Empyema.—Muller reports a series of ninety-nine cases of acute empyema following pneumonia with six deaths (6.1 per cent). The death rate in children under 2 years was 15.4 per cent; in adults over 50 it was 40 per cent. In children under 14 years it was 3.9 per cent. The mortality was largely affected by the age, state of the lung, infecting organism, and infective complications. The author believes that, except for aspiration, thoracotomy should be delayed until the metapneumonic stage. Drainage in many cases can be effected by interrib tube drainage. In others, rib resection may be necessary. Rib resection is not open drainage if properly managed. Closed drainage is the proper method in nearly all cases and will effect a cure in nearly every case.

Diaphragmatic Hernia.—According to Harrington, diaphragmatic hernia is relatively common. The symptoms of diaphragmatic hernia are usually definite and depend on the amount of mechanical interference with function of the organs involved. Diagnosis from clinical symptoms only is often difficult, because the syndrome often stimulates that of other organic diseases, the most common of which are cholecystitis, gastric ulcer and heart disease. Roentgenologic examination of the stomach is important in establishing a definite diagnosis. Operative replacement of the herniated viscera into the abdomen, and repair of the abnormal opening in the diaphragm, is the only treatment which insures complete relief of symptoms. Palliative phrenicotomy may be used in selected cases in which operation is contraindicated. Preliminary phrenicotomy is often of value in the repair of enlarged hernial openings if there has been considerable loss of structure. Of the forty-five surgical cases reported by the author, radical operation was performed in thirty-eight. There were five operative deaths and no recurrences.

Hernia or Eventration of Diaphragm.—Eggers calls attention to the fact that there are three main varieties of maldevelopment of the diaphragm: 1. A false congenital hernia is one without a sac. It is really a defect in the diaphragm due to failure of its various components to fuse properly. Abdominal contents may slip through this defect and lodge in the thorax without any covering. 2. A true congenital hernia, on the other hand, develops through a weak spot in an already formed diaphragm. As the abdominal contents slip into the chest, the peritoneum and pleural layers covering the weak spot are pushed ahead and form the sac of the hernia. This condition is much less common than false hernia. 3. Eventration of the diaphragm is comparatively rare. It may be congenital or acquired. There is no defect or hole in the diaphragm; it is simply relaxed and atrophic and bulges into the thorax often to the level of the third or fourth ribs. The congenital form is said to be due to failure of development of the muscle elements or of the phrenic nerve. Not much is really known about the underlying cause. The acquired type is occasionally seen as a complication of an acute infectious disease probably by the toxin acting on the nerve. It may also follow trauma to the neck in which the phrenic nerve is injured, as for instance during difficult labor. In either event one finds or expects to find a dome shaped bulge extending from the diaphragmatic attachments into the thorax. One would expect a uniform bulge, and one might reasonably think that the circumference at the base, meaning at the diaphragmatic attachments, would be larger than at the apex of the dome. In that case no constriction of the contents would occur. A case observed by the author did not quite correspond to such a picture. It was no doubt an eventration, but it seemed at the same time to be a hernia. The explanation seems to lie in the finding that apparently not all the elements of the diaphragm were involved in the process. It was the central tendon which had become stretched to form the large intrathoracic sac while the muscular elements were sufficiently developed to form a thick margin of what looked like a hernial ring. It appeared to be a localized eventration, or even a sacculated or diverticular eventration, due to partial paralysis or weakness of the diaphragm.

Respiratory Movements.—Brock and Blair describe an adaptation of the heart-lung preparation of Starling as modified by Daly, by means of which the exudate from each lung may be separately collected for a period of hours. In this way it was possible to show that in a living preparation the formation of a pleural effusion is dependent on the respiratory movements, an observation that corroborates the conclusions previously drawn by Graham from experiments which utilized dead lungs in an artificial thorax. Under direct visualization, fluid can be seen to drip from an edematous lung in expiration, and it is suggested that the rise in negative pressure during the act of inspiration fills the subpleural lymphatics, and when expiration follows, these filled lymphatics empty part of their contents into the pleural space. An edematous condition was produced (1) by pouring acidified fluid directly into the bronchi, (2) by means of passive congestion, and (3) by an active inflammatory process; namely, exposure to a dilute chlorine mixture. On the living intact animal, after an edematous lung has been produced either by methods 1 or 2, fluid can be collected by means of a cannula inserted into the pleural space. In this way it was possible to show that the rate of formation of the fluid is dependent on the force of the respiratory movements and the associated pressure changes. A quiet, easy respiration produces a small effusion; a deep, labored breathing causes a much more rapid accumulation. In addition to fluid of an inflammatory nature passing from the lung to the pleural space, it has been shown that an ordinary Ringer's solution, if introduced into the bronchi and alveoli, will, by the respiratory movements, be made to pass into the pleural cavity. Part of a broth culture of a streptococcus was added to Ringer's solution and introduced into the lung in the same way. The organisms were found to pass through the pleura with the fluid almost immediately and without the aid of cellular activity. It is suggested that this may be an important mode of infection in the body and may indeed be the point of entry of some of the septicemias of obscure origin. Just as the rate of formation of fluid is influenced by the character of the respiratory movements, so also is the rate of absorption of fluid affected. With quiet, easy respiration the absorption is slow; with deep, labored breathing it is much more rapid. A large accumulation of fluid with a consequent large surface area of contact is in any case absorbed at a slightly more rapid rate than a smaller collection; this increase is, however, in no way comparable with the marked effect of increase of the force of the respiratory movements.

Reflex Relationships Between Lungs and Other Viscera.—Pottenger states that vagal afferent fibers are distributed to all the abdominal organs except the colon and sigmoid, and there is some question about the proximal colon. Vagal centers in the medulla, however, may be reflexly influenced by afferent stimuli carried over the sacral nerve, which together with the afferent vagal fibers would bring the centers into reflex relationship with all important thoracic, abdominal and pelvic viscera. Afferent vagal impulses from any viscus may express reflex activity through the pulmonary efferent vagal fibers, and by so doing, if the conditions are favorable, produce bronchial constriction and bronchial shortening, and an altered secretion of the glands of the bronchial mucous membrane, usually an increase in amount. Furthermore, afferent vagal impulses acting on the respiratory center may produce inhibition of inspiration (which carries with it an inhibitory effect on inspiration). These are the conditions noted in pulmonary collapse. It is also known that while stimulation of an afferent vagal fiber may act on the respiratory center and produce either inspiration or expiration, it usually produces the latter. Thus the mechanism through which the stimuli necessary to produce reflex effects in the lungs act is present and could be called into play by operations which affect either the vagus, pelvic or any other mediating nerve. In operation on the important viscera below the diaphragm, ample opportunity for excessive irritation of both sympathetic and vagus afferent systems exists. In explanation of the vagal preponderance of action in the lung it must be remembered that the afferent sympathetic neurons from the abdominal organs which unite with efferent sympathetic neurons and antagonize vagal activity mediate in the lower six thoracic segments and not in the upper six from which the pulmonary sympathetics arise. Sympathetic reflexes from the abdominal viscera would express themselves by inhibiting muscular action in the gastro-intestinal tract, as in the ileus which now and then occurs. So while the pulmonary vagal fibers are stimulated the antagonistic sympathetics are not, and so a condition favorable to overvagal activity is brought about, which might be sufficient to produce the syndrome of collapse in certain individuals, particularly those of the vagotonic type.

Urinary Diseases in Pregnancy.—Crabtree and Prather emphasize as of extreme importance postdelivery care of urinary tract disease. From the hospital clinic all patients with urinary tract disease return to the outpatient clinic, where they are treated and followed until cured whether or not symptoms are present. Symptoms, especially those of cystitis, are extremely deceptive in pregnancy. Often urinary tract infection will exist for six months to a year after delivery before cystitis symptoms develop. The reason for this is not clear. On return to the outpatient clinic, the patients with surgical diseases are referred elsewhere for treatment. All cystoscopic treatment is given in the clinic. The ureters are seldom dilated except for definite *stricture. Pelvic lavage is not often used in the first three* months post partum. Infection cases are kept on formaldehyde drugs and increased fluids, and the social service department helps to arrange family duties so that the patient can get sufficient rest to enable her to return to health and strength as soon as possible. Most previously normal patients are bacterially well by the end of the fourth month. If pyuria or bacilluria persists beyond that time, complete cystoscopic study is made. It is in this group that many interesting anomalies are found together with cases suitable for plastic surgery and other corrective measures. A certain group of cases is found in which the patients show only atony from extreme degrees of overdistention. These recover in longer periods of time. Other pregnancies before complete recovery of the infection has taken place are undesirable.

Ureteral Meatotomy.—From a clinical and roentgenographic study of about seventy-five cases in which ureteral meatotomy was performed covering a period of seven years, Moore draws the following conclusions: 1. The operation, though comparatively minor, is technical and deserves just consideration. 2. When properly applied, the high frequency meatome is effectual and safe. It is possible to continue work higher up the ureter at the same sitting. There should be no alarming complications. There was no stricture formation following the operation in any of the cases observed. The author has found a number of cases in which the ureteral opening was amply large to admit number 7 to 9 catheters, after the passage of which there was temporary relief. The same patients have shown more permanent, if not definitely permanent, relief following a good wide incision of the opening. In a clinical and roentgenographic study of a series of cases it was impossible to find any symptoms or signs of regurgitation at any time following the operation.

Empyema of Ureteral Stump.—Dourmashkin reports four cases of empyema of the ureteral stump, which is a collection of thick pus within a dilated ureteral stump following incomplete ureterectomy. It differs from pyo-ureter in that the latter denotes pus mixed with urine coming from a kidney above. Of course, it is possible in cases of suppuration of the ureteral stump for the pus to be mixed with the regurgitated bladder urine secreted by the remaining kidney. Such was the case in at least one of the patients, in whom the aspirated purulent contents of the empyemal sac contained urea. That persistence of pyuria may follow nontuberculous nephrectomies in which a diseased ureter was not carefully followed down to the bladder leading to the empyema of the stump is a condition which has not been sufficiently emphasized in the literature. The comparative infrequency of ureteral stump suppuration following nephrectomies on human beings would indicate that while normal ureters do retain their patency they do not, however, exhibit a tendency toward infection. The local pathologic changes consist in a marked periureteritis, dilatation of the ureter and firm adhesions of the stump to the surrounding tissues. Absence of local symptomatology was the feature in all the cases in the author's series. None of the patients had symptoms of bladder irritability. Cystoscopy uniformly showed the escape of thick tapelike masses of pus from the orifice (or orifices) on the affected side. The latter was definitely stenosed in two cases. In one patient a ureterocele was present with two ureteral orifices, each leading to an empyematous sac. The escape of pus from the ureteral orifice on the nephrectomized side, as visualized by the cystoscope, does not necessarily indicate the presence of a dilated ureter filled with pus. To complete the diagnosis it is essential to outline the ureteral stump with an opaque solution injected into the stump. Cases that are free of vesical or other local symptoms and do not show a tendency to extension of the infection into the remaining kidney should be left alone. The possibility of involvement of the remaining kidney should always be borne in mind. It is for this reason that the infected stump should be excised in recent cases which have not yielded to cystoscopic treatment and in cases of persistent cystitis. The extirpation of the sac is generally a difficult procedure because the sac is firmly embedded in the pelvis and is adherent to the pelvic vessels.

Large-Holed Head Mirror. E. Amberg, Detroit.—p. 784.

Heart Disease in Rheumatic Fever.—Wilson emphasizes the fact that, although acute rheumatic fever is one of the chief causative agents of cardiac disease, the latter may not be apparent at the time of recession of joint symptoms, so that all patients need careful observation for at least three months following such an attack and six months periodic physical examinations thereafter. Patients should not be discharged from the hospital unless the white blood count is normal. All patients should be tonsillectomized at a reasonable period following the acute attack of rheumatic fever, if there is the least sign of tonsillar infection. Immediate apparent effects of rheumatic fever are less important than late results, which often cause marked valvular deformity, more common in the mitral, quite common in the aortic, and occasionally in the other valves.

Cardiac Pain.—According to Freund and Cooksey, the cardinal points on which a true differential diagnosis of cardiac pain may be made are as follows: A careful history of the nature, duration, inciting factor and location of the pain, with its possible radiation, is of major importance. It is often possible, without touching the patient, to make a diagnosis of cardiac pain on the basis of a careful history alone. One is frequently surprised by the gross neglect of this essential detail. In the physical examination, all the signs of arteriosclerosis should be carefully sought, for, although coronary thrombosis and angina pectoris often do occur without demonstrable signs of a generalized arteriosclerosis, they are most commonly found in arteriosclerotic individuals. The blood pressure, with especial reference to the diastolic reading, is a highly important detail. Well over fifty of the patients with coronary thrombosis had a previous hypertension, and the association of angina pectoris with simple coronary sclerosis and a previous or present hypertension is well known. In coronary thrombosis, possibly the one most important sign is a blood pressure below 100 systolic or a sudden fall of blood pressure below a previous known level. The authors have been able to make a diagnosis of true cardiac pain on this basis alone, in two atypical cases of coronary thrombosis. While the results of physical examination of the heart and lungs sometimes closely approach the normal, a cardiac dilatation, a muffled first heart sound, and râles at the base of the lungs are of extreme importance in accurate diagnosis. The electrocardiograph has perhaps done more to clarify the field of cardiac pain than almost any other factor. While in the present state of knowledge one must admit that coronary sclerosis may be present in severe degree without alteration in the electrocardiogram being present, nevertheless in many cases of simple coronary sclerosis electrocardiographic evidence is obtainable. During the last two years the authors followed closely nineteen cases of coronary thrombosis. Because of the availability of the modern portable electrocardiograph, they have been able to make careful and repeated electrocardiographic studies in these nineteen cases. There has not been a single case in which, sooner or later, definite evidence of coronary thrombosis with cardiac infarction was not found, electrocardiographically. In some cases the evidence was obtained as early as one hour after the complete occlusion; in one case such evidence did not appear until the end of forty-four hours after the occlusion. In other cases, several days had elapsed before the initial tracing was made. All these nineteen cases have been verified by subsequent history or by necropsy.

Cardiology.—Luten believes that simple tachycardia in many instances represents an adjustment of the circulation to pathologic processes and should not receive special therapeutic consideration. Therapy in such cases obviously should be directed not toward slowing the heart but toward mitigating the cause of the tachycardia. Mere slowing may indeed on occasion be harmful. The initiation of direct measures to lessen the heart rate in hemorrhage, in pneumonia, in fright or in exophthalmic goiter would appear as illogical as the taking of similar means to slow the respiratory rate in the same circumstances; as illogical as trying to slow it after exercise. The assumption is widespread that tachycardia itself is attended by serious danger if long continued; that the heart cannot long withstand rapid beating. This conception has received an emphasis which appears to be unwarranted. The heart is physiologically adapted to rapid action. Increase in rate alone does impose added burden, but a normal heart bears the burden well. Furthermore, compensatory adjustments usually supervene. Even a diseased heart usually appears to suffer little impairment of function from tachycardia of considerable extent, provided the muscle is activated in normal fashion; i. e., provided the tachycardia originates at the normal pacemaker. In a diseased heart obviously the danger of fatigue from tachycardia may be enhanced, but even in such cases compensatory adjustments in stroke output and in vascular tension usually relieve the heart of this added danger. In many instances, indeed, the accelerated action itself appears to be a compensatory adjustment, tachycardia representing the effect of circulatory impairment, not its cause. The chief indication of therapy in such cases should be the protection of the heart from further danger, not an unphysiologic adaption to injury already received. Not only is it inadvisable, in many instances, to slow the rate in simple tachycardia, but in adults it is rarely possible by therapeutic means to do so. In therapeutic dosage digitalis rarely, if ever, in adults causes slowing of consequence by direct action on the cardio-inhibitory apparatus. The physician who pushes digitalis in such an attempt, even if slowing is desirable, subjects his patient to the serious danger of digitalis intoxication. Abnormal rhythms in the vast majority of instances do not require special therapeutic measures. Some of them frequently are valuable hints in diagnosis and useful guides in therapy. They call for general examination and treatment, not merely for examination of the heart and cardiac drugs. The abnormal rhythm itself is rarely dangerous; it is frequently annoying. Special treatment, therefore, when indicated, is rarely an emergency measure. In most instances a complete history is more important than a complete cardiac examination.

*Myelotomy in Treatment of Syringomyelia. T. J. Putman and D. Munro, Boston.—p. 747.
*Sarcoma of Bladder in Children: Case. E. R. Mintz, Boston.—p. 756.
*Results of Use of Stramonium Datura in Parkinson's Disease and Postencephalitic Parkinsonism. O. J. Menard and L. M. Hurxthal, Boston.—p. 759.
Progress in Laryngology. L. A. Schall, Boston.—p. 763.

Myelotomy in Syringomyelia.—Putnam and Munro present four cases of syringomyelia in which the patients were treated by myelotomy. One patient showed practically no improvement. Immediate improvement was slight in two others, but striking in one instance. From a survey of the literature it appears that the operation has had a favorable, but not curative, result in the great majority of cases. In some instances the results have been permanent, in others the disease has progressed. Symptoms have apparently not been increased by operation. Only one fatality is recorded in cases reported since 1926. Roentgen treatment probably acts by arresting gliosis, operation by relieving pressure. Sometimes one, sometimes the other, may be more effective. Radiation should always be employed as an adjunct to operation. Pending further experience, the authors believe that operation should be reserved for patients who are not relieved by roentgen treatment, or who have root-pains, or spinal block or who are incapacitated by the disease. To these it offers real hope of improvement.

Sarcoma of Bladder.—Mintz reports a case of sarcoma of the bladder in a boy aged 5 years. He states that approximately fifty-five authentic cases of sarcoma of the bladder have been reported in children under 5 years of age. The etiology is obscure. The pathologic changes are varied. All histoid elements have been reported. Hematuria is usually not a presenting symptom. Frequency, dribbling, acute retention and bed-wetting are common symptoms. Recurrences are frequent and early. Metastases are not common. The course is invariably fatal. Operation seems to hasten death. In all the recent cases, diagnosis was made by cystoscopy. Partial excision of the bladder wall, excision of the tumor and diathermy have been tried with little success. Total cystectomy with resection of the urethra is the only hope for cure.

Stramonium in Parkinson's Disease.—From their observations in twenty-two cases, Menard and Hurxthal conclude that stramonium datura in adequate dosage is a helpful drug in attempts to alleviate some of the distressing symptoms of either Parkinson's disease or postencephalitic parkinsonism. They believe that it should be tried in all such cases.

*New Treatment for Acute Bursitis. T. K. Richards, Boston.—p. 812.
Progress in Psychiatry. I. H. Coriat, Boston.—p. 814.

Hemorrhage in Disease of Gallbladder.—According to White and Jankelson, severe gastro-intestinal hemorrhage in disease of the gallbladder is rare, but the possibility is important in diagnosis. Such cases are apt to be mistaken for peptic ulcer, especially if the history is doubtful and if adhesions cause some deformity of the duodenum or pylorus. In cases of hematemesis with jaundice, the possibility of gallbladder disease should be considered. Coincident ulcer and gallstones are not rare and may be misleading; the ulcer may heal after hemorrhage and only gallstones be found at a later roentgen examination. Jaundice was not an important factor in causing the hemorrhage in a group of cases studied by the authors. Hepatitis associated with gallbladder disease may be a factor, but the evidence from the cases studied is not clear. In a few cases the hemorrhage may be explained by perforation of the gallbladder, fistula formation, or hemorrhagic infarction of the gallbladder; in the large majority, Naunyn's theory seems best, that toxins in the blood coming from the infected gallbladder cause bleeding from the mucosa of the stomach or duodenum, as occurs in cases of essential hematuria or epistaxis.

Branchial Cysts and Fistulas.—Shedden presents a summary of the modern concept of the embryology of "branchial" cysts and fistulas. He further shows, in the study of forty-two cases of branchial cyst and nine cases of fistula, that: (1) they occur in young adult life; (2) the disease exists a long time before the patient demands relief because it progresses slowly and pain appears late, if at all, and usually only from secondary infection; (3) tuberculosis rarely causes secondary infection; (4) it does not affect the patient's general health; (5) the diagnosis should not be difficult if one keeps the entity in mind, and (6) the treatment involves complete removal of the pathologic process.

Treatment for Acute Bursitis.—While treating a patient for boils who also had symptoms consistent with a mildly inflamed subacromial bursa, Richards gave intramuscular injections of iron-arsenic compounds along with other forms of therapy. This particular patient was a chemist by profession, familiar with drugs and unusually observant of his own reactions to them. After each injection of the iron-arsenic compound he volunteered the information that this bursa felt better. Shortly after this the bursa became more acute and it was decided to try the iron-arsenic preparations intravenously. Accordingly, iron cacodylate was chosen because of its apparently less severe reaction and 1 cc., or one-fifth grain, was given. The dose was repeated every third day, increasing the amount by 1 cc. until 5 cc., or 1 grain, was given. Following the first injection there was a distinct improvement; the shoulder was less painful and its motions were freer. At the end of five injections the acute symptoms had disappeared and there was no restriction of the shoulder motions. The result was so startling that other patients suffering from acute bursitis were asked if they were willing to try these injections—all being told beforehand that there was no adequate explanation for the drug working. In all there were approximately seventy cases of acute bursitis—the subacromial, subscapular and infrapatellar bursae being involved. In many cases of acute bursitis uncomplicated by a focus of infection elsewhere in the body there was a lessening of the acute symptoms within three or four hours following the first injection. The vast majority of the patients returned to their normal activities or play with complete absence of symptoms and no restrictions of motions, from ten to twenty-one days following the first intravenous injection. In this series all other forms of treatment were avoided so as not to complicate the picture of recovery. There was no restriction of use beyond that of pain. In other words, patients were told to use their arms as much as they pleased or could. Both iron-arsenite and iron cacodylate were employed, but the iron-arsenite seemed to be more frequently accompanied by immediate severe reactions, which were not present when the cacodylate was used. Accordingly, the use of the iron-arsenite was abandoned and all injections were made with the iron cacodylate. The author gives three case histories to illustrate the effectiveness of this form of treatment of acute bursitis.

Clinical Laboratory Findings in Thyroid Diseases: Brief Review of Literature and of Starling-Loving Hospital Records. Edith M. Miller, Columbus.—p. 799.

Mitral Stenosis.—In a clinical pathologic review of seventy cases of mitral stenosis, Einsel and his associates found that fifty-six, or 80 per cent, of the patients died as the result of cardiac disability; i. e., congestive failure, embolism, and subacute bacterial endocarditis. The period of invalidism with failure varied from one month to eight years, with an average duration of twenty-two months. Subacute bacterial endocarditis caused death in three instances (4.2 per cent). Auricular fibrillation was present during the hospital admission in forty-one cases of the failure group, or 58 per cent. The heart weights varied from somewhat below normal to 800 Gm. and did not definitely depend on the combined valve lesion. Tricuspid stenosis could be predicted in 39 per cent of the cases with mitral stenosis and aortic valvulitis.

Cardiac Beriberi in Nursing Infants. J. Albert.—p. 368.

Blood Viscosity.—Hilario's material consisted of about 100 males recruited from among medical students of 20 to 30 years of age, and apparently in good health. Those who, after the viscosity test had been made, became ill were discarded, so that the figures noted represent the values obtained from those who were apparently healthy at the time of the examination and afterward. The test was made in most of the cases three hours after luncheon. It was found that the blood viscosity averaged 5.18, the maximum being 6.36 and the minimum 3.98. These figures may be slightly higher than usual, owing to the finger massage applied prior to the pricking of the finger tip in an effort to get enough blood to fill the viscosimeter tube up to the 0 mark. The relatively better nutrition of the subjects included in this series, compared with the state of nourishment of the general masses, may be held partly responsible for the slightly increased figures.

Effect of Hemolytic Streptococci on Leukocytes.—Evans summarizes thus the results of experiments on the effect of hemolytic streptococci and their products on leukocytes: In filtrates of broth cultures of Streptococcus scarlatinae there is a trace of a substance toxic for leukocytes which can be detected by the bioscopic test but not by the phagocytic test or by the deterioration of cells as shown in stained microscopic preparations. The addition of kidney tissue, blood serum, or washed leukocytes to broth cultures does not increase the production of the leukocidic substance. On the other hand, the addition of washed erythrocytes to broth cultures definitely promotes its increase. The thermolability of the trace of leukocidic substance in filtrate of broth culture is the same as that of the more abundant leukocidic substance in filtrate of culture in broth plus erythrocytes. Presumably the two substances are identical. A specific neutralizing agent for the leukocidic substance could not be demonstrated in normal or immune serum. Two lines of evidence are offered which show that the leukocidic substance is not identical with hemolysin. They differ in thermolability. There is no correlation of toxicity for the two types of blood cells manifest by filtrates of cultures grown under varying conditions. The decrease of leukocidic substance in purified and concentrated skin toxin indicates that leukocidic substance and skin toxin are not identical.

Toxic Goiter.—Fraser calls attention to the fact that there are patients, usually young women, who, with no evidence of previous thyroid trouble, develop the typical picture of exophthalmic goiter, and in the course of a few months, or longer, recover apparently completely. There are others, with a similar onset and initial recovery, who relapse, perhaps repeatedly. There are others who never quite recover but in whom the condition subsides only to light up again and again with greater or less severity over a number of years. In those with repeated relapses or exacerbations the thyroid is usually found to be nodular. There are still other patients, who, when they come under observation for the first time because of toxic symptoms, present a nodular gland. It is known that the gland responds to physiologic stimuli, such as puberty, pregnancy and lactation, by increased activity; and it responds in a similar way to pathologic stimuli, such as infections; but in both conditions signs of thyroid intoxication are rare, and the gland usually returns by involution to a normal condition. If the involution is not perfect, and areas of hyperinvolution and of hypoinvolution result on repeated occasions without the occurrence of symptoms of intoxication, a nodular gland might be expected to develop in time. This accounts for those patients in whom such a gland is found on the first appearance of toxic phenomena. The absence of nodules and of fibrosis is not evidence that hypertrophy, hyperplasia and involution have not occurred, but a nodular goiter is good evidence of a past history in which the thyroid has had to respond to stimuli and then has involuted, perhaps repeatedly and over a number of years. These nodules are not adenomas, but true adenomas may occur, though much more rarely; and pathologic processes, other than those that result from the involutionary changes described by Rienhoff, are encountered in glands associated with toxic goiter. The author believes that patients with thyroid intoxication, or toxic goiter, should be treated as early as possible by removing any causal factors that can be discovered, by the administration of iodine, and by reduction of the amount of functioning thyroid tissue. This can be accomplished with the greatest certainty by operative treatment; but if a surgeon with special skill and experience in such cases is not available, treatment by roentgen rays or radium should be tried while the case is still mild and the patient able to work.

Puerperal Sepsis.—In his experience, Hobbs finds it exceptional for women with puerperal sepsis to develop pyrexia at the outset. Many patients have offensive lochia, red lochia, and purulent discharge and yet for some days remain entirely apyrexial. Further, while severe cases of puerperal inflammation are due to bacterial invasion of the raw uterine surfaces, there is a much greater number in which inflammatory changes occur as a result, purely, of the retention of placental fragments and blood clot, and those are the cases that frequently lead to chronic invalidism among women. Unfortunately, little or nothing is done at the very time when much could be done, and the most favorable opportunity to deal with them is lost. Following labor or miscarriage, much blood and serum, together with fragments of placenta, normally continue to escape from the uterus for several days. Anything that interferes with the natural drainage will undoubtedly give rise to signs and symptoms; one must learn to recognize these, for they are certainly the earliest heralds of possible trouble later. A full appreciation of their significance will enable one to begin early and efficient treatment, by which alone one can hope to reduce maternal mortality.

Treatment of Anemia by Tryptophan and Histidine.—Cuthbertson and his associates state that tryptophan and histidine injections produced an early but small reticulocyte response in two cases of *pernicious anemia. There was no appreciable* increase in the hemoglobin or red cell count. In one case the injections were given intravenously and in the other subcutaneously. In two cases of "secondary" anemia in which the patients had had prolonged courses of iron, arsenic and liver *without benefit, tryptophan and histidine* caused a moderate reticulocyte response in one case, but no improvement in the blood count in either. Both patients, however, responded rapidly to subsequent iron and arsenic. Subjective improvement during the course of injections was noted in three of the four cases. The *injections* caused little discomfort and appeared to be harmless. While the cases described are "insufficient" in number to afford conclusive evidence in support of the theory of Fontès and Thivolle, they indicate that these amino-acids have some stimulant action on the hematopoietic tissue.

Blood Extravasation and Albuminuria.—According to Browne, damaged tissue, or altered blood, liberates some toxic substance which is known to act in minute quantities and with great rapidity. All authorities are agreed that uteroplacental changes, under different names, are almost invariably found in association with some kidney lesion. Albuminuria develops with great rapidity subsequent to blood extravasation and tissue injury in different parts of the body. Removal of the toxin producing extravasation is followed by rapid recovery of the endothelial damage. These four facts force one to the conclusion that albuminuria undoubtedly develops subsequent to the reabsorption of some toxic material. This can occur as the result of an extravasation in any part of the body.

Low-Back Pain in Gynecologic Practice.—Cochrane believes that in low-back pain due to lumbosacral and sacroiliac strain the aim of treatment should be to restore the back and the body as a whole to a state of good posture, so that correct function may then be possible. The means employed are rest, massage, heat, reeducation of the muscles, and support of the spine and pelvis. The patient is put to bed for three weeks, on a very firm mattress. She lies on the back with a low pillow beneath the head and knees. Thrice daily, for half an hour after meals, she is put into a position of what is called *superextension. A pillow* is placed beneath the chest and the hands are clasped behind the head. The effect of this is to throw the chest forward and, by leaving the lumbar spine unsupported, to cause flattening of the lumbar spine. The patient is turned over and made to lie face down on a pillow placed lengthwise beneath the trunk for half an hour following the superextension position, and hot fomentations are applied to the lower part of the back. In a few days' time the back is massaged and the patient is taught a simple list of exercises to be performed when lying down to teach her how to obtain active, conscious control of the muscles of the trunk and pelvis; thus she is taught to correct the lordosis. When she gets up, the remedial exercises are continued and should soon result in an individual whose posture in standing, sitting and walking is habitually correct. To help the patient to maintain the correct position a strong, back-lacing corset is often required for a time, until the muscles are strong enough to do the work for themselves.

Gastric Juice Acidity.—On the basis of their experimental observations on cats, Bolton and Goodhart conclude that the average acidity of normal gastric juice at the height of secretion from the whole stomach is 0.134 normal (0.49 per cent) and the inorganic chloride 0.07 per cent. These figures, however, vary to some degree in different animals even with the same stimulus, but the total chloride percentage is almost constant. In all animals as the secretion is beginning its acidity is on the average 0.082 normal (0.3 per cent); that is to say, below the normal average by 0.052 normal (0.19 per cent) for the first few minutes, and correspondingly the neutral chloride is in excess of the average by the same amount. This low acidity is in some measure due to escape of neutral chloride at the expense of the acid. When fully established after this initial phase the acidity remains constant, showing a slight fall in about half the experimental animals when the secretion is stopping. This final fall in acidity, when it occurs, is insignificant and only about a third of that which is invariably present in the initial phase. There is a corresponding small rise in the neutral chloride, owing to escape of this substance at the expense of the acid. It is therefore only in the higher reaches of acidity that any variation is observable, and then only when small amounts of juice are being secreted. So long as a few drops are secreted the acidity is high and the juice is not transformed into a neutral diluting fluid, such as could lower the acidity of the gastric contents. The stomach has no power of regulating the acidity of the gastric juice either by its final transformation into a neutral solution or by the addition of pyloric juice, which appears to play no greater part in this respect than the mucous secretion of the body of the stomach. When any substantial reduction in acidity of the gastric juice occurs, the percentage of total chloride falls, showing neutralization and dilution by mucus, and not replacement of acid by neutral chloride. Mucus is secreted in varying amounts during the flow of gastric juice and is most in evidence at the end of the flow. It is alkaline in reaction to about 0.039 normal (0.14 per cent) and contains from 0.28 to 0.36 per cent inorganic chloride and with strong stimulation up to 0.5 per cent. The mucus can produce an effect on only small quantities of gastric juice, such as occur at the beginning and end of secretion, but there is no great reduction in acidity at the end until the flow of juice has actually stopped, when the acidity drops to zero and alkalinity develops. The mucus both dilutes and neutralizes the acid of the juice but only dilutes the total chloride, and this to a less extent than it does the acid because mucus already contains inorganic chloride. The unaided stomach has no means of lowering the acidity of the gastric juice secreted into it unless the volume of the latter has diminished to a minute quantity at the end of secretion, and even then there is no great reduction until the secretion has actually stopped. This effect is due to the alkaline mucus secreted by the stomach. The authors noted that the gastric secretion continued with undiminished acidity although it was allowed to accumulate in the stomach, thus disproving the hypothesis that the presence of a certain concentration of acid in the stomach inhibits the further secretion of acid.

Stomach Innervation.—McSwiney and Robson made preparations of smooth muscle obtained from the fundus of the stomach with a dual innervation of vagus and sympathetic nerves. They describe experiments which demonstrate that the response of smooth muscle to stimulation of the periarterial nerves may be reversed by stimulation of the vagus nerves. Inhibition of the vagus response produced by stimulation of the periarterial nerves was also demonstrated. The duration and factors regulating the inhibitory effect were investigated. Evidence is advanced to show that the type of response resulting from nerve stimulation is determined by the liberation of chemical substances in the periphery.

Harmalol in Treatment of Parkinsonism. H. A. Cooper and J. A. Gunn. —p. 901.

Serum Therapy of Plague.—Naidu and Mackie have produced a more potent antiplague serum than any that has theretofore been available. In preparing this, attention was paid to three points which are considered to be of importance—the choice of the animal, the virulence of the strain used, and the method of immunization. Cattle were chosen rather than horses, on the ground that they are naturally susceptible to organisms of the pasteurella group. A highly virulent strain of Bacillus pestis was used in the production of serum. The serum of immunized cattle was found to possess good agglutinative power and to be possessed of antitoxic as well as antibacterial properties. The use of this serum as a curative measure resulted in the saving of the lives of a high proportion of rats and rabbits as compared with the controls. In all these desirable properties the serum was shown to be far superior to any other antiplague serum tested. When it was applied to a small human epidemic, the results were promising. Out of a total of seventy-six cases, forty-three patients were treated with serum, generally in one dose, and of these fifteen died, while of the controls (alternate cases) twenty-three out of thirty-three died. Several patients with advanced Bacillus pestis septicemia recovered, and seven out of eight with early septicemia survived, as compared with an invariable fatality in the former group and 75 per cent mortality in the latter.

Pneumococcus Peritonitis. A. Bréchot and Nové-Josserand.—p. 533.

Treatment of Postoperative Peptic Ulcer.—Gosset asserts that postoperative peptic ulcer is relatively rare (2 to 3 per cent of cases), but as it is a serious complication and often extremely difficult to treat, it should be given attention. After a review of the cases from the literature and a discussion of his own observations, the author concludes as *follows:* The rules for surgical treatment are dominated by the tendency of peptic ulcer to recur, a tendency most marked in young patients and in those in whom the original ulcer was duodenal. In case of a peptic ulcer subsequent to gastro-enterostomy, one can try anatomic restoration, but that operation is insufficient unless one performs a complementary plastic operation on the pylorus. The late results of gastro-enterostomy alone demonstrate the frequency of recurrences of duodenal ulcer. Pyloroplasty to be efficacious should include resection

In a few days' time the back is massaged and the patient is taught a simple list of exercises to be performed when lying down to teach her how to obtain active, conscious control of the muscles of the trunk and pelvis; thus she is taught to correct the lordosis. When she gets up, the remedial exercises are continued and should soon result in an individual whose posture in standing, sitting and walking is habitually correct. To help the patient to maintain the correct position a strong, back-lacing corset is often required for a time, until the muscles are strong enough to do the work for themselves.

Gastric Juice Acidity.—On the basis of their experimental observations on cats, Bolton and Goodhart conclude that the average acidity of normal gastric juice at the height of secretion from the whole stomach is 0.134 normal (0.49 per cent) and the inorganic chloride 0.07 per cent. These figures, however, vary to some degree in different animals even with the same stimulus, but the total chloride percentage is almost constant. In all animals as the secretion is beginning its acidity is on the average 0.082 normal (0.3 per cent); that is to say, below the normal average by 0.052 normal (0.19 per cent) for the first few minutes, and correspondingly the neutral chloride is in excess of the average by the same amount. This low acidity is in some measure due to escape of neutral chloride at the expense of the acid. When fully established after this initial phase the acidity remains constant, showing a slight fall in about half the experimental animals when the secretion is stopping. This final fall in acidity, when it occurs, is insignificant and only about a third of that which is invariably present in the initial phase. There is a corresponding small rise in the neutral chloride, owing to escape of this substance at the expense of the acid. It is therefore only in the higher reaches of acidity that any variation is observable, and then only when small amounts of juice are being secreted. So long as a few drops are secreted the acidity is high and the juice is not transformed into a neutral diluting fluid, such as could lower the acidity of the gastric contents. The stomach has no power of regulating the acidity of the gastric juice either by its final transformation into a neutral solution or by the addition of pyloric juice, which appears to play no greater part in this respect than the mucous secretion of the body of the stomach. When any substantial reduction in acidity of the gastric juice occurs, the percentage of total chloride falls, showing neutralization and dilution by mucus, and not replacement of acid by neutral chloride. Mucus is secreted in varying amounts during the flow of gastric juice and is most in evidence at the end of the flow. It is alkaline in reaction to about 0.039 normal (0.14 per cent) and contains from 0.28 to 0.36 per cent inorganic chloride and with strong stimulation up to 0.5 per cent. The mucus can produce an effect on only small quantities of gastric juice, such as occur at the beginning and end of secretion, but there is no great reduction in acidity at the end until the flow of juice has actually stopped, when the acidity drops to zero and alkalinity develops. The mucus both dilutes and neutralizes the acid of the juice but only dilutes the total chloride, and this to a less extent than it does the acid because mucus already contains inorganic chloride. The unaided stomach has no means of lowering the acidity of the gastric juice secreted into it unless the volume of the latter has diminished to a minute quantity at the end of secretion, and even then there is no great reduction until the secretion has actually stopped. This effect is due to the alkaline mucus secreted by the stomach. The authors noted that the gastric secretion continued with undiminished acidity although it was allowed to accumulate in the stomach, thus disproving the hypothesis that the presence of a certain concentration of acid in the stomach inhibits the further secretion of acid.

Stomach Innervation.—McSwiney and Robson made preparations of smooth muscle obtained from the fundus of the stomach with a dual innervation of vagus and sympathetic nerves. They describe experiments which demonstrate that the response of smooth muscle to stimulation of the periarterial nerves may be reversed by stimulation of the vagus nerves. Inhibition of the vagus response produced by stimulation of the periarterial nerves was also demonstrated. The duration and factors regulating the inhibitory effect were investigated. Evidence is advanced to show that the type of response resulting from nerve stimulation is determined by the liberation of chemical substances in the periphery.

Harmalol in Treatment of Parkinsonism. H. A. Cooper and J. A. Gunn. —p. 901.

Serum Therapy of Plague.—Naidu and Mackie have produced a more potent antiplague serum than any that has theretofore been available. In preparing this, attention was paid to three points which are considered to be of importance—the choice of the animal, the virulence of the strain used, and the method of immunization. Cattle were chosen rather than horses, on the ground that they are naturally susceptible to organisms of the pasteurella group. A highly virulent strain of Bacillus pestis was used in the production of serum. The serum of immunized cattle was found to possess good agglutinative power and to be possessed of antitoxic as well as antibacterial properties. The use of this serum as a curative measure resulted in the saving of the lives of a high proportion of rats and rabbits as compared with the controls. In all these desirable properties the serum was shown to be far superior to any other antiplague serum tested. When it was applied to a small human epidemic, the results were promising. Out of a total of seventy-six cases, forty-three patients were treated with serum, generally in one dose, and of these fifteen died, while of the controls (alternate cases) twenty-three out of thirty-three died. Several patients with advanced Bacillus pestis septicemia recovered, and seven out of eight with early septicemia survived, as compared with an invariable fatality in the former group and 75 per cent mortality in the latter.

Pathogenesis of Postoperative Peptic Ulcer. R. Leriche.—p. 465.
*Treatment of Postoperative Peptic Ulcer. A. Gosset.—p. 491.
Immediate Surgical Treatment of Open Fractures of Leg. G. Roux and J. Sénèque.—p. 515.
Pneumococcus Peritonitis. A. Bréchot and Nové-Josserand.—p. 533.

Treatment of Postoperative Peptic Ulcer.—Gosset asserts that postoperative peptic ulcer is relatively rare (2 to 3 per cent of cases), but as it is a serious complication and often extremely difficult to treat, it should be given attention. After a review of the cases from the literature and a discussion of his own observations, the author concludes as follows: The rules for surgical treatment are dominated by the tendency of peptic ulcer to recur, a tendency most marked in young patients and in those in whom the original ulcer was duodenal. In case of a peptic ulcer subsequent to gastro-enterostomy, one can try anatomic restoration, but that operation is insufficient unless one performs a complementary plastic operation on the pylorus. The late results of gastro-enterostomy alone demonstrate the frequency of recurrences of duodenal ulcer. Pyloroplasty to be efficacious should include resection of two thirds of the pylorus. When sphincterectomy cannot be performed (half of the cases) there are two resorts: One should either establish a better drainage of the stomach by a new and better gastro-enterostomy or make a prophylactic resection of the stomach. The first method exposes the patient to the dangers of gastro-enterostomy, that is to say the appearance of peptic ulcer after gastro-enterostomy in a patient with a predisposition to ulcers. Gastro-enterostomy alone can be considered only in old patients in whom peptic ulcer is rare. The second recourse is gastrectomy. To be preventive, gastric resection ought to be extended: (1) to two thirds of the stomach, if the gastro-intestinal continuity is reestablished by a terminolateral gastrojejunal anastomosis; (2) but only to one third (region of the pyloric glands) if the stomach and the duodenum can be reunited by a terminoterminal or terminolateral (Haberer) anastomosis. The author prefers extensive resection of the stomach because it has been followed by the fewest recurrences. In the surgical treatment of perforative peptic ulcer, the following procedures are considered: Excision of the ulcer, better drainage of the stomach, anatomic restoration, and frequently merely closure of the perforation. The operation can be done in two stages; namely, simple closure of the perforation and, several weeks afterward, anatomic restoration or prophylactic resection. In colic fistula, the best operation is the simple liberation of the fistulized organs, with, each time that it is possible, anatomic restoration. One-stage gastrectomies are, in the main, formidable interventions with a mortality that is not entirely justified by the late results.

Residual Nitrogen in Urinary Diseases. G. Basile.—p. 201.
*Renal Insufficiency in Prostatic Hypertrophy Without Vesical Residue. T. Katz.—p. 207.
*Modification of Microbic Flora in Treatment of Hemorrhagic Cystitis. L. Sas.—p. 221.

Renal Insufficiency in Prostatic Hypertrophy Without Vesical Residue.—Katz asserts that hypertrophy of the prostate is a mechanical or dynamic obstacle to the evacuation of urine, that the bladder is the first to be affected by this difficulty, and that it combats the dysuric state and the increasing obstacle by hypertrophy of its musculature. When the hypertrophy becomes insufficient, the patient enters the period of the disease characterized by residual urine. An examination of 1,500 cases of hypertrophy of the prostate revealed that in 30, or 2 per cent, there was no residual urine and the renal function was not impaired. The conclusions were as follows: Intravenous pyelography in prostatic hypertrophy is advantageous. Operative procedures should not be postponed because the vesical residue is minimal. Various laboratory methods should be used in examination for renal function; in prostatic hypertrophy these examinations should not be limited to dysuria or pollakiuria phenomena. The general health of the patient and the condition of his cardiovascular system must also be considered in surgical intervention. The author plans to incorporate roentgenography of the seminal vesicles in relation to the ductus deferens and the ureters in a great number of cases of hypertrophy of the prostate without residue and to interpret the latter through anatomic researches in a large series of cadavers.

Modification of Microbic Flora in Treatment of Hemorrhagic Cystitis.—Sas based his observations in Bacillus coli and streptococcus inflammation of the bladder on a consideration of the semeiology, cystoscopic picture, character of the infectious development, and finally the response to treatment. He found that colibacillary cystitis is a secondary infection, the primary source being the upper urinary tract; colibacillary cystitis is responsive to treatment. On the other hand, streptococcus and micrococcus cystitis is a primary infection and much more difficult to eradicate. When general and local treatment of a coccus cystitis did not avail, the author decided to substitute for the streptococcus and micrococcus flora a Bacillus coli flora; this made subsequent treatment much more efficacious. The reaction of the urine was of great importance in the process of transition. The following procedures were incorporated: Acidification of the urine was accomplished by diet and the administration, three or four times a day, of from 15 to 20 drops of diluted hydrochloric acid and 0.5 Gm. of methenamine. Local therapy consisted in lavage of the bladder with 3 per cent solution of hydrogen dioxide followed by instillation of 0.5 per cent solution of silver nitrate or 2 per cent solution of strong silver protein. This was continued until the pseudomembrane covering the mucosa disappeared (controlled by the cystoscope). The removal of the pseudomembrane removed the collections of bacteria and urine that prevented the adjustment of the reaction and the action of therapeutic agents. Then followed the injection into the bladder of 10 cc. of a suspension of a twenty-four to forty-eight hour agar culture of Bacillus coli (one billion organisms). The process of acidification of the urine was continued, but the methenamine was entirely discontinued and the local therapy was discontinued for two or three days. Bacteriologic control of the flora governed any necessity for repetition of the injection of the bacterial suspension. When the flora has changed to a monobacterial infection, the acidifying process is discontinued and the usual treatment for colibacillary cystitis is instituted. Lavage of the bladder may or may not precede treatment. Treatment consists of preliminary lavage of the bladder with 0.05 per cent solution of potassium permanganate and instillations with 0.5 per cent solution of silver nitrate or 2 per cent solution of strong silver protein. Once the infection has changed to a colibacillary cystitis, alkali treatment supplants the acidification. It is important to know that acidity of the urine favors the development of B. coli and alkalinity the development of the streptococcus. However, the author remarks that Bacillus proteus may grow equally well in a strongly alkaline or a markedly acid medium. Four case histories (three of chronic cystitis and one of acute hemorrhagic cystitis) are reviewed.

*Lysate-Vaccines in Puerperal Infections and Abscess of Breast. P. Brocq and L. Duchon.—p. 483.
Biologic Diagnosis of Pregnancy by Animal Tests. R. Bouc.—p. 505.

Lysate-Vaccines in Puerperal Infections and Abscess of Breast.—In 1926, Duchon proved that Bacillus pyocyaneus in contact with many living pathogenic bacteria such as diphtheria, staphylococcus, streptococcus, pneumococcus and gonococcus demonstrated bactericidal, bacteriolytic and antitoxic properties. He and Brocq explain the phenomena that take place as a state of immunization, active vaccination with development of antibodies, manifested in the body as intense leukocytosis, phagocytosis, decrease or disappearance of the bacterial agents of the focus of infection and tinctorial and morphologic modification of the infecting pathogens. They utilized "lysate-vaccines" prepared by the filtration of cultures of the etiologic organisms grown in contact with pyocyaneus. They have reported elsewhere results in various surgical cases of phlegmons, abscess, lymphangitis and cellulitis as well as medical cases of bronchopneumonia and purulent pleural exudates due to streptococci. The authors report the treatment in eleven cases and the resultant improvement in nine cases of streptococcus septicemias. Thirty patients were treated for abscess and lymphangitis of the breast. Culture of closed abscesses gave pure cultures of hemolytic staphylococci while cultures of open abscesses gave mixed cultures of staphylococcus, streptococcus and other more or less pathogenic organisms, such as common skin pathogens, enterococcus and Bacillus pyocyaneus. The lysate of the staphylococcus was used for the treatment of the closed abscesses and the lysates of the staphylococcus and streptococcus were used for the treatment of the open abscess. The authors used mixed lysate-vaccines, especially in those types of diseases with particularly frequent secondary infections. Lymphangitis of the breast was frequently improved by the application of wet dressings. When lysate-vaccinotherapy was substituted, there was rapid improvement in four or five days. Their studies suggested that there may be a close relationship between uterine and general infection, and that the uterine flora should therefore be studied before labor and before obstetric intervention. Several instances of concomitant streptococcic infection of the ureter in the male led the authors to believe that sporadic streptococcus infection like gonococcus infection may be a result of sexual contamination. In streptococcus puerperal septicemias, the authors utilize the lysates of the streptococcus and also the polymicrobic lysates of the bronchopulmonary infections. They find, however, that immunity against streptococci is of short duration and insurance against recurrence is not always guaranteed.

*Acute Optic Neuritis Associated with Myelitis. Milian, Lhermitte, Schaeffer and Horowitz.—p. 257.
Tonic Reflexes of Posture. O. Balduzzi.—p. 280.
Malarial Therapy and Cerebral Lesions in Dementia Paralytica. D. Paulian and I. Bistriceanu.—p. 293.

Acute Myelitis with Optic Neuritis: Case.—Milian and his co-workers summarize their case as follows: A man, aged 37, on presentation gave negative reactions to blood and spinal fluid tests and in the following days proved to have signs of paresis in the lower limbs and visual disturbances which appeared about the same time as the signs of paresis. Shortly after the onset, the patient presented a distinct spasmodic paraplegia with marked exaggeration of the reflexes and extension of the toes, accompanied by dystrophies in subjective and objective (tactile and deep) sensitivity ascending to the sixth and seventh thoracic nerves and sphincterial difficulties marked by impotence. The paraplegia was accompanied by an increase in the albumin content of the spinal fluid without appreciable hypertension. The visual difficulties consisted in a decrease in visual acuity with edematous papillitis accompanied by a central scotoma for colors. In spite of treatment, the paraplegia increased; the spastic manifestations and accentuation of the sensitivity were the two chief manifestations. Appearance of an ascending urinary infection was concomitant with the sphincterial dystrophies, complicated finally by visceral localizations, particularly pulmonary and renal, which led to death in from six to seven weeks after the onset. Anatomically, the essential, fundamental lesion was present in the spinal cord and consisted in areas of demyelinization accompanied by neuroglial reactions, and in the optic nerve there was degeneration and inflammation. The authors believe that the case represented an autonomic disease, probably due to a neurotropic virus, different from other diseases described in the past. This disease of the brain and spinal cord was elective for the spinal cord and optic nerves, differing from analogous syndromes such as may be produced by syphilis of the brain and spinal cord, multiple sclerosis, necrotic myelitis, epidemic encephalitis, and all the types of leuko-encephalitis. They do not agree with other workers that this disease is a syndrome.

*Pseudovalves of Heart. G. Dagnini.—p. 953.
Observations on Sudanophil Leukocytes. M. Gavazzeni and L. Beltrametti.—p. 995.
Organotherapy in Anemia. A. Lo Jacono.—p. 1007.

Pseudovalves of Heart.—Dagnini carried out an anatomopathologic study on the peculiar formations termed "pseudovalves of the heart," which are observed on the parietal endocardium of the left ventricle, with especial frequency in insufficiency of the aortic valves. From a critical examination of the literature on the subject and from researches in seven personal cases, he is convinced that the development of the pseudovalves is not controlled by a single factor but that they may originate from thickening of the tissues, inflammatory processes of the wall, or from a changed disposition of the muscles—of congenital origin, through the action of the aortic regurgitation in cases of insufficiency of the aortic valves, or through the exclusive mechanical action of the aortic regurgitation in the defect mentioned, a regurgitation which causes first circumscribed thickening of the tissues of the endocardium and secondly cavities in the form of pockets or pouches. This hypothesis finds support in the constant association with the aortic valvular defect, in the localization below the point of the maximal valvular defect, and in the histologic changes that are observed, indicating a repeated mechanical stimulus.

Angioneurotic Disturbances of Lower Limbs (Buerger's Disease). D. Giordano.—p. 1471.
*Differential Venosocapillary Glycemia in Diseases of Liver. A. Tarsitano. —p. 1474.
Conservation of Control Serums for Wassermann Test. G. Delpiano.— p. 1481.

Differential Venosocapillary Glycemia in Diseases of Liver.—In ten patients with diseases of the liver (three cases of Morgagni-Laënnec cirrhosis, one of cancer, two of syphilitic hepatomegalia, two of liver disorder due to cardiac stasis, one of hepatomegalia due to chronic malaria, and one of hepatomegalia with icterus and fever), Tarsitano studied the behavior of the capillary glycemic curve, the venous glycemic curve and the differential venosocapillary curve after oral administration of 1.5 Gm. of dextrose per kilogram of weight. According to the Falta method, he compared the values obtained for (1) glycemia fasting, (2) the degree of hyperglycemia in an absolute sense and relative to the glycemia fasting, (3) the degree and duration of the hypoglycemic phase when that occurs, and (4) the degree of differential venosocapillary glycemia—fasting and during the tolerance test. From the results obtained, it may be deduced that the differential glycemia is usually lower, the more grave the functional lesion that affects the liver, and that often when there is a low differential glycemia the hypoglycemic phase is absent. Since to these two characteristics the Falta school attributes the value as exponents of a deficiency of the insular function, it must be assumed that in grave liver disorders there exists this deficiency of functioning. The results obtained show the need of taking account of the hepatic factor whenever one applies the test of the differential venosocapillary glycemia with dextrose to determine the functioning of the pancreas.

*Bleeding Nasopharyngeal Fibroma of Puberal Period in Boys: Treatment. H. Zubizarreta.—p. 953.
Physiopathology of Pulmonary Circulation in Mitral Stenosis. R. Naveiro.—p. 957.
*Surgical Semeiology of Peripheral Nerves and Treatment of Cranial Trauma. M. Balado.—p. 982.
Traumatic Congenital Pemphigus with Epidermal Cysts. E. P. Fidanza, F. Carrillo and T. Ocaña.—p. 990.

Bleeding Nasopharyngeal Fibroma of Puberal Period in Boys.—Zubizarreta advises high voltage roentgen treatment for the special type of bleeding nasopharyngeal fibroma which occurs in some boys during puberty. In his patient, aged 15, a large tumor developed in the right nasal fossa and extended to the maxillary sinus, filling it entirely. The exact nature of the growth was proved by its characteristics (red color, hard consistency and other peculiarities), by the symptoms (especially profuse bleeding) and by a biopsy of the tumor. High voltage roentgen treatment caused the regression of the tumor till complete disappearance, and the results still persist seven years later.

Surgical Semeiology of Peripheral Nerves and Treatment of Cranial Trauma.—Balado describes the impairment of certain muscular functions, under nervous control, after trauma with injury of the spinal or cranial nerves or their roots. The condition of the nerves or nerve roots supplying the given muscle may be determined by the exploration of the functions of the muscles. In acute cranial trauma or fractures of the skull, the most important symptoms are those referred to the cerebral injuries. Cerebral edema, which is a constant occurrence in cranial trauma with injury of the cortex, is limited to the proximity of the traumatized area and may undergo a spontaneous regression if the injury of the cortex is minimal. However, if the injury involves laceration of the pia mater, cerebral edema spreads through the entire lobe of the traumatized side, and it spreads also through the entire hemisphere if there is coexistent hemorrhage. The condition determined by the hemorrhage may be more or less grave. The least serious intracranial hemorrhage is the subpial (nonfatal), caused by injury of the cortex by a splinter of the lamina interna, detached by trauma. Next in importance is the intradural hemorrhage caused by the detachment of a vein at its site of insertion, due to concussion of the brain. In this type of trauma the vault of the skull may or may not have suffered a fracture. In the first case (with fracture of the vault) some cerebral substance is lost through the gap of the fracture. The prognosis for the life of the patient may be favorable if the development of meningitis can be prevented. In the last case of this type of trauma (without fracture of the vault), either the intradural hemorrhage acts as an internal tumor, rapidly causing intracranial hypertension and death of the patient, or it escapes into the orbital cavities through a communication of the skull (provided the concussion produced a slight crack at its base); the victim's life in this case is spared as under the action of a decompressive trephination. However, all these possibilities of saving the victim's life do not minimize in the least the seriousness of this type of hemorrhage. Next in importance is the intradural hemorrhage caused by the section of a branch of the sylvian artery by a cutting splinter. This type of hemorrhage, as well as rupture of the cavernous sinus following a radiating fracture of the base of the cranium is always fatal. The victim either rapidly dies or rapidly falls into coma and dies during the first twelve hours. In cases of craniocerebral trauma caused by a projectile, this acts as the traumatic and fracture-causing agent as well as the resecting agent whose principal damage is that caused by the section of the choroid plexuses which determines the profuse hemorrhage into the ventricles.

Siglo Médico, Madrid

88: 249-272 (Sept. 12) 1931

Large Epithelioma of Limbus Corneae: Removal. M. Marin Amat.—*p. 249.*
*Asthma: Intrapulmonary Treatment by Epinephrine. F. Fernández Arratia.—*p. 250.*

Intrapulmonary Treatment by Epinephrine in Asthma.—García Vicente's method, a simple technic for intrapulmonary therapy, was described in the *Deutsche medizinische Wochenschrift* (**54**:1835 [Nov. 2] 1928; abstr. The Journal, Jan. 19, 1929, p. 273). Fernández Arratia used this technic for the intrapulmonary administration of an emulsion of epinephrine and iodized peptone for the treatment of asthma. The only contraindication is the presence of hypersensitiveness to iodine. The mixture for the injections is prepared thus: In a sterilized capsule, from 3 to 10 drops of a 1:1,000 solution of epinephrine, from 5 to 10 drops of iodized peptone (and sometimes from 5 to 10 drops of a 1 per cent solution of jaborandi) are mixed with from 2 to 4 cc. of the substance which is going to be used as a vehicle (such as aromatized oil or eucalyptol). The mixture is given in endobronchial injections, at a temperature of 38 C., either daily or every other day (about eight injections). In a large number of cases treated by the author, the treatment failed only once. In this case, desensitization, climatotherapy, and some other medical treatments also failed. The presence of some lesions of the organs of reproduction was proved in this patient, and sterilization by roentgen irradiations caused relief. The mixture of epinephrine, iodine and jaborandi seems to have an action on the mechanisms of sensitization, by paralyzing the vagus nerve and by stimulating the sympathetic nerves. Among the asthmatic patients observed by the author, tubercle bacilli were not found. The endobronchial treatment of asthma should be given during the intervals between the attacks. The author concludes that asthma is an allergic and anaphylactic disease. Desensitization should be resorted to, though it should be previously determined whether or not the patient has any other disease responsible for the causation of asthma. If so, he should be properly treated; one should remember that the allergens in asthma are represented by the products of the underlying disease. Roentgen rays, desensitization, and surgical and medical treatments, sometimes give good results, while at other times they fail. The technic of endobronchial treatment with epinephrine and iodized peptone is simple and the treatment gives good results. Any general physician may give the injections; anesthesia is not used. When the problems of desensitization are better understood, the combined treatment of desensitization and endobronchial therapy according to the author's method will offer the means of complete recovery in asthmatic patients.

Treatment of Carbuncles.—Huang describes the household remedies that many Chinese employ in the treatment of carbuncles. The author has tried the various methods of treatment that have been recommended in the medical literature of recent years. However, because many of the patients were already in a desolate state, he found that radical treatment was necessary and he resorted to radical excision in the healthy tissue, a procedure which Riedel advocated in 1891 and to which attention had been called in later years by other authors. The excision is done with ethyl chloride anesthesia. Ligation of veins is dispensed with, and a pressure bandage of iodoform gauze is applied. In the further treatment the author takes advantage of the modern methods of shock therapy. He employed this method in uncomplicated carbuncles as well as in carbuncles in diabetic patients. Of fifty-nine patients treated in this manner, two died; the death of one was the result of tetanus, and the other one had for years been subject to cardiac weakness. The diabetic patients all recovered from the carbuncle, and the healing was rapid. The author considers every carbuncle a sign of acidosis and he thinks that, in addition to the total excision, the administration of insulin or of insulin and carbohydrates should not be neglected.

Reflex and Toxic Vascular Shock.—In reviewing the literature on shock, Gurewitsch did not find definite statements on the essential changes in the vascular system in reflex shock; that is, he found no information on the types of vascular changes following stimulation of sensory nerves. In order to solve this problem he made experiments on dogs. On the basis of his observations and the results of other investigators, he classifies the disturbances that are combined under the term surgical (traumatic) shock into two main types: (1) the toxic vascular shock (anaphylactic, infectious, histamine and other forms) with a definite etiology, an exact localization and a clear pathologico-anatomic picture, and (2) the reflex shock, which has the character of a functional disturbance and in which the pathologico-anatomic changes are not clearly defined. According to the mass and type of the injured tissues, to the character and to the intensity of the irritation of the sensory nerve, there may develop either the toxic shock, the typical reflex shock, or a combination of the two types. The severity of the reflex shock is dependent on the condition of the organism and on the severity of the irritation. The irritation of the sensory nerve is accompanied by a marked increase in the blood pressure. After the irritation ceases, the blood pressure sinks below the normal and then gradually returns to normal. The sudden death following intense irritation of the peripheral nerves is not always caused by shock manifestations but may also be caused by changes in the organism which are connected with the abnormally increased blood pressure and which precede the reflex shock. The rapid increase in the blood pressure and the subsequent decrease should be taken into consideration in every surgical intervention on weakened and aged persons, in whom the blood vessels are brittle. The alveolar and the spermatic nerves are much more susceptible than many other sensory nerves and should therefore be treated with especial care.

Callus Formations on Tibia Without Fracture.—As a military physician, Ollonqvist observed a large number of soldiers who had a peculiar disorder of the tibia. He gives several case reports and also shows roentgenograms. All of the patients were young (about 20 years) and otherwise healthy and of normal development. The pains developed either in one or in both of the tibias and became so severe that it was impossible to continue the military exercises. The pain is felt on the inner margin of the tibia and it is noticeable when the leg is active; that is, during walking and especially while running and jumping. During rest the painfulness disappears. Simultaneously with the development of the painfulness there also appears a swelling on the surface of the tibia. The skin covering the swollen portion is generally normal. The swelling is due to edema of the tibial periosteum. In the beginning it is so marked that, if the finger is pressed against the tibia, a pit remains. The swollen area is extremely sensitive to pressure. The edema is always limited to the surface of the tibia. The ankle joint and the foot are not swollen. The sensitiveness likewise involves only the bone, for the adjoining tendons and muscles are not painful. In the beginning, roentgenoscopy reveals normal conditions; but gradually, in the course of several weeks and months, newly formed periosteal bone appears, increases and becomes more compact. As the ossification process progresses, the edema, the hypersensitiveness and the pains disappear and there remains only a nonsensitive elevation. The cure is spontaneous, without any other treatment than rest; but, if the leg is overtaxed, relapses are liable to occur. The microscopic examination of specimens of the process, which were obtained by exploratory excision, revealed that the histologic structure was the same as that which is ordinarily found in callus formation. Although periostitis of the tibia is generally considered as of syphilitic origin, there were no signs of syphilitic infection in any of the patients in whom this peculiar callus formation was noted. In discussing the pathogenesis of the process the author expresses the opinion that it develops in a similar manner to the disorders that develop in the metatarsal bones after long and strenuous marching. The tibia is overtaxed and at the site of the severest pressure microscopic contusions develop, bone cells break down and hemorrhages set in. The periosteum reacts to these irritations in its usual manner; i. e., it commences to form new bone by way of callus formation.

Studies on Metabolism in Fructosuria. H. Steinitz.—p. 401.

Significance of Chamber Count of Eosinophils.—Domarus aims to show that the diagnostic evaluation of the number of leukocytes will be of greater practical value not merely if the counting is done on stained smears but if in addition to this the chamber count is done. He first reports the results of the chamber count of the eosinophils on healthy persons and then the characteristics of the eosinophil count in various diseases such as gastric ulcer, anemia, rheumatism, tuberculous meningitis, lymphogranuloma, carcinoma, echinococcus disease, cardiac insufficiency, certain forms of nephropathies, hypertension and poisoning. The chamber count of the eosinophils is more valuable if it is repeated from time to time. In the conclusion the author points out that, although it is as yet not possible to give a satisfactory biologic explanation for the behavior of the eosinophils in the various diseases, his investigations have nevertheless proved that the determination of the absolute number of eosinophils by means of the chamber count is in many disturbances a valuable addition to the diagnostic instrumentarium. He thinks that this method should be employed at the bedside whenever possible and that it is of equal significance with Schilling's hemogram method. Moreover, in some cases it reveals characteristic changes, not detectable by other methods. It cannot be denied that this method, like all others that are based on biologic processes, has some shortcomings, but the same can be said of the hemogram method. For this reason it would be wrong to overvalue the one at the expense of the other; but it is advisable to use both of them especially since in many cases they complement each other excellently.

Distribution of Protein Bodies in Blood in Hemorrhagic Diatheses.—Jürgens employed a combination of titrimetry and of Kjeldahl's method. He determined the total protein content of the plasma, albumin, globulin, fibrinogen and volume of the plasma; also the thrombosis time, coagulation time, agglutination and retraction. The studies were made on patients with essential thrombopenia, thrombasthenia, symptomatic thrombopenia, hemorrhagic diathesis during sepsis, hemophilia, scurvy, purpura rheumatica, aplastic anemia and fibrinopenia. For comparison, cases of pernicious anemia, secondary anemia, leukemia, nephritis, nephrosis, tuberculosis, pneumonia, acute infectious diseases, thrombosis and diseases of the liver were studied. Further, hemorrhagic diatheses were produced in animals by acute and chronic benzene poisoning and by lead poisoning, and the test animals were examined in the same manner as the patients. It was found that in hemorrhagic diathesis accompanied by thrombopenia the albumin is regularly increased. A considerable increase in albumin is also noted in rabbits with acute poisoning by benzene or lead. The increase in albumin goes parallel with certain hematologic changes of the hemorrhagic diatheses; namely, with thrombopenia, reduced platelet agglutination, prolonged bleeding time in spite of normal coagulation, and prolonged "thrombosis" time in the capillary thrombometer. Hemophilia, scurvy, thrombasthenia, purpura rheumatica, and hemorrhagic diathesis in sepsis show a normal condition of the blood protein. The author also calls attention to relations between increased albumin content and "hemorrhagic tendency" in thrombopenic hemorrhagic diatheses and to relations of globulin fibrinogen increase to "thrombosis tendency" in infectious conditions and in thrombosis.

Arteritis Obliterans (Thrombo-Angiitis Buerger) as Familial Disease.—Mészáros points out that the etiology of arteritis obliterans is not entirely clear as yet. Some assume an infectious cause, others a predisposition in certain races, and still others consider it a heredodegenerative manifestation. From the latter point of view it is especially interesting if the disease occurs in several members of the same family. The author reports an instance of a family in which eight members (of two generations) showed changes indicative of arteritis. The symptoms were especially severe in three of them.

Suicide in Germany. H. Dornedden.—p. 1750.

Treatment of Retinitis Pigmentosa with Female Sex Hormone.—In the introduction, Wibaut points out that retinitis pigmentosa is much more frequent in men than in women. It usually sets in after puberty and progresses until, at the age of 40, the person is almost blind. Periods during which the process is nonprogressive are possible, but spontaneous recovery is unknown in this disease. The author thinks that the lesser predisposition of women may perhaps be due to hormones that are produced only in the female organism. On the basis of this hypothesis he attempted to influence retinitis pigmentosa by the administration of female sex hormones. Small doses were without effect. But when other investigators found female sex hormone helpful in thrombo-angiitis obliterans, which has certain aspects in common with retinitis pigmentosa, the author resumed the subcutaneous hormone therapy with larger doses. Of five cases treated in this manner, three showed considerable improvement, one slight improvement, and one extremely old cas not show improvement.

Methylene Blue Test for Demonstration of Bilirubin.—Following Franke's suggestion that methylene blue (methylthionine chloride, U. S. P.) is a suitable reagent for bilirubin, Seide and Zink employed in examinations of urines, besides the usual tincture of iodine test, also a methylene blue test. They wished to determine whether the positive reaction always indicates disease or involvement of the liver, and also whether the urines containing bilirubin always give the peculiar color reaction when methylene blue is added. To 5 cc. of urine, a 2:1,000 aqueous solution of methylene blue is added drop by drop. If bilirubin is present, the specimen becomes green as soon as a drop of the methylene blue solution is added. It remains green when more drops are added. But as soon as the number of drops stands in a certain ratio to the quantity of bilirubin contained in the urine, the color becomes bluish green and then dark blue. The number of drops necessary to effect a change from green to blue indicates the quantity of bilirubin. Two drops corresponds to 0.1 mg. of bilirubin. The authors designate as strongly positive urine specimens for which more than 10 drops is required to effect the change, weakly positive when from 2 to 10 drops is sufficient to produce the change in color; and if the typical blue color appears when the first drop is added, the reaction is negative. Strongly positive reactions were noted in diseases of the liver with icterus (catarrhal icterus, carcinoma or syphilis of the liver, and cirrhosis), and in stasis of the liver as the result of circulatory insufficiency. A weak positive reaction was obtained in pernicious anemia, lead poisoning, malaria, nephrolithiasis, cholecystitis, cholelithiasis, influenza and slight stasis of the liver. It was observed that the methylene blue test was much more sensitive than the tincture of iodine test, and a positive iodine test in case of a negative methylene blue test was never observed.

Treatment of Tuberculous Diabetic Patients.—Proceeding from the assumption that the low resistance of diabetic persons to tuberculous infections is perhaps due to a reduction of the sugar consumption of the tissues, Kutschera-Aichbergen attempted in three cases of diabetes and of severe exudative tuberculosis to increase the sugar consumption. When large quantities of carbohydrates and the corresponding amounts of insulin were given, the tuberculosis lost its former malignancy and took an unusually mild course. These favorable experiences in patients in whom progressive tuberculosis concurs with severe diabetes favor a continuation of the therapeutic experiment with a diet that is rich in carbohydrates. Besides the dietetic treatment, collapse therapy should of course not be neglected; on the contrary, in diabetic patients it should be instituted earlier than is usually the case, because in these patients tuberculosis is usually more progressive than in other persons. The author also points out that in diabetic patients the tuberculosis is almost symptomless in the beginning and causes no other clinical disturbances than a reduction of the carbohydrate tolerance. But in spite of this deficiency of symptoms it is usually malignant, and when finally clinical symptoms such as fever become noticeable, the tuberculous process has already reached an advanced stage. The prognosis of the combined tuberculosis and diabetes can be improved if the tuberculous process as well as the metabolic disorder is early recognized and adequately treated from its incipience. Besides the improvement in the tuberculous process the author also noted an increased sugar tolerance. In spite of a greater carbohydrate intake the insulin requirements are now less than they were before, during the time when the patients' carbohydrate intake had been curtailed.

*Syphilis of Urinary Bladder. I. Jovanovitch.—p. 1398.
Clinical Aspects and Pathology of Primary and Secondary Atherosclerosis Pulmonalis with Consideration of Aneurysm of Pulmonary Artery. A. Posselt.—p. 1403.

Syphilis of Urinary Bladder.—According to Jovanovitch, syphilis of the bladder is not as rare as is commonly assumed. It is much more frequent than tuberculosis of the bladder, but it never develops during the primary stage of syphilis, appearing only after the syphilis has become constitutional, and it disappears again, together with the other manifestations of syphilis. First the blood vessels become involved and, since the vascularization of the bladder is most pronounced in the region of the trigon and of the fundus, it is here that vesical syphilis becomes first noticeable. Then the submucosa becomes affected, and only in the more advanced stage does the mucosa become involved. During this stage the vesical syphilis presents the aspects of an ulcerous cystitis with pyuria and hematuria. The fact that the submucosa becomes involved before the mucosa not only aids in differentiating syphilitic cystitis from an ordinary cystitis but also explains why in its beginning stages syphilis of the bladder is painless and does not have any distinctive symptoms, while the normal capacity of the bladder is not reduced. The diagnosis of vesical syphilis is often difficult. It can be based on cystoscopy and on the efficacy of antisyphilitic therapy. If the serologic tests for syphilis are positive, a lesion of the bladder may be considered syphilitic; yet a negative serologic reaction does not necessarily speak against the syphilitic character and other vesical disorders must be excluded before a definite diagnosis is made. In regard to the treatment, the author states that syphilis of the bladder yields only to antisyphilitic therapy. Antiseptic irrigations, electrotherapy and internal treatments are, especially during the beginning stage before the mucosa becomes involved, more harmful than curative, since they irritate the mucosa.

Analysis of Tumor Resistance: Studies on Fermentation.—Waterman points out that investigations on the problems of fermentation are of greatest significance for cancer research, for the cancer cell is generally considered the product of fermentative degeneration. Glycolytic degeneration as well as proteolytic degeneration has already been investigated, and the author studies lipatic or fat-splitting processes of the cancer cell. He discusses the significance of the lipatic systems for cell action and cell form and states that the lipatic process represents the coordinated action of ferment and of activator. In the blood as well as in the tissues such an activator is present, and this activator is sensitive to oxidation and to reduction. The lipatic action is accelerated by oxidation and weakened by reduction. Accordingly it may be assumed that in the intracellular mechanism there is a connection between oxidation and lipatic processes. Activator substances can be extracted by various procedures from organs such as the spleen and the lymph nodes. The extract can be purified by segregating the lipatic activator from the substance sensitive to rays. The latter substance can be removed by adsorption.

Tumor Resistance: Experimental Investigations on Increased Resistance by the Use of Spleen Extracts.—In summarizing the results of these researches, Waterman states that resistance to tumors, although often doubted, really does exist and that it may be induced by the injection of certain substances. The resistance produced in this manner can be demonstrated on implanted tumors as well as on tar cancers. The substances that produce resistance are contained in extracts from the spleen and from the lymph nodes. The author admits that this method is still in its infancy and that the extracts still have to be improved, particularly as far as purity and concentration are concerned. Nevertheless, he considers his method of preparing them as a distinct progress. He then stresses once more the significance of his investigations on lipase, which were reported in the two preceding articles.

Nature and Treatment of Edema.—Lovtskiy discusses the various theories of nephritis and edema, and attacks the problem as a phase of colloid-chemical phenomena. In his early studies he found that when ammonium chloride was administered orally to help the sleep of persons with edema a diuresis resulted. Using fixed doses of ammonium chloride, he determined the free carbon dioxide and bicarbonate of the blood (van Slyke's method) and obtained the value for the alkali reserve. His observations were as follows: Ammonium chloride causes a fall in the alkali reserve of the blood, the acid-base balance shifting toward the acid side. The shift toward acidosis brings about swelling in the tissue colloids resulting in diuresis. Acidosis causes a dissociation of the bicarbonate buffer of the blood; at the same time there follows in the liver a synthesis of the ammonia group into urea with increased excretion of urea into the blood and urine. The sodium chloride content of the urine also increases absolutely and proportionately. Considered as colloid phenomena, the passage of the sodium ion is necessary; its hydropigenous rôle is due to the increase in oncotic or osmotic pressure of the proteins. The author believes that there is no edema without retention of the sodium ion and no dehydration without its elimination. Calcium chloride as well as ammonium chloride was administered in combination with merbaphen and resulted in some instances in greater diuresis. The author stresses the importance of the recognition of cardiac edema with noncardiac manifestations. He also stresses the importance of the consideration of metabolic factors in the study of decompensation of the heart.

Sympathicotonic Symptom of Upper Lip.—Shillnikova asserts that the sympathicotonic symptom of the upper lip (similar to Chvostek's sign) as well as the sympathicotonic anisocoria symptom are indicators of changes in tonicity of the cervical sympathetic nervous system. The integrity of the facial nerve is necessary for the symptoms to appear. In case of paralysis or paresis of the cervical system, the symptom of the upper lip does not appear. Anisocoria as a symptom appears more often than the upper lip symptom, and the latter more often than the symptom with asymmetrical sympathetic widening of the palpebral fissures. The symptom of the upper lip (found most often in tuberculosis of the lungs) is present in from 18 to 25 per cent, and the symptom of the asymmetrical palpebral fissure in from 10 to 13 per cent of tuberculous patients. The symptom of the upper lip is almost an exclusive factor in localized disorders of the cervical sympathetic nervous system but can also appear in generalized sympathicotonia. The author advises further research.

Menstrual Disturbances as Affected by Hormones.—Van der Hoeven aims to throw light on the physiology and pathology of the menstrual cycle. He is aware that his theories are based on many hypotheses not fully established, but the success of his treatment has induced him to publish this preliminary report of his experiences. In his treatment of the various disorders of menstruation, he proceeds on the supposition that the wrong functioning of one or more endocrine glands is the cause. When a woman suffers from scantiness of the menstrual discharge, it may be due to underfunctioning of the thyroid. Overfunctioning of the suprarenals may likewise play a part. The hypophysis, owing to impairment, may produce too little prolan B, and, finally, the ovaries may be impaired. In some cases the disorder may be traceable to an abnormal functioning of all these four glands. In choosing the form of treatment, one will often find it difficult to decide what particular gland is involved in a given case. The author follows this method: If the menses are too profuse and the thyroid is enlarged, he prescribes epinephrine. Nearly always this medication is more or less successful. If, however, the loss of blood following the administration of epinephrine is increased, the blood flow without doubt is not menstrual but due to follicular bleeding. In that case, thyroid must be given. If, on the other hand, the thyroid is enlarged, there is strong likelihood of a disorder of the hypophysis and possibly also of the ovaries, and the treatment must be changed in that direction. If the blood flow is scanty (when the thyroid is not palpable) thyroid tablets should be prescribed. If, however, the thyroid is normal or too large, epinephrine must be administered; for the scanty blood flow is due to the fact that a partially mature ovum has been discharged, with the result that the quantity of lutein formed is too small and the blood flow too scanty. A discharge that contains many blood clots may be an indication of a follicular bleeding, but it may also be due to the fact that, owing to the scanty lutein formation, too little of the coagulation-preventing ferment is formed, especially since, during the menstruation, there is a reduced sympathicotonia. Thus, in this last case, thyroid tablets must first be given, in order to stimulate the formation of prolan B, and later, during menstruation, epinephrine in order to enhance the sympathicotonia. When the patient reports, after a few months, on the effects of the tentative treatment, the author is able to form a much more exact opinion as to the cause of the disorder. He then establishes a new diagnosis. In this manner, with the cooperation of the patient, good results can usually be secured.

*Pernicious-Like Anemia of Pregnancy. Conc'n. V. Aalkjœr.—p. 918.
Pirquet Tests in Ejde Medical District in Faroe Islands. R. K. Rasmussen.—p. 926.

Pernicious-Like Anemia of Pregnancy.—Aalkjœr cites from the literature thirty certain cases of pernicious-like anemia of pregnancy. He reports a personal case, in which liver treatment together with blood transfusion was followed by an immediate rise in blood values with the pregnancy uninterrupted, and compares the reticulocyte reaction in this case with the one that occurs in the treatment of true pernicious anemia. The few cases with liver treatment during pregnancy which have been reported to date are discussed.

74: 939-950 (Sept. 17) 1931

*New Strain of Chicken Leukosis. J. Engelbreth-Holm.—p. 941.

New Strain of Chicken Leukosis.—Engelbreth-Holm reports on the first ten "generations" of a strain of transmissible chicken leukosis distinguished from other strains by a short incubation period (down to one week) after the first few passages, by being effective after the seventh generation in 100 per cent of the cases, and by consisting exclusively of erythroleukosis cases except for the first generation, with long incubation period, which consists of two mixed myeloid-erythroleukotic cases. Subcutaneous as well as intramuscular inoculation is effective. He is inclined to agree with Furth that the so-called lymphatic leukosis in chickens is not connected with chicken leukosis. The two other forms, erythroleukosis and myeloid leukosis, may be regarded as early and as late manifestations, respectively, of the same pathologic process.

Hygiea, Stockholm

Intracapsular Cataract Extraction. F. Kugelberg.—p. 689.
*Parathyroids and Calcium Metabolism in Organism. E. Ask-Upmark.—p. 704.

Parathyroids and Calcium Metabolism in Organism.—Ask-Upmark states that, in sixty-three out of ninety-two cases of parathyroid enlargement from the literature or from personal observation, there were diseases of the bones, forty-eight of the cases being instances of osteitis fibrosa generalisata. The parathyroid enlargement, practically always present in this disease, is probably to be regarded as a toxic adenoma primary to the disturbance in the bones and in the mineral metabolism. In the differential diagnosis of osteitis fibrosa generalisata, exploratory operation on the parathyroids should be done if necessary; and palpation of the neck, and particularly determination of the blood calcium are advised in all cases of more generalized involvement of the bones. Removal of the parathyroid adenoma (Mandl) has been done, with improvement in sixteen cases.

*Two Cases of Purulent Infection with Bacillus Influenzae Pfeiffer. E. Waaler.—p. 715.
*Case of Peculiar Perforation of Esophagus. P. Treider.—p. 721.
Crossed Plate Suture in Median Laparotomies. S. Høyer.—p. 724.
Crossed Plate Suture in Fracture of Patella and Similar Fractures. S. Høyer.—p. 728.

Mineral Metabolism in Pregnancy.—The Toveruds state that the negative calcium and phosphorus balance established by them three years ago in a number of primiparas in the last half of pregnancy seems to occur frequently but disappears after regulation of diet according to the recognized principles for a normal calcium and phosphorus metabolism. The negative calcium and phosphorus balance is experimentally proved to play a decisive part in the bone composition in the new-born, whether the diet deficiency is in vitamins, in the mineral salts calcium and phosphorus, or in both. To what extent pronounced rickets or osteoporosis with slight rachitic symptoms will be more marked in the child will then depend on the nature of the postnatal diet with regard to the important factors for calcification, unless the postnatal diet is so ideally balanced as to repair the inborn deficiency.

Exposure to Tuberculosis and Tuberculosis Infection in Childhood.—Ustvedt concludes from his investigation in Trondheim that even in the first years of school life the infection of Pirquet-positive children in cities occurs mainly outside of house and home. In Oslo as in Trondheim only about one fourth of the children between the ages of 7 and 15 are infected, although it is most likely that all children, at least after the age of 7, have been exposed to infection. This may point to unknown factors active in the threatened organism and temporarily able to prevent infection.

"New" Muscular Tumor: Case of "Myoblast Myoma."—Berner believes that he has lately seen, in a small specimen from the tongue of a young man, an instance of the tumor type described by Abrikossoff. The tumor has an organoid appearance, the connective tissue regularly inclosing the elements, so that pictures are seen which are strongly reminiscent of an alveolar sarcoma. Possibly because of this organoid characteristic, the tumor has no especial tendency to recur, in spite of the apparently marked "immaturity" of the cells. As far as the author knows, metastases have not been described.

Case of Keratoconjunctivitis from Acne Rosacea.—Mohn's patient had had acne rosacea for fifteen years and frequently recurring irritation of the eyes for nine or ten years, with intense rubor in the conjunctiva, without severe pain. A violent rosacea keratoconjunctivitis then set in, with ulcerations advancing to the center. Nonspecific protein therapy was instituted with sterile milk given intramuscularly, 1 cc. the first day, 3 cc. the next, increasing to 5 cc. every other day for a week, then every third or fourth day; in all, seven injections in two weeks. Local treatment of the eyes with resorcinol solution was given, together with treatment of the seborrhea and acne rosacea. Recovery followed.

Purulent Infection with Bacillus Influenzae Pfeiffer.—Waaler's first case was in an infant, aged 20 months, with cold and fever followed by painful swelling of the knee joint and symptoms of meningitis; death occurred after one month. A pure culture of Bacillus Pfeiffer was found in pus from the knee joint and also in the blood. In the second instance, in a man with chronic disease of the maxillary, sphenoid and ethmoid sinuses of fifteen years' duration, B. Pfeiffer in a practically pure state was isolated from the nasopharyngeal discharge. Both strains showed a typical growth of B. influenzae. The first strain gave complement fixation in the serum down to a dose of 0.0125 cc.; the other, down to a dose of 0.05 cc.

Perforation of Esophagus.—Necropsy in Treider's case revealed a slit, 7 cm. long, in the mucous membrane of the esophagus, presumably due to the sharp edge of a prune pit which had lodged in the patient's esophageal stricture and been forced through the membrane by the pressure of the rather stiff sound used by the patient.

Nupercaine Anesthesia Based on First Fifty Cases.—Thomsen used a 1:1,000 solution of nupercaine as a local anesthetic in various major and minor operations. Epinephrine was not added. He considers nupercaine an excellent local anesthetic in most cases. An instance of grave intoxication following the application of nupercaine points to the need of considerable care in its use.

Death During Nupercaine Anesthesia.—In Kühnel's patient, a girl aged 16, with Little's disease, spasms set in shortly after the injection of a dose of nupercaine well under the maximum according to the literature, and death occurred one hour after the start of injection. The case is regarded as a warning to use general anesthesia as far as possible in operations on patients with Little's disease.

Acute Nupercaine Intoxication.—In With's patient with exophthalmic goiter, the subcutaneous injection of 35 mg. of nupercaine in Heidenhain's anesthesia was followed by violent intoxication. Intradural injection was excluded, and the result is ascribed to the intravenous injection of 10 mg. of nupercaine at the most. Care is urged in deep injections in regions where there are chances of a partial intravenous injection.

Silicosis Among Women Employed in Manufacture of Abrasive Powder.—Gudjonsson reports six fatal cases of silicosis among women working for years, under primitive conditions, in the manufacture of scouring powder. Of the two survivors, one has marked silicosis; in the other, employed for five or six years, silicosis is not yet clinically demonstrable.

CHOLECYSTITIS AND CYSTIC DUCT OBSTRUCTION

SIGNIFICANCE IN THE FORMATION OF GALLSTONES RICH IN CALCIUM CARBONATE AND IN CALCIFICATION OF THE GALLBLADDER WALL: PRELIMINARY REPORT *

D. B. PHEMISTER, M.D.
ALLAN G. REWBRIDGE, M.D.
AND
HILLYER RUDISILL, M.D.
CHICAGO

Large gallstones in man consisting of a high percentage of calcium carbonate have been but rarely reported and no associated factors have been mentioned as specifically influencing their formation. In a study of seven cases diagnosed as such, the observation was made that in every case the cystic duct was obstructed by a cholesterol-bile pigment, or cholesterol stone, indicating that the duct obstruction was a precursor to and a determining factor in calcium carbonate stone formation in the gallbladder.

Following this obstruction the calcium carbonate was thrown out in large quantities, forming either a separate stone or a mold of the gallbladder which incorporated preexisting cholesterol-bile-pigment stones. A thick mucinous suspension of calcium carbonate may be found which has been described as "calcium milk bile" by Volkmann.[1] In some instances the deposit of calcium carbonate produced the roentgenographic appearance of very markedly concentrated tetiothalein sodium N. N. R. in a gallbladder that was either free from stones or contained radiotranslucent stones. In other cases there was in addition a deposit of calcium carbonate on the gallbladder side of the stone obstructing the cystic duct, thereby making it possible to diagnose the presence of duct obstruction as well by means of the roentgenogram. Four cases have been encountered among 235 cases of gallstones at the University of Chicago Clinics during the past three years and eight months. Three cases are from the outside. The first two cases are reported in full as illustrative of the condition, and the other five are summarized:

Case 1.—A woman, aged 44, had had repeated attacks of pain in the epigastrium and (curiously) left upper quadrant, extending to the left scapular region for the past fifteen years. Following an attack, cholecystography was performed, March 28, 1928. The roentgenogram taken before the dye was given showed a quarter moon shaped dense shadow in the gallbladder region (fig. 1). There was no change in density in the gallbladder region in the pictures taken after the dye was administered. A second roentgenogram taken seventeen days later showed a shadow of the same size which had taken on a serpentine configuration. In June, 1928, an abdominal hysterectomy was performed for fibroids, at which time palpation revealed a stone in the cystic duct. Following a moderately severe attack of colic another roentgenogram was taken, May 31, 1930. It revealed marked enlargement of the dense shadow in the region of the gallbladder, which had taken on an oval form, and there was a faint half moon shaped shadow in the region of the cystic duct (fig. 2). The patient continued to have slight attacks of colic at irregular intervals. Feb. 28, 1931, a roentgenogram showed slight enlargement of the shadow and a change in contour to that of a half moon. Three days later the shadow had the contour of an agar slant (fig. 3). The shadow in the region of the cystic duct had increased in density. Another roentgenogram, April 27, showed a return of the shadow to approximately the configuration of May 31, 1930.

At operation, April 29, 1931, the gallbladder was found to be moderately contracted and its wall thickened. A stone was found in the gallbladder and one in the cystic duct. Cholecystectomy was performed including the cystic duct containing the stone. A roentgenogram of the specimen (fig. 4) shows a large dense oval shadow in the fundus of the gallbladder, numerous flecks throughout its remaining portion, and an irregular half moon shaped shadow cast by the gallbladder side of the stone in the duct. An attempt at aspiration yielded a small amount of very thick mucus. A longitudinal section of the specimen (fig. 5) showed a cholesterol stone about 0.75 cm. in diameter in the first portion of the duct, with a white deposit on its side projecting into the gallbladder. There was a soft pliable white oval stone in the fundus weighing 4.580 Gm. The rest of the gallbladder was filled by a clear, very thick mucinous material which was dotted irregularly with white flakes. Chemical analysis showed 600 mg. of calcium per hundred cubic centimeters. The wall of the gallbladder was moderately thickened. Aerobic and anaerobic cultures of the mucin and of the wall were negative.

Microscopic sections of the wall revealed moderate fibrous thickening with scattered areas of round cell infiltration. The mucosa was intact in most of its extent but had disappeared over many of the villi, which showed an increase in the number of fibroblasts and round cell infiltration. Some of the villi showed glands markedly distended with mucus.

Chemical analysis of the white stone gave calcium carbonate, 85 per cent, and calcium phosphate, 2.5 per cent. The rest consisted of organic matter. There was no bile pigment or cholesterol.

The second case illustrates the type of calcium carbonate stone which was deposited about other stones forming a cast of the greater extent of the lumen of the gallbladder and giving the roentgenologic picture resembling concentrated tetiothalein sodium:

Case 2.—A woman, aged 55, had attacks of gallstone colic at irregular intervals for several years. There had never been jaundice but some of the attacks had been accompanied by fever. Physical examination was of no especial interest aside from

tenderness in the right upper quadrant. A roentgenogram (fig. 6) revealed a dense shadow conforming roughly to the outline of the gallbladder but incorporating irregular areas of greatly reduced density suggestive of bile pigment-cholesterol stones. Roentgenograms taken after administration of tetiothalein sodium showed no change in the shadow. At operation March 15, 1927, a thickened gallbladder was found contracted on stones with a stone obstructing the orifice of the cystic duct. Cholecystectomy was performed. On longitudinal section of the gallbladder its wall was found to be slightly thickened. There was a small amount of turbid fluid in the gallbladder that was not bile stained. The rest of the space was occupied by calculi. There was a soft oval white calculus 6 cm. long occupying the central portion. A small white calculus occupied the tip of the fundus and a brown calculus was wedged in the orifice of the cystic duct with a white cap on its gallbladder side. Three small brown pigment stones lay free alongside the large stone. The large soft white stone was found to contain several mottled grayish brown bile pigment-cholesterol stones on the inside.

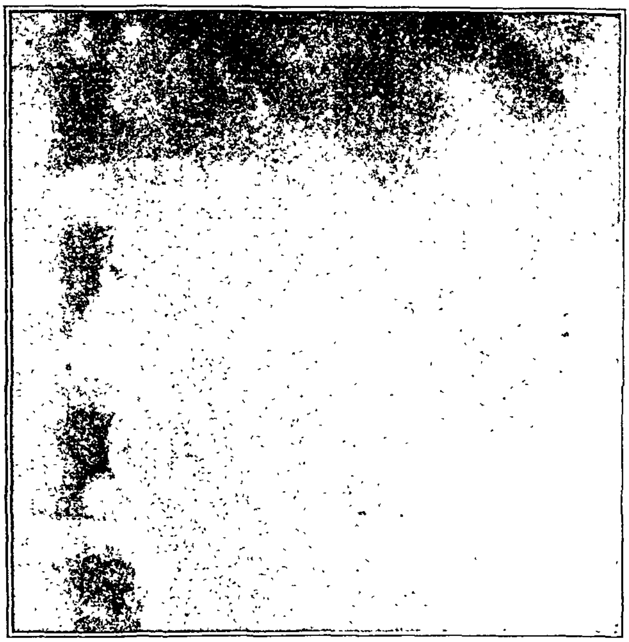

Fig. 1 (case 1).—Shadow in gallbladder region, April 23, 1928.

Cultures of the fluid in the gallbladder were negative. Microscopic examination of the wall showed moderate thickening with loss of mucous membrane and villi over about nine tenths of the surface lining. At irregular intervals there were small stretches of mucosa and of glands embedded in the deeper tissue. There was moderate fibrosis and round cell infiltration of the wall. Chemical analysis of a portion of the white material comprising the largest stone gave the following results: calcium carbonate, 75 per cent; calcium phosphate, 2 per cent; cholesterol, trace; bile pigment, 0; organic matter the remaining portion.

A summary of the observations in the remaining five cases follows:

Case 3.—A man, aged 65, had had mild attacks of gallstone colic at intervals for seven years. A roentgenogram showed a dense shadow in the gallbladder region of the shape and size of the gallbladder. Cholecystectomy was performed by Dr. E. M. Miller at the Presbyterian Hospital. There was a stone impacted in the cystic duct and a large one in the gallbladder. The gallbladder wall was moderately thickened. The lumen contained a small amount of yellowish green fluid and a grayish oval stone measuring 6.5 by 2.5 cm. with a brown pigment stone incorporated and showing at one end. The stone weighed 18.258 Gm. Chemical analysis of the gray stone revealed calcium carbonate, 80 per cent, calcium phosphate, 0.46 per cent; bilirubin present, and cholesterol absent. Because of the bile stained character of the fluid and interior of the stone there must have been some bile entering the gallbladder past the stone in the cystic duct.

Case 4.—A man, aged 32, had mild attacks of pain in the right upper quadrant at intervals for one year. He was never jaundiced or febrile. A roentgenogram showed a large dense cup-shaped shadow in the region of the fundus of the gallbladder with a smaller ring shaped shadow proximal to it. There was no change in the gallbladder shadow after injection of tetiothalein sodium.

At operation, stones were found in the contracted gallbladder and one in the cystic duct. Cholecystectomy was performed. There was 8 cc. of turbid mucous fluid very slightly bile stained. Chemical analysis of the fluid showed the following: p_H, 7.195; carbon dioxide, 5.55 volumes per cent; calcium, 163 mg. per hundred cubic centimeters; phosphorus, a trace. The gallbladder contained an oval white stone 2.5 by 1.25 cm. with two small bile pigment stones embedded on one side. Chemical analysis of the white material revealed: calcium carbonate, 74 per cent; calcium phosphate, 3.1 per cent; bile pigment and cholesterol, present in traces. There was a smaller cholesterol stone present which showed a calcareous deposit on one side. Cultures from the gallbladder wall yielded anhemolytic streptococci.

Case 5.—A woman, aged 26, had attacks of pain in the right upper quadrant at intervals for two years. A roentgenogram showed a large, somewhat irregular, dense shadow in the gallbladder region. No change occurred in the gallbladder shadow after administration of tetiothalein sodium. Cholecystectomy was performed. There was a stone impacted in the cystic duct near the common duct. The slightly contracted and thickened gallbladder, on being opened, was found to contain a milky white semisolid mass embedded in which were six small white stones. Cultures were negative. A chemical analysis of the white deposit showed it to be composed largely of calcium, but no attempt was made to determine the amounts of carbonate or phosphate present. The white stones were calcium carbonate.

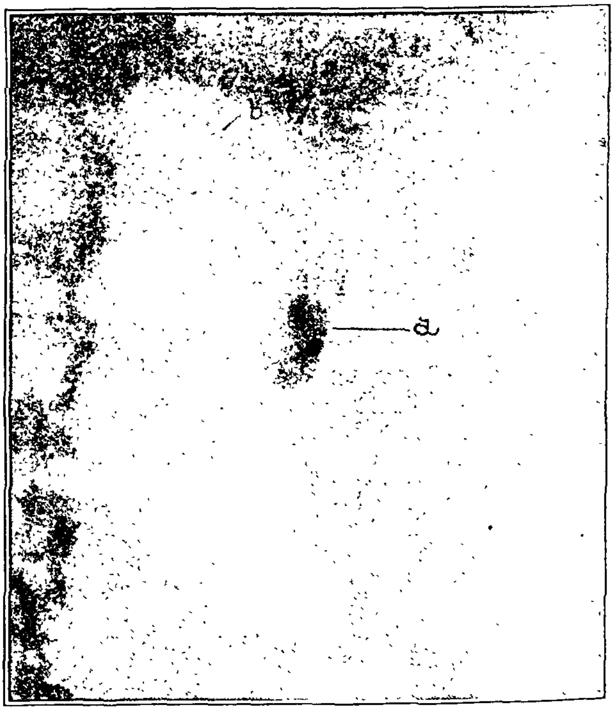

Fig. 2 (case 1).—Shadow in regions of (*a*) gallbladder and (*b*) cystic duct, May 31, 1930.

Case 6.—A woman, aged 31, had had attacks of pain in the right upper quadrant for five months. She had no jaundice or fever. Examination showed slight tenderness in the gallbladder region. Cholecystography was done and the roentgenogram taken before tetiothalein sodium was given revealed a dense shadow of the outline of the gallbladder and containing numerous negative shadows indicative of small radiotranslucent stones. There was a ring-shaped shadow in the region of the cystic duct. No change took place in the shadow twelve hours after the tetiothalein sodium was given.

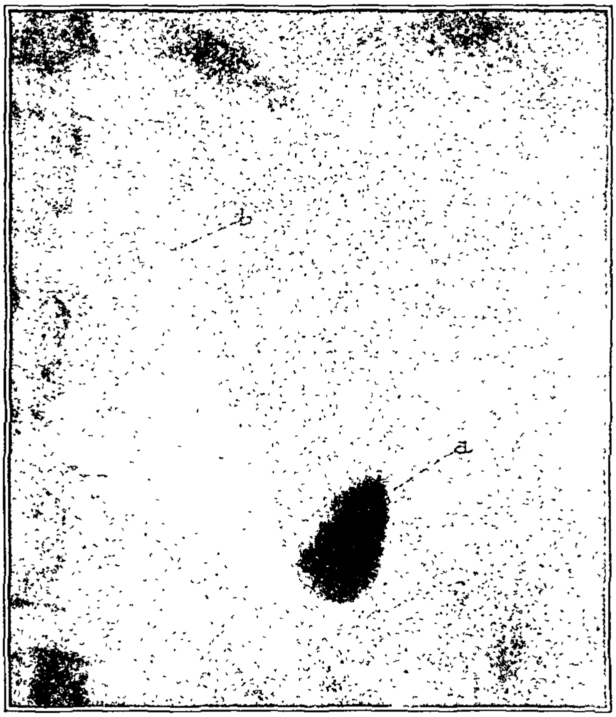

Fig. 3 (case 1).—*a*, gallbladder shadow and *b*, cystic duct shadow, March 2, 1931.

Case 7.—A woman, aged 37, had had attacks of gallstone colic for seven years. She had no jaundice and had never been severely ill. Physical examination showed no changes of especial interest. Cholecystography was done. The roentgenogram before dye administration revealed a large dense sausage-shaped shadow in the region of the gallbladder and a ring-shaped shadow in the region of the cystic duct. There was no change in the size and density of the shadow in roentgenograms taken after dye administration, but there was a change to a dumb-bell shaped form. A roentgenogram twenty-four hours later showed further change in form.

Patients 6 and 7 were not operated on, but in view of the similarity of roentgenographic observations in them and the other patients a diagnosis in each case of cholelithiasis with cystic duct obstruction and subsequent deposition of calcium carbonate in the gallbladder and on the cystic duct stone was made.

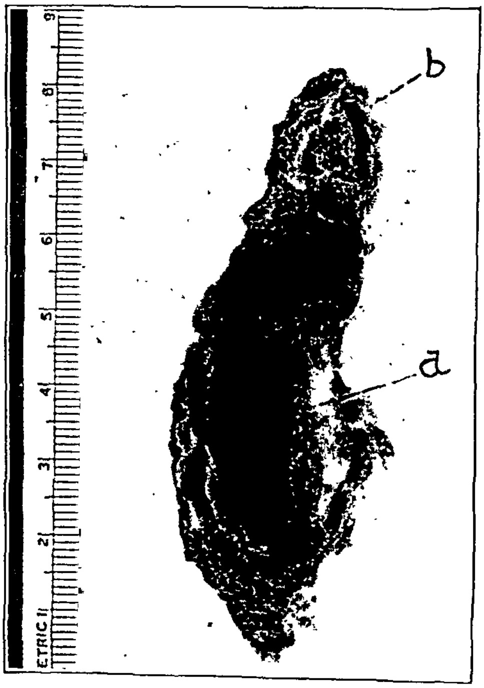

Fig. 5 (case 1).—Gallbladder and cystic duct incised showing (*a*) white stone in gallbladder and (*b*) gray cholesterol stone in duct with white deposit on its gallbladder side. Thick mucus containing white flecks filled the rest of the gallbladder.

COMMENT

It appears that the order of development of changes was as follows: First there was cholecystitis and cholesterol or cholesterol-pigment stone formation. The controversy as to the relationship between these two processes and as to which one precedes the other need not be discussed here. The cholecystitis was mild to moderate in grade, the mucosa showing the most marked changes, and the stones were multiple in at least five of the seven cases. A stone then passed into the cystic duct, lodging at various levels from the orifice to the common duct end. The obstruction was of high grade and in some cases the passage of bile into and of secretion out of the gallbladder appeared to have been completely blocked. Thus, in six cases tetiothalein sodium was administered and in no instance was there a shadow indicative of dye in the gallbladder region. The cholecystitis resulted in moderate thickening of the gallbladder wall and in serous exudation, but in no case was the gallbladder larger than normal and in most cases it was contracted. A moderate to a large amount of mucus was poured out. Calcium carbonate and a trace of calcium phosphate were then excreted by the wall of the gallbladder, forming a semisolid to soft white stone, incorporating other stones when they were present.

Hastings and Zachariasen of the University of Chicago demonstrated by x-ray spectrograms that the calcium carbonate present in three cases was in the crystal form of aragonite. The indications are that these calcium carbonate stones are formed only when bile is excluded from the gallbladder by the obstructing stone or when the amount entering it is greatly reduced. There is probably variation in the degree of obstruction in some cases with the variations in the amount of infection in the gallbladder and duct. The only direct references found to the subject were by Kaufmann,[2] who in discussing the pathologic condition of the gallbladder in cystic duct obstruction says that in some cases the gallbladder wall is degenerated and its cavity filled with a mortar-like mass of calcified thick secretion, and by Volkmann, who found the duct obstructed in one case.

---

[2] Kaufmann, E.: Lehrbuch der pathologischen Anatomie, Berlin, W. de Gruyter & Co., 1922.

No explanation has been found for the selective excretion of calcium carbonate over long periods of time in such cases, giving rise to these large white masses. It may be that it occurs only when the inflammatory process and the obstruction are of certain degrees of severity and chronicity. Certain it is that in most cases of cholelithiasis with cystic duct obstruction and hydrops, calcium carbonate stones are not formed. In the cases here reported the inflammation appeared to be mild and chronic and there was no history pointing to the previous existence of a severe acute cholecystitis. Wilkie[3] reported that, when he produced cholecystitis in rabbits by bacterial injection and ligated the cystic duct, gallstones rich in calcium were formed but that, when the duct was not ligated, stones composed of cholesterol formed. Naunyn[4] asserted that the calcium carbonate of all gallstones is poured out in connection with the mucin formed by the epithelium of the gallbladder. This is supported by the fact that the only other calculi consisting of as high a percentage of calcium carbonate are found occasionally in the salivary ducts[5] and in the pancreas,[6] where there is also mucous secretion.

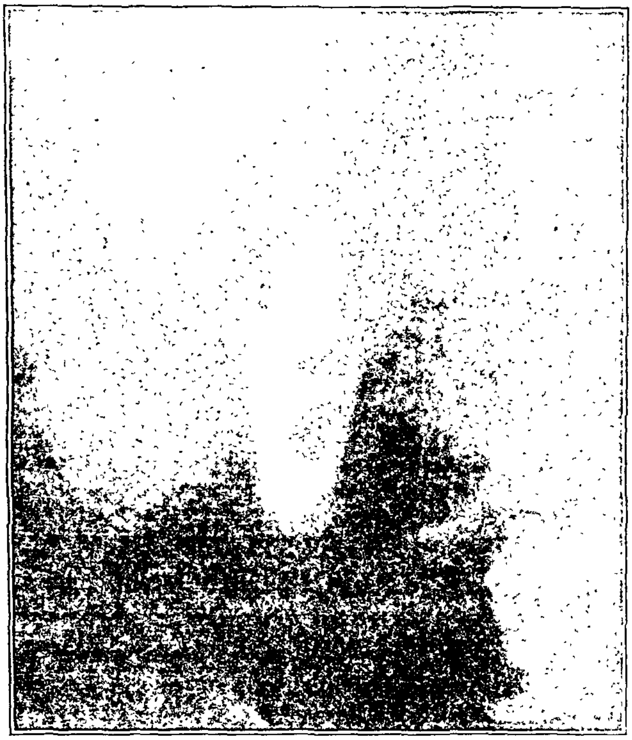

Fig. 6 (case 2).—Appearance before administration of tetiothalein sodium. The dense shadow is due to calcium carbonate, and the negative shadows are due to incorporated cholesterol and bile pigment stones.

The question arises as to whether or not the calcium carbonate deposited in layers on cholesterol or mixed cholesterol-bile pigment stones is excreted by the gallbladder during periods of temporary obstruction of its outlet.

CALCIFICATION OF THE GALLBLADDER

In cases of chronic calculus obstruction of the cystic duct with extensive degeneration and fibrosis there may be calcification of the gallbladder wall and of the wall of the cystic duct about the impacted stone. In three autopsy specimens that have been studied the cystic duct was completely blocked and the epithelial lining and glands of the gallbladder were entirely destroyed. The wall of the gallbladder was converted into fibrous tissue and the calcareous deposits were irregularly distributed throughout it. The wall of the cystic duct and the surface of the stone were fused by a calcareous deposit where they were in contact. In the gallbladder shown in figure 7 a chemical analysis of the calcareous deposit showed that it consisted almost entirely of calcium phosphate, which amount is unusually high for calcified tissue, although this process has the appearance of ordinary calcification of degenerating tissue. In a fourth case of calcification of the wall of the gallbladder the cystic duct was not obstructed by a stone but the gallbladder lumen was filled by a large stone and the cystic duct was obliterated by fibrous tissue at its orifice so that no bile entered the gallbladder. A review of articles on calcification of the gallbladder by Robb,[7] Talbot,[8] and Fowler[9] brings out the fact that the cystic duct was obstructed either by stone or by scar tissue growing over its orifice in nearly all the reported cases, although no special attention was called to the relationship between the obstruction and the calcification. In none of our cases was there found a combination of a calcium carbonate stone in the lumen of the gallbladder and calcification of the gallbladder wall, but Robb has reported a case which from the illustration appeared to be such. Robb believes that in some cases hypercontraction is produced by the stones, leading to fibrosis and calcification of the walls.

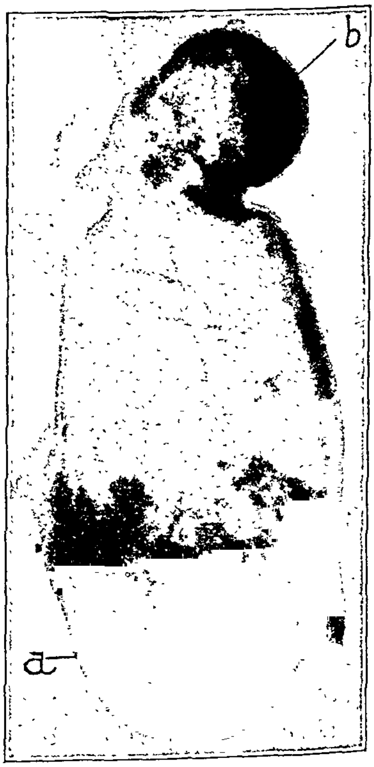

Fig. 7.—Roentgenographic appearance of specimen; cholesterol-pigment stone obstructing cystic duct with calcification of (*a*) wall of gallbladder and (*b*) wall of cystic duct and surface of stone.

CONCLUSIONS

1. Large calcium carbonate stones may form in the gallbladder in cases of cholelithiasis and cholecystitis with chronic obstruction of the cystic duct by a stone, and it appears that duct obstruction is essential for their formation. The calcium is apparently excreted by the mucosa of the gallbladder.

2. Calcium may also be deposited on the stone in the duct, so that the diagnosis of its presence as well as that of the calcium carbonate stones in the gallbladder may be made from roentgenograms.

3. Calculous obstruction of the cystic duct followed by extensive degeneration and fibrosis of the gallbladder may result in marked calcification both of its wall and of that of the cystic duct at the point of impaction.

"LIVER DEATHS" IN SURGERY OF THE GALLBLADDER *

CHARLES GORDON HEYD, M.D.
Professor of Surgery, New York Post-Graduate Medical School and Hospital
NEW YORK

From time to time there have appeared in the medical press a number of papers analyzing the causes of death following operations on the gallbladder and ducts. In a recent contribution by E. M. Stanton, 500 fatal cases were analyzed in a combined series of approximately 10,000 gallbladder operations. Even on casual reading one is impressed with the number of ascribed causes of death in this series wherein over thirty-eight individual causes were designated as the lethal factor. The causes of death given in the order of their frequency were peritonitis, pneumonia, embolism, cardiac failure, spontaneous perforation, sepsis and renal failure. It is rather surprising that so-called shock and hemorrhage constituted 10 per cent of the fatal cases.

In analyzing our mortalities at the New York Post-Graduate Hospital we were impressed with a small group of fatal cases in which the cause of death could in no way be placed under such obvious types of mortality. There was about this group of cases an unexplained chemical mechanism as the outstanding feature in the production of death, and which was directly sequential to operative intervention.

We were able to distinguish with variations three distinctive types of death following gallbladder surgery and for want of a better term we have designated them as "liver deaths" and apparently due to a change in the physiologic status of the liver-gallbladder unit.

Type 1 is best depicted by a history of a typical case. A woman, aged 37, entered the Post-Graduate Hospital complaining of gas after eating and occasional pain in the right upper quadrant. There had been one attack of pain requiring a hypodermic of morphine. On examination the blood count was normal, the Wassermann test was negative and a phenolsulphonphthalein test for kidney function was normal. The patient was operated on at 9 o'clock in the morning. A simple cholecystectomy was performed, the common duct was not involved, and nothing noteworthy was found in the pancreas or in the remainder of the abdomen. The liver, however, showed a slight enlargement. The edges were crenated, the consistency was leathery. From the area of the gallbladder region was a white, rosetlike tissue, extending well over the dome and inferior surfaces of the right lobe of the liver. The patient had a simple ether anesthesia. The immediate postoperative reaction was normal. However, the patient did not completely come out from the anesthetic and was not awake by 3 o'clock in the afternoon. At the end of twelve hours the patient was decidedly lethargic or semicomatose and there was a gradual ascent in temperature, successively through 102, 103, 104, 105 and 106 F. The pulse rate and respiration paralleled the temperature rise. The chemical examination of the blood showed a normal icteric index and a gradual ascending scale of urea nitrogen. Clinical examination of the lungs gave no evidence of pneumonia. The patient died at the end of thirty-six hours.

We know that there is a close association in temperature regulation between the heat center of the brain and the heat production in the liver, as one third of the heat production of the body is due to liver activity. According to Crile, when the temperature of the liver is reduced 1 degree the chemical activity of the organ is reduced 10 per cent and it is possible when the abdomen is opened for the temperature of the liver to fall from 1.5 to 3 degrees even if the viscus is not directly exposed. Furthermore, when as the result of hepatic exhaustion incident to disease or surgical intervention, the chemical activity of the liver is reduced to 10 per cent of its normal capacity, death will occur. The anatomic result of cholecystectomy is the removal from the liver of an infected gallbladder, leaving a gallbladder fossa of varying degree of surface area capable of protein transudation and absorption together with a sudden change in the hydrostatics of bile flow.

Deaver, Pfeiffer, Sudler and Braithwaite have contributed noteworthy papers on the lymphatic and vascular association of liver, gallbladder and pancreas, and to a lesser extent of the viscera of the lower abdomen. It is not without significance that there is no anatomic block in the lymphatics between liver and gallbladder, the lymphatic channels passing uninterruptedly from gallbladder to liver and from liver to gallbladder. It is also noteworthy that lymphatic drainage from the area of the cystic duct and Calot's triangle is along the common duct to the under surface of the pancreas. The clinical association of pancreatitis and gallbladder disease is not without its effect on the reparative power of the patient. In addition to the functions usually ascribed to the liver, there is the ability of the bile acids to combine with the alkaline metals. The gastric chyme which leaves the stomach has an acidity of p_H 3 and is neutralized by an alkaline bile to give a duodenal mixture of a p_H of approximately 11. In alkalosis there are some changes in these differentials, but up to date we have found no constant factor of variation.

Clinical and laboratory studies indicate that both acidosis and alkalinity are associated with marked liver impairment and ketogenesis, and later with secondary kidney failure. In the type of mortality listed under type 1 there was no evidence in the preoperative study to indicate any renal impairment, either actually or potentially. In the past five years we have had fourteen gallbladder cases with a carbon dioxide combining power of over 80 volume per cent and of this group six patients died, with a clinical picture of stupor, hyperpyrexia and rapid death. In the fatal cases no alkali had been administered preoperatively and all exhibited a condition of pronounced alkalosis, as shown in the accompanying chart.

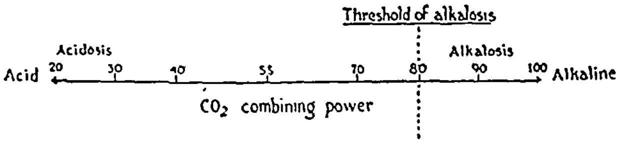
Type 2, a form of liver death much more infrequent than type 1, has occurred in patients who have had a previous cholecystectomy and rarely a drainage of the common duct. The patient is jaundiced, and the secondary operation consists of a choledochotomy, with T tube drainage. For the first few days after operation the postoperative course is normal and satisfactory.

---

* Read before the Section on Surgery, General and Abdominal, at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 11, 1931.

Then there is a distinct change in the character of the drainage. The biliary discharge becomes less and less in amount and more watery in consistency. In spite of the constantly diminishing jaundice, as shown by the decreasing icteric index, the patient becomes delirious; there is marked cerebral excitation, subsultus tendinum and carphology occur and finally stupor and coma. There is no clinical evidence of intra-abdominal hemorrhage or infection, yet in spite of a diminishing jaundice, coma develops, which in all of its clinical manifestations is similar to that which occurs in a terminal cholemia. By reason of the marked cerebrospinal irritation, spinal puncture has been made and practically normal fluid obtained with a slight globulin reaction and cell count of 9 or 10 cells per cubic millimeter. What has been the effect of the more or less sudden removal of the common duct obstruction? Have we induced a secondary acute reactive hyperemia in an already compromised liver? Do the liver cells function for a short time postoperatively and then fail?

Type 3 occurs much less frequently than either type 1 or type 2 and apparently is more amenable to treatment. These patients have diseases of the common duct and pancreatitis, do not have jaundice, and for the first twenty-four to thirty-six hours after a choledochotomy with T tube drainage have an apparently normal postoperative course. Then the pulse rate becomes markedly accelerated. The patient becomes markedly prostrated, with a fall in blood pressure and a cessation of urinary secretion, and exhibits cold, clammy, moist extremities. The abdomen is without any clinical evidence of infection, hemorrhage or any unusual postoperative abdominal condition. A negative gastric lavage demonstrates an empty stomach and no gastric dilatation. One is impressed that while the clinical condition herein presented is very similar to shock it occurs from twenty-four to thirty-six hours after the operation and seems to be a complete vasomotor collapse from an overwhelming intoxication, probably of pancreatic origin. Transfusion and repeated infusions of physiologic solution of sodium chloride with 10 per cent dextrose are usually sufficient to save the patient.



An increase in the carbon dioxide combining power toward 80 indicates an alkalosis; the reverse, an acidosis.

From a practical point of view, the acid-base balance of blood plasma should be accurately determined preoperatively in all cases of gallbladder disease.

In the postoperative treatment of gallbladder cases, chief consideration should be given to the following:

1. A continuous and persistent effort should be made to combat the dehydration. This is best accomplished by using known quantities of fluid, through all channels —water with 10 per cent dextrose in the form of the rectal drip, physiologic solution of sodium chloride with 5 per cent dextrose by hypodermoclysis and physiologic solution of sodium chloride with 5 or 10 per cent dextrose solution intravenously. If the carbon dioxide combining power tends to the left, indicating a condition of acidosis, the dextrose is particularly beneficial because in the oxidation of dextrose there is a destruction of the ketogenic bodies. If the carbon dioxide combining power moves to the right, indicating an alkalosis, the administration of dextrose is primarily to prevent dehydration and in an important but secondary rôle to prevent protein destruction.
2. When vomiting is a conspicuous feature, with or without tetany, gastric rest should be maintained by an indwelling intranasal (Levine) tube.
3. If symptoms of tetany appear, 5 cc. of a 10 per cent solution of calcium chloride is given intravenously and repeated in eight hours if necessary.
4. Sodium bicarbonate should not be used in any form. As sodium bicarbonate is frequently employed for gastric lavage, it is particularly important to bear this point in mind.
5. It is essential to make repeated chemical determinations of the blood to control or indicate further therapy.

116 East Fifty-Third Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. PHEMISTER, REWBRIDGE AND RUDISILL, AND DR. HEYD

Dr. Damon B. Pfeiffer, Philadelphia: Dr. Phemister's contribution is another example of the fact that the cholecystogram is not an infallible indicator of the presence or absence of a surgical lesion of the gallbladder. This is not said in detraction of this valuable test, but the knowledge that false positives and negatives exist should sharpen the attention of the radiographer and the clinician. Dr. Heyd has drawn attention to a group of fatalities not readily explainable under the common causes of death. In some it seems probable that the outcome is due to some derangement, not thoroughly understood, of certain essential hepatic functions. It is well to appreciate the dangers that lurk in operations on individuals with a damaged liver. I should deprecate, however, the too facile adoption of such terms as "liver death" or "liver shock" to cover such deaths as appear mysterious and unexplainable. I suspect that some are not due to disordered hepatic chemistry but to fulminating infection of a sort not readily demonstrable. It is realized, as Dr. Heyd has said, that some of these deaths are due to disturbance of the acid-alkali balance of the blood, a condition that is usually preventable, and often remediable if recognized promptly and treated appropriately. I urge the more general adoption of his advice to employ the laboratory aids in detecting and in treating intelligently such chemical abnormalities. Alkalosis is especially liable to occur in connection with upper abdominal surgery. In all cases of so-called gastric dilatation or prolonged vomiting this condition occurs to a greater or less degree. The stomach tube, abundant fluids, sodium chloride, and dextrose are the specifics. In this type of surgery I am constantly exhorting interns to keep the stomach empty and the circulation full. There are exceptions to all rules. I have a patient, operated on for a gallbladder condition, a large man, who reacted badly to anesthesia and vomited profusely for three days. He had a high fever and low urinary excretion. Clinically I should have thought that he would exhibit alkalosis. To the contrary, the laboratory showed that he had an acidosis, which was explainable by the fact that he had renal insufficiency. The retention of abnormal acids more than counterbalanced the loss of acid in the stomach contents, to which the alkalosis is usually due. The warning against the use of sodium bicarbonate as a routine measure for gastric lavage or rectal instillation is important. I am glad the routine sodium bicarbonate rectal instillation has gone into the discard. Acetone in the urine does not mean acidosis. It may be present in alkalosis, in which case alkali treatment would greatly increase the danger. To a certain extent it is no longer necessary to postulate unknown chemical disturbances to explain clinical disorders. A more general use of recent contributions to blood chemistry is of great importance to the surgeon.

Dr. I. S. Ravdin, Philadelphia: Dr. Phemister and his associates have presented an extremely interesting pathologic picture of the calcium carbonate stone. One might speculate as to why hydrops did not occur more frequently in these cases. In my studies on calcium absorption from the gallbladder I have found that in the damaged gallbladder the bicarbonate concentration increases above blood level and at this time calcium is precipitated from the solution. The precipitation first occurs under the mucosa of the gallbladder, and as this increases the mucosa disappears and a calcium carbonate plaque occurs on the surface of the mucosa with mucosal degeneration. Undoubtedly certain of the deaths reported by Dr. Heyd are due to ligation of the hepatic artery which may be in an anomalous position. If this ligation is done accidentally at operation, death will occur in from twenty-four to forty-eight hours from hypoglycemia and an increase in nitrogen content in the blood, regardless of the type of therapy that is instituted. I have felt that anesthesia is an important factor in these cases. For some time I have preferred spinal anesthesia. Ether can at times, especially if previous liver injury exists, cause marked liver necrosis with an associated hyperpyrexia and nitrogen retention. The existence of alkalosis in the cases described by Dr. Heyd may have been due to persistent vomiting, as Dr. Pfeiffer said. I have felt that slow decompression of an overdistended bile duct is an important factor in these cases. It is well known that portal obstruction occurs with bile duct obstruction, and in perfusion experiments of the hepatic artery and portal vein, obstruction of the bile duct results in a steady retardation of blood flow into the liver. A sudden release of this pressure in the bile ducts causes an acute reactive hyperemia of the liver, and there is no doubt that in certain of these cases, death similar to the death that occurs after an acute decompression of an overdistended bladder may occur. I have been using a simple method based on the work of Gamble for correcting dehydration in my cases. I feel that it is more important to correct dehydration than to correct blood reaction. If the dehydration is associated with salt loss, physiologic solution of sodium chloride is used; if it is associated with fluid restriction, tap water is given by rectum. If ketosis exists, dextrose is given either with or without physiologic solution of sodium chloride intravenously.

Dr. P. B. Salatich, New Orleans: I was greatly interested to hear Dr. Heyd talk about some of these deaths that he couldn't account for. I am going to try to explain some of those unaccountable deaths. I shall take it for granted that the patient has been thoroughly studied before operation and that the proper technic is carried out in operating. I mean by proper technic that the cystic duct is carefully dissected and not mass forceps put on, catching lymph nodes (for very often there is a chain of lymph nodes right at the cystic duct) and that the gallbladder is removed, as is usually done, and so on. First is the interference with the liver function. That is a big subject with which all of us are concerned. For years I have been using epinephrine, with excellent results, and I know that epinephrine helps liver function. If I have a bad case I give epinephrine frequently in repeated doses, and if one gives solution of epinephrine to a normal patient, he gets a pretty good reaction from ten drops. In a patient whose liver function is interfered with, if one gives 10 minims of solution of epinephrine one can repeat that every three hours and that patient has very little reaction. After twelve, twenty-four hours, or more, the liver function, I believe, is restored, my patient begins to get quite a reaction from the epinephrine. Then I either stop or diminish the dose, depending on how bad the case is. I think it is wrong to wait until one can see the bulging of the stomach before introducing a tube. Very often one will find that twelve hours afterward the patient will have a good deal of ugly material in the stomach, and the stomach does not appear distended. Some of the patients that die in an unexplainable manner run along for twelve or twenty-four hours doing well, and then suddenly they become distended; they get depressed and have cold, clammy sweats and kidney interference and very often there is a history of alcoholism. There are three important danger signs: high temperature, acetone in the urine, and dilatation of the stomach. The patient may have either one of them alone and recover, but when he has all three together, generally the mortality is high.

Dr. Moses Behrend, Philadelphia: I believe that we have all encountered these sudden deaths after cholecystectomy, and, as Dr. Heyd has stated, the causes vary. They have been called liver deaths, but there are many causes about which nothing is known. Certainly chemistry plays an important part in the causes of death of these individuals. I have operated on patients, performed a cholecystectomy, and within twenty-four hours the temperature would rise to 106 and even 108 F., and the patient would die within twenty-four hours. These deaths are unexplainable. I believe there will be less of these liver deaths on account of the use of spinal anesthesia. I believe that in former years, prior to the universal use of spinal anesthesia, many deaths were due to rough handling of the site of operation. Spinal anesthesia has eliminated that altogether. One can make a dissection, such as has been spoken of here, in a very anatomic manner. There is another cause of death, and that is operating on acutely inflamed gallbladders. One should never operate on an empyema of the gallbladder in the acute stage. The great danger in waiting is supposed to be rupture of the gallbladder. I have seen only one rupture of the gallbladder in thirty years. I am sure that this need not be considered as an argument to operate on an empyema of the gallbladder immediately; an empyema of the gallbladder should be operated on a week or ten days after the inception of the attack. Ligation of the hepatic artery has been mentioned. I have done a lot of experimental work on the ligation of hepatic arteries, and I am sure it is one of the causes of death in these cases. Last year, I operated on a physician of this state and found a thrombosis of the hepatic artery. One half of the liver was pale and anemic; the other half was of normal color. In addition, he had an empyema of the gallbladder, which contained many stones; the gallbladder was removed. At the time of operation I told his accompanying physician that this case was a very serious one on account of the anemia of half of the liver. This is the first time I have seen a case of this sort.

Dr. Charles Gordon Heyd, New York: I think the discussion has brought out that all have had the experience of standing at the bed of a patient on whom one has operated that morning. One asks oneself: "What is the mechanism that is killing that patient?" A few hours later the patient is dead. The death certificate is made out: terminal pneumonia, heart failure, or uremia, three insecure diagnoses—terminal events. Some chemical change has taken place; whether it has been the unfortunate misadventure of the time of operation or something else, the result has been sequential to the operative intervention.

Dr. Dallas B. Phemister, Chicago: In reply to Dr. Ravdin as to the source of the calcium in these two types of lesions, there can be no question about its coming from the blood stream in the case of calcification of the wall of the gallbladder. No bile is entering the gallbladder, and calcium phosphate and calcium carbonate are deposited in its degenerating wall as in the calcification of other tissues. There is more question about the origin of the calcium carbonate which forms the gallstones. However, I believe that it is secreted by the mucosa of the gallbladder in the presence of obstruction of the duct. One of the stones weighed 18.5 Gm. and it is difficult to conceive of that amount of calcium carbonate coming from bile working by a large stone obstructing the cystic duct.

Etiology of Endometriosis.—In 1908 Cullen examined a number of specimens of diffuse endometrioma of the uterus, or diffuse adenomyoma as it was then called, and found as a result of his investigations that in places there was direct continuity between the endometrium proper and that contained within the tumor, and frequently an actual communication between the uterine cavity and several of the cystic spaces in the growth. This became known as the diverticular theory, and may be regarded as the simplest form of endometriosis. In certain other uterine endometriomata no such continuity can be demonstrated, and in these it must be assumed that the misplaced endometrium has reached its new situation by metastasis through the lymph vessels or venous channels of the uterine wall. Similar tumors not infrequently follow tuberculosis of the uterus or tubes, so it is possible that an inflammatory process may be a factor of some importance.—Dougal, D. D.: Remarks on Endometriosis and Endometriomata, *Brit. M. J.*, Nov. 21, 1931, page 929.

NEUROLOGIC SYNDROMES ASSOCIATED WITH HYPOGLYCEMIA *

ARCHIE D. CARR, M.D.
ST. LOUIS

Hypoglycemia as the cause of a variety of neurologic pictures has been most forcefully brought to attention during the past year by the coincidence of several similar cases which appeared in Barnes Hospital. One of these, which was referred to us with a previous diagnosis of epilepsy, was found to show a classic picture of hypoglycemia caused by an adenoma of the pancreas.[1] It was possible to demonstrate and remove the adenoma, with the disappearance of hypoglycemia and the clinical cure of the patient. A patient of Womack, Gnagi and Graham,[2] in whom an adenoma of the pancreas was demonstrated, had had periods of confusion and convulsive movements for over a year, had been placed on phenobarbital and considered as a brain tumor suspect. Another case,[3] diagnosed as syphilis of the nervous system, terminated fatally in convulsions. At autopsy a small adenoma of the pancreas was found.

ETIOLOGY AND INCIDENCE OF HYPOGLYCEMIA

Evidence accumulated during the past few years has demonstrated that hypoglycemia is by no means a rare condition. In its study, various workers have rather arbitrarily placed the fasting blood sugar level at figures ranging from 70 to 90 mg. per hundred cubic centimeters of blood, the most generally accepted level being 70 mg. or lower.

Since the discovery of insulin, values for blood sugar below normal levels have been described in a number of pathologic conditions. Seale Harris,[4] in 1924, first hypothecated a "hyperinsulinism" which should produce a definite picture of hypoglycemia and its concomitant symptoms. At that time he reported three cases with fasting blood sugar levels from 47 to 67 mg. per hundred cubic centimeters which showed weakness, ravenous hunger and nervousness. Harris advanced the idea that hyperactivity of the islands of Langerhans causes the sensation of hunger and a greatly increased consumption of carbohydrates.

Experimentally, many drugs having a toxic action on the liver, such as chloroform, phosphorus and hydrazine, will produce a hypoglycemia apparently secondary to the decreased glycogen store in the liver. Removal of parts or all of the liver causes a marked or fatal hypoglycemia.

Porges,[5] working with cats, states that the removal of the suprarenals is followed by a hypoglycemia reaction.

Jonas,[6] in his survey of the literature, pointed out that hypoglycemia is found associated with so many conditions that it may be ascribed as a causative factor in the production of weakness and easy fatigability.

Holman[7] cites three cases, one in detail, which, twenty-four hours following subtotal thyroidectomy, showed low blood sugars with symptoms of semistupor, extreme restlessness and marked weakness. He calls attention to the fact that the immediate effect of the active thyroid substance is to produce a tremendous increase in general body metabolism, necessitating a utilization of all the available carbohydrates, including the glycogen reserve in the liver and in the muscle tissues. Eventually, if sufficient active substance has been taken up by the circulation, the consumption of all available carbohydrate takes place and hypoglycemia supervenes.

Schwarz,[8] in 1926, reported a case in which a patient in late pregnancy suffered from moderate hyperthyroidism. This patient, following a sugar tolerance test, showed a series of low blood sugars with complaints of weakness, nervousness and periods of anxiety. He suggested that these lowered blood sugars could be accounted for by a combination of two factors: the storage of carbohydrates by the fetus during late pregnancy and the depletion of glycogen stores consequent on the hyperthyroidism.

During the past few years, several authors have presented cases of hyperinsulinism due to disease of the pancreas. In 1926, Warren[9] was able to collect fifteen cases of benign tumors of the pancreas and report five of his own. In his series he studied only the pathology, with no correlation of clinical and pathologic data. Margaret Smith,[3] in searching for the cause of death in a patient who had been known to have syphilis, found an adenoma of the pancreas. Blood sugar as low as 58 mg. per hundred cubic centimeters had been recorded in this case.

Wilder and his co-workers[10] stimulated interest in hypoglycemia and hyperinsulinism by their classic study of a case of carcinoma of the pancreas. It was demonstrated that the hypoglycemia was definitely associated with an overproduction of insulin and its constant liberation into the blood stream.

Thalhimer and Murphy[11] report a case of adenoma of the pancreas, demonstrated at autopsy, which occurred in a patient who, for two and a half years, had suffered from attacks of stupor which had been complicated by epileptiform seizures during the year before death. At no time during the observation of this patient had the blood sugar been over 60 mg.

McClenahan and Norris[12] likewise reported a case of adenoma of the pancreas demonstrated at autopsy, in which hypoglycemia was present. Howland and his co-workers[13] reported the first cure by removal of a tumor of the pancreas in a patient with hypoglycemia.

Allan[14] and others have reported cases of hypoglycemia not necessarily due to focal disease of the pancreas, yet presenting as characteristic a picture. Hartmann,[15] in 1929, added a case in a man, aged 43, with blood sugars as low as 32 mg., who died with symptoms suggesting hypoglycemia.

Waters[16] reported three cases of paroxysmal tachycardia associated with hypoglycemia and repeats the belief that prolonged high carbohydrate diet stimulates

excessive insulin formation with a resulting spontaneous hypoglycemia.

Suprarenalectomy may be accompanied by hypoglycemia and, according to Britton and Silvette,[17] may be controlled by the use of extracts of suprarenal cortex, prepared according to the method of Swingle and Pfiffner. This cortico-suprarenal hormone, however, has no effect in relieving the hypoglycemia and convulsive reactions following the administration of insulin, varying in this respect from epinephrine.

SYMPTOMATOLOGY

Nervous symptoms form a predominant part of the clinical picture of hypoglycemia. They are varied and numerous, although not all of them are present in any one case. They seem to depend on the hypoglycemia itself and are not materially modified whether the lowered blood sugar is caused by administration of insulin, by liver damage or by pancreatic tumor. The intensity of symptoms, moreover, seems to bear a more or less definite relationship to the degree of hypoglycemia. Moderate lowering of blood sugar values is accompanied by ravenous hunger, sweating, restlessness, anxiety, and weakness which has been so striking as to suggest to some observers that cases of supposedly organic weakness may have a similar origin. McCrudden and Sargent[18] believe that the hypoglycemia (64 mg. per hundred cubic centimeters) in their case of progressive muscular atrophy was the cause of extreme weakness, for when they increased carbohydrates sufficiently to raise the blood sugar level they brought about an increase in strength and weight.

Nervous Symptoms in Spontaneous Hypoglycemia

Author	Cause of Hypoglycemia	Nervous Symptoms
Holman........	Thyrotoxicosis.........	Stupor, restlessness, weakness
Schwarz........	Hyperthyroidism; late pregnancy	Nervousness, anxiety, weakness
Smith...........	Adenoma of pancreas..	Stupor; convulsions
Wilder et al.....	Carcinoma of pancreas	Restlessness; anxiety; stupor; convulsions
Thalheimer and Murphy	Adenoma of pancreas..	Periods of stupor, convulsions
Howland et al..	Adenoma of pancreas..	Hemiparesis with slurring speech, stupor, convulsions
Hartmann......	Unknown...............	Weakness, diplopia, confusion, stupor, convulsions
Womack et al..	Adenoma of pancreas..	Confusion, stupor, convulsions
Carr et al.......	Adenoma of pancreas..	Diplopia; confusion, stupor, automatic behavior

With more advanced hypoglycemia, patients become more stuporous, usually completely amnesic, not infrequently comatose. There may be twitching or actual convulsions, which have been mistaken for those of idiopathic epilepsy. Deep reflexes are diminished or abolished. Hemiparesis disappearing with restoration of normal blood sugar level was reported by Howland. Death may occur during the attack, but many cases have shown a surprising and somewhat mysterious tendency toward recovery after the attack has fully developed.

The picture of hypoglycemia resulting from overdosage of insulin is too well known to require any elaboration. It is of some interest, however, to detail the nervous symptoms that have been reported in connection with spontaneous hypoglycemia from different origins. These may be seen in the accompanying table.

Several of these cases are of such interest as to merit further comment. Womack, Gnagi and Graham's patient was a man, aged 44, who had had periods of confusion for over one year, a tentative diagnosis of cerebral tumor had been made, and the patient had been placed on phenobarbital. The attacks consisted of periods of confusion, talking at random, and convulsive movements.

Hartmann's patient with a definite hypoglycemia died of status epilepticus in an epileptic colony.

In Howland's patient, following several of the attacks of stupor the left arm and left leg were paretic, and, while at first this lasted only a few hours, in later attacks it remained for several days and was associated with a thick slurring speech.

In our patient it was possible to follow the progress of symptoms on several occasions over periods of from six to eight hours. With fasting blood sugars of from 72 to 86 mg. there were no symptoms. When the blood sugar fell to between 60 and 65 mg., there was restlessness, apprehension, and sweating with lethargy. Below the 60 mg. level the patient was unresponsive but moved with stimulation. With the level between 36 and 48 mg. the patient could not be aroused and had involuntary muscle movements of a convulsive character.

The outstanding feature of the history consisted of periods of sudden onset in which activity was continued, but with complete amnesia. On one occasion, about a year before he was first seen, the patient was dressing for mess, heard the bugle, but remembered nothing more until he found himself being examined by the adjutant. He had dressed clumsily, had appeared in the mess hall and had awkwardly begun to eat, when it was suspected that something was wrong. At another time, while with a friend, he had driven through a fairly busy section of a large city, had at least one minor accident, paid for the damage, and later had no recollection of the drive. During each of these episodes, behavior was entirely automatic, permitting him to dress himself and to drive an automobile. Following each of these episodes, he became stuporous and remained so for some hours. On the first occasion he remained stuporous for thirty-six hours before some compensatory and life-saving mechanism caused him to become sufficiently alert to take food, which promptly cured the attack.

COMMENT

The mechanism of the spontaneous recovery from fully developed attacks of hypoglycemia is by no means clear. Cannon, McIver and Bliss,[19] in experiments on cats, demonstrated a mechanism or series of mechanisms having the function of maintaining the physiologic percentage of blood sugar when there is danger of deficiency. They state that, if the blood sugar falls below a critical point in consequence of a deficiency, the splanchnic neurons of the sympathetic system are set in action as indicated by increased suprarenal secretion. Both the nerve impulses and the increased secretion of epinephrine have the effect of liberating sugar from the liver into the circulation, thus tending to restore the equilibrium.

In Wilder's and Howland's cases, as well as in ours, an increase in blood sugar was found following the administration of epinephrine; so at least in these cases there was an available supply of glycogen in the liver, which could be mobilized by such a mechanism. It seems possible that in our patient this mechanism might have been responsible for spontaneous recovery after fairly long periods of stupor.

[19] Cannon, W. B.; McIver, M. A., and Bliss, S. W.: Am. J. Physiol. **69**: 46 (June) 1924.

In this discussion it is not intended to imply that idiopathic epilepsy or other common neurologic conditions have reduced blood sugar or that hypoglycemia is a frequent cause of amnesia or hemiparesis. It is apparent, however, that mistakes may easily occur and that the early recognition of this condition is of the utmost importance. The symptoms which have been detailed are so distinctive that they can hardly be missed if the condition of hypoglycemia is considered at all. Most important in the diagnosis, therefore, is to have the condition in mind. To confirm or reject the suspicion of hypoglycemia, it is only necessary to determine the blood sugar level, which today is so simply performed that it should not be omitted in any doubtful case.

SUMMARY

No matter what the cause, hypoglycemia may be manifested by stupor, amnesia, muscular twitching or convulsions and a number of less striking symptoms, such as restlessness, weakness, anxiety and fatigability.

Diagnosis of various functional and organic nervous diseases may be made if the condition of hypoglycemia is not considered.

The diagnosis of hypoglycemia depends on a careful history of preceding symptoms, the recognition of coexisting diseases and, above all, the determination of the blood sugar level.

3720 Washington Boulevard.

ABSTRACT OF DISCUSSION

Dr. Eugene F. Traut, Chicago: Dresel produced hypoglycemia by stimulating the vagus and caused hyperglycemia by stimulating the splanchnics. Some hold that the hypoglycemic symptoms are due to overaction of the suprarenals, an effort of the organism to reestablish its blood sugar equilibrium. The pallor, rise in blood pressure, and dilated pupils substantiate this. The usual immediate sequence of an insulin reaction is a rise in the blood sugar. The symptoms consequent on lowering of blood sugar depend on whose blood sugar one lowers. I have intentionally produced lowering in patients in certain conditions. I have lowered the blood sugar to 46 mg. per hundred cubic centimeters without producing any symptoms at all. Children stand a low blood sugar much better than do adults. A school teacher, aged 36, had taken large doses of insulin with varying diets over a long period. She experienced frequent attacks of headache, dizziness and diplopia before her meals. She had showed slight edema of the disks. She was referred to a neurologic surgeon, and under exact control of diet and reduction of insulin the signs and symptoms disappeared. A child, aged 4 years, entered the hospital in a deep coma from acidosis. Large doses of insulin were employed. Acetone bodies disappeared from the urine. The coma continued, but her body became spastic. There was opisthotonos. She had strabismus, dilated pupils and positive Babinski signs. The diagnosis of tuberculous meningitis was considered, as the spinal fluid sugar level was normal. There was, however, no pleocytosis. Reduction of the insulin brought her out of the coma. Her right hand and arm were paretic for many weeks. Apraxia of the right hand persists. A man, aged 64, had had both legs removed at the thigh for diabetic gangrene, thus reducing the body volume considerably. On discharge from the hospital he was given a diet. He was not seen until two years later and within those two years, retaining that diet and dosage of insulin, he had changed personality. He was irritable and, at times, violent. Morphine failed to control him. Withdrawal of the insulin abolished the symptoms. He remained sugar-free. Dr. Carr's diagnosis, followed by the successful removal of the causative pancreatic neoplasm, should serve to emphasize the necessity of more frequently considering the possibilities of hypoglycemia in patients showing suggestive symptoms.

Dr. Frank N. Allan, Rochester, Minn.: The symptoms attributed to hypoglycemia do not always correspond to the level of the blood sugar. In diabetic patients treated with insulin the symptoms sometimes appear when the blood sugar is not subnormal; in fact, they may occur when the blood sugar is above normal. I have seen distinct symptoms of hypoglycemia with the blood sugar above 0.3 Gm. per hundred cubic centimeters. On the other hand, a subnormal level of the blood sugar may exist without the appearance of any symptoms. The blood sugar may be as low as 0.04 Gm. per hundred cubic centimeters without any symptoms. There is need for investigation to determine the exact cause of the symptoms which are attributed to hypoglycemia. In the diagnosis of hypoglycemia it must be remembered that, if a test of the blood sugar is made at a time when the symptoms are not present, the condition may be overlooked. At the onset of hyperinsulinism, the blood sugar may be unstable; it may be normal, or even much above normal after food is taken. Even the fasting blood sugar test made in the ordinary way may be practically normal. In some cases it may be necessary to have the patient miss his meals and undergo strenuous exercise in order to induce the appearance of the symptoms and make recognition of hypoglycemia possible. After our experience with the case studied at the Mayo Clinic four years ago, in which a tumor of the islands of the pancreas was found, it was thought that early recognition of similar cases and early operation might lead to cure of the condition. This hope was realized when Howland, Campbell, Maltby and Robinson at Toronto reported their case two years ago. Since that time three cases of hypoglycemia, including the one described by Dr. Carr, have been cured by removal of a tumor. The prospect of cure by surgical treatment is not always so satisfactory. To my knowledge, operations have now been performed on ten patients with hyperinsulinism. In five a tumor has been found; in four it has been removed successfully with cure. In five cases the pancreas has appeared normal. Resection of part of the pancreas has brought about some benefit, but there has not been complete cure.

THE RÔLE OF THE FEMALE SEX HORMONE *

ROBERT T. FRANK, M.D.
NEW YORK

To describe the rôle of the female sex hormone ten years ago would have been a simple matter, as this hormone alone would have had to be considered, the main attention then being focused on the corpus luteum.[1] Four years ago the situation became more complicated when Philip Smith,[2] and almost simultaneously Zondek and Aschheim,[3] showed that the prepituitary was necessary to activate the ovaries. A further complication was added when Hisaw[4] discovered an aqueous corpus luteum factor which affected the pubic ligaments of the gopher, and Corner[5] concentrated "progestin," the special lipoid extract of the corpus luteum.

Today, therefore, when analyzing the processes of the sex physiology in the female, it is necessary for one to consider all these chemical messengers. The structures to be analyzed now include the follicle,[6] which excretes female sex hormone alone except in pregnancy, at which time prepituitary hormone also may be found in the follicular fluid, the corpus luteum, which elaborates not only female sex hormone but "progestin," the placenta from which female sex hormone,[1] prepituitary hormone,[7] and, according to Collip,[8] "emmenin," another prepituitary-like substance, have been obtained, as well as at least two fractions from the prepituitary gland.[9] With so many hormones acting either directly or indirectly on the sexual sphere, it is not surprising that a basic analysis of the many phenomena encountered proves difficult. Yet the great majority of clinicians are satisfied to arrive at diagnoses, based on single predominant symptoms such as amenorrhea, oligomenorrhea, menorrhagia or metrorrhagia, due, as I shall show, to a number of hormonal variations, without making any attempt to investigate the hormone contents of the body fluids and excretions, although methods for these hormonal determinations are now available. In other disciplines of medicine such neglect would be frowned on as, for example, the failure to determine the basal metabolic rate in thyroid disturbances, to obtain electrocardiograms in cardiac disease, or to study the blood sugar in diabetes.

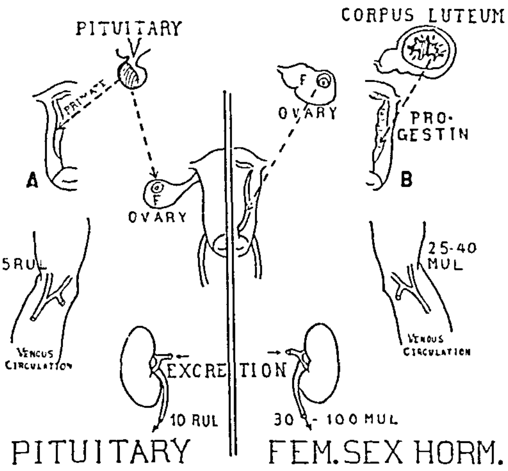

Fig. 1.—Schema of interaction, circulation and excretion of prepituitary and female sex hormones in the nonpregnant woman: To left: The prepituitary stimulates follicle (*F*) growth. In the castrate it can induce menstruation, according to Hartman (*A*). As much as 25 rat units per liter (R. U. L.) may be obtained from the venous blood; 10 rat units per liter from the urine. To right: The follicle (*F*) produces female sex hormone, which stimulates the endometrium, the rest of the tubular tract and the breasts. After ovulation the corpus luteum elaborates "progestin," causing the pregravid endometrial change (*B*). Before menstruation, from 25 to 40 mouse units per liter are recovered from the venous blood. From 30 to 100 mouse units per liter are excreted by the kidneys.

The female organism, from the neonatal age to the menopause, and perhaps beyond this critical period, is under the influence of the prepituitary hormone and the female sex hormone. After puberty, it is affected at intervals by the progestational hormone. The mechanism by which the female sex hormone influences the female tubular tract and breasts is well known.[10]

To summarize these various endocrine influences, the anterior lobe hormone stimulates the ovary to produce follicles (fig. 1). The follicle in turn elaborates the female sex hormone, which reaches the tubular tract (tubes, uterus, vagina) by means of the blood stream.[11] The tubular tract, after sufficient blood concentration has been reached, then undergoes the early premenstrual changes. Following ovulation, the corpus luteum develops. This transitory gland continues to produce female sex hormone as well as a special hormone, whose presence in the circulation has not yet been demonstrated, enhancing the local uterine and breast changes necessary for the nidation and early nutrition of the fertilized ovum. Among these changes, sensitization of the uterine mucosa, requisite for successful embedding, is particularly important.[12] If the corpus luteum is removed at this early stage, the ovum fails to secure the necessary firm hold in the endometrium and abortion results.[13] The chorion epithelium, later developing into the placenta, an important gland of internal secretion, takes up the production of both female sex hormone and prepituitary hormone. Probably as a safety factor the circulation is flooded with these two internal secretory products to such a degree that an enormous amount is excreted through the kidneys [14] and bowel [15] throughout pregnancy (fig. 2).

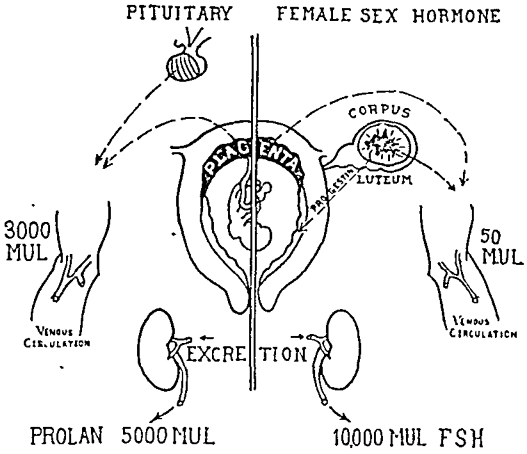

Fig. 2.—Similar schema of the pregnant female: To left: The prepituitary and placenta secrete prolan A and prolan B; 3,000 mouse units per liter can be recovered from the venous circulation, 5,000 mouse units per liter from the urine. To right: The corpus luteum and the placenta secrete female sex hormone (F. S. H.); 50 mouse units per liter can be recovered from the circulation, 10,000 mouse units per liter from the urine. "Progestin" is secreted by the corpus luteum at least during early pregnancy.

The clinical conditions to be covered in this paper have been limited arbitrarily to adolescents and mature women with functional disturbances. The discussion

will be further limited to the group of cases in which we have studied the hormone content of the blood and excretions.

In order actually to confine the survey to these groups, it is first necessary to exclude organic causes such as tumors (especially fibroids) or infection of the genital tract. Next, we have found it essential to discover whether patients who show disturbances in their sexual sphere are free from other demonstrable endocrine disease, such as the well understood classic syndromes, for example, Froehlich's dystrophia adiposogenitalis, thyroid overactivity or underactivity (recognizable as exophthalmic or toxic goiters, and myxedema) for in these conditions the genital disturbances are usually secondary. I have purposely tried to eliminate these secondarily genital deviations, as far as possible, in order to simplify the already sufficiently complicated problems encountered.

Among the primary functional diseases of the female, hyperfunctional conditions have proved most difficult to analyze. They include bleeding, either excessive in amount or too frequent in occurrence, or a combination of the two, often accompanied by symmetrical enlargement of the uterus.

The hypofunctional conditions, on the other hand, can be classified under the general headings of amenorrhea (also oligomenorrhea) and sterility, which embrace the large majority of cases. Rarely, continuous bleeding is noted in patients whose hormonal examination has convinced us that the underlying disturbance is of hypofunctional nature. This apparently anomalous phenomenon emphasizes the fact that little or nothing is known about the actual mechanism of menstruation, which until recently has been ascribed to the abrupt withdrawal from the circulation of the female sex hormone, with consequent changes in nutrition of the stimulated endometrium, manifested by bleeding.[16] According to the most recent work of Hartman,[17] however, it would appear that menstruation can be brought on in the castrate by prepituitary hormone alone.

Whether the finding of a small number of red blood cells in the vaginal washings can be regarded as "menstruation" in the rhesus monkey (which species normally, as well as after preliminary female sex hormone injection, menstruates freely for several days) requires further confirmation.

In addition to the usual clinical examinations, which, in those cases which are worked up, include a careful history, anthropometric measurements, basal metabolism, differential blood count, and, when indicated, sugar tolerance, sellar roentgen and visual field examinations, certain hormone tests should be performed.

This does not signify that every patient with menorrhagia and metrorrhagia of short duration, or every obese patient with amenorrhea is put to the trouble and inconvenience of having to submit to all these tests. Were this the routine, both patient and physician would have just cause for complaint of the overemphasis on laboratory investigation. On the other hand, the patient who bled from her fourteenth to her twenty-eighth year, during which time she was thrice curetted, repeatedly subjected to radium application, and referred to internists, gynecologists and psychoanalysts without ever having a basal metabolism and blood hormone tests made, had just cause for complaint.

The hormone tests which I advocate in properly selected instances include the evaluation of the female sex hormone blood level throughout a cycle, or, if no periodicity exists, over a period of from five to six weeks, with simultaneous determination of the hormone excretion through the urine. For the last six months we have extended our studies to the prepituitary hormone in the blood and urine, but are not as yet prepared to consider these data conclusive.[18] The technics are now sufficiently standardized to permit the study of a considerable number of cases each month in small laboratories not possessing special equipment.

A brief summary of the technic of these tests should suffice, as detailed descriptions are accessible elsewhere.[10]

FEMALE SEX HORMONE TEST OF THE BLOOD[19]

In testing for the female sex hormone, advantage is taken of its preferential solubility in lipoid solvents. The standard amount of blood used is 40 cc., which is dried with anhydrous sodium sulphate and fully extracted with ether. The ether soluble residue is injected into castrate mice, whose vaginal spread is examined according to the method described by Allen and Doisy.[20]

In the fully normal, fertile woman, one mouse unit can be demonstrated in 40 cc. of blood from seven days before the menses to the onset of menstruation (fig. 5 *A*).

FEMALE SEX HORMONE TEST OF THE URINE

After Loewe[21] had shown that the female sex hormone appears also in the urine, our our attention was increasingly directed toward the amount excreted through the kidneys. We use a simple technic consisting of automatic continuous extraction by means of chloroform, which, if run for ten hours, completely extracts the hormone (fig. 3). By running a combined sample (500 cc.) of the total urine collected over three days, injecting the chloroform residue corresponding to 100, 75, 50 and 30 cc. of urine, the number of mouse units per liter (M. U. L.) from 10 to 30 are quickly determined. If larger amounts of hormone are demonstrated by these preliminary tests, injection of smaller doses of extract supplies the necessary data.

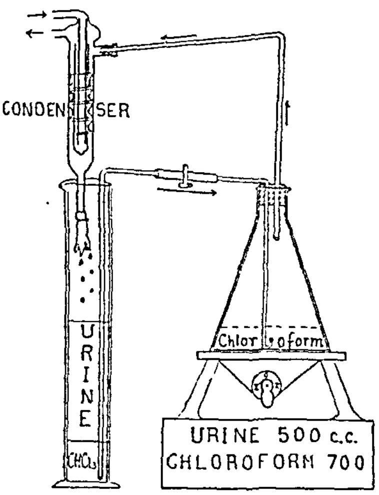

Fig. 3.—Apparatus for the automatic extraction of female sex hormone from the urine: The chloroform in a 2 liter flask on an electrical hot plate is distilled over and drips through the urine, collecting at the bottom of the cylinder. By siphonage it is returned to the flask, a 100 cc. turnover taking place every three minutes.

We have found that a normal woman excretes at least from 800 to 1,500 mouse units during an entire cycle. Two periods of maximum excretion correspond to the time of ovulation and from one to two days before menstruation (fig. 5 *A*).

PREPITUITARY MATURITY FACTOR TEST OF THE BLOOD

Our technic for evaluating the prepituitary maturity factor in the blood is based on the extraction of the residual blood and sodium sulphate mixture previously utilized for study of the female sex hormone. This residual powder, after having been freed of its female sex hormone content, is extracted with 60 per cent alcohol, at which dilution the prepituitary hormone is fully soluble but only a minimal quantity of sodium sulphate is dissolved. The alcoholic fluid is concentrated at room temperature by an air current, and when a volume of from 6 to 8 cc. has been reached the aqueous residue is injected into immature female rats weighing from 20 to 30 Gm. One hundred hours after the first injection the animals are killed, the ovaries sectioned and the amount of ovarian stimulation (manifested by the degree of follicle ripening) determined according to the standard described by Aschheim and Zondek.[22] Follicle ripening *alone signifies anterior pituitary reaction* I (*prolan* "A" effect, A P R I); blood spots signify A P R II; atretic corpora lutea A P R III (prolan "B").[18]

In the normal woman the greatest blood concentration is noted from six to nine days following the onset of the preceding menstruation. At this time as much as 25 rat units per liter (R. U. L.) of prolan A may be found. In a few instances a trace of the luteinizing factor (prolan B) has been noted.

PREPITUITARY MATURITY FACTOR TEST OF THE URINE

The prepituitary factor present in the urine is determined by the "concentration technic" described by Zondek[23] for the pregnancy test. We have found it of advantage to use 120, 100 and 80 cc. of acidified urine. To these amounts of urine four times their volume of 95 per cent alcohol is added. The prolan A and B are precipitated at this concentration, removed from the supernatant fluid by centrifugalization and freed from female sex hormone by washing with ether. The ether insoluble residue is dissolved in water and injected into immature mice.

Our data obtained from the urines are as yet incomplete.

By the preceding methods we are able to determine the female sex hormone level in the blood as well as the amount excreted in the urine.

An encouraging beginning for similar determinations of the prepituitary factor is under way. These results will be reported in a subsequent article.

Reichert, Pencharz, Simpson, Meyer and Evans[24] since this article was completed, have raised the question whether the maturity factor obtained from the prepituitary and the similar factor found in the urine of pregnant women, both called "prolan" by Zondek, are identical. His experiments show that the urinary "prolan" is ineffective after hyophysectomy. They further suggest[25] that the urinary "*prolan*" *may be an activator* of the inactive prohormone of the hypophysis and that possibly it converts the growth hormone into the gonad stimulating one.

CLINICAL APPLICATION OF THE HORMONE TESTS

Prepituitary.—The work along these lines has not as yet been sufficiently advanced to determine an absolute norm. Consequently no attempt has been made to draw conclusions from such abnormal cases as have been investigated. However, much evidence points to the fact that many of the ovarian functional disturbances eventually may be traced definitely to functional hypophyseal derangements.[18]

Ovarian Overfunction.—Puberty Bleeding: More than a dozen of these adolescents have now been followed for from six to three years. Both the clinical and the hormonal picture in every member of this group is alike. The abnormal bleedings may be of either the menorrhagia or the metrorrhagia type and eventually lead to grave exsanguination. In contrast to the abnormal functional bleedings of mature women, the blood hormone level for female sex hormone appears constantly high, so that an overloading of the circulation is demonstrated (fig. 4 *A*). Coincidentally the bleeding mucosa shows marked cystic endometrial hyperplasia. The urine excretion of these girls also demonstrates the marked overproduction of the hormone, as an undue amount is excreted constantly, often without typical cyclic variation.

Preclimacteric Bleeding: Climacteric bleeding of purely functional character likewise shows a high hormone blood level, but usually some cyclic variation is noted. The resulting endometrial changes strikingly resemble those of the puberty group although in most instances the myometrium appears to be simultaneously stimulated to hyperplasia (which, according to Teel,[26] is a prepituitary growth hormone effect).

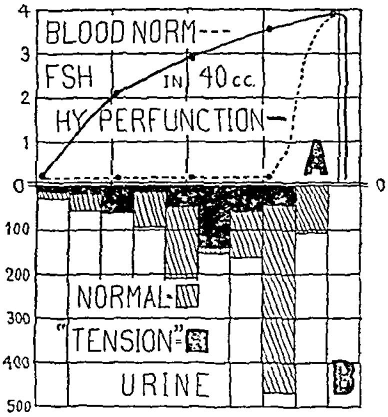

Fig. 4.—Graphs of blood and urine showing curve of female sex *hormone: The blood* represents the amount found in 40 cc.; the graph of the urine shows the total excretion in mouse unit hyperfunction. *A*, puberty and preclimacteric bleeding; dotted line shows normal function, solid line hyperfunction. *B*, urine of premenstrual tension: normal urine in shaded lines; "hypertension" due to underexcretion shown in solid black.

In another group, which I have named "premenstrual hypertension," the local genital symptoms may be absent, the entire clinical picture being dominated by the marked nervous and vascular symptoms preceding menstruation. These symptoms are explained by our hormone studies. In some instances the condition appears to be due to an overproduction of the hormone, as shown by the excessive amounts recovered premenstrually from the circulation (from two to three times normal), the excretion being normal (fig. 4 *A*). In other members of this group, I have gathered the impression that the overloading of the circulation is due to an underexcretion of the hormone, as the amount excreted during an entire cycle is less than half of that normally found in cyclic females[27] (fig. 4 *B*).

Maturity Menorrhagia and Metrorrhagia: Maturity menorrhagia and metrorrhagia has not been elucidated by our hormone studies. Occasionally a blood cycle can be demonstrated, apparently unaffected by the continuous bleeding. In the majority of cases, however, the blood tests prove negative throughout the cycle. Possibly, studies of the pituitary cycle may prove of value in determining the basis of these conditions. The endometrium may be at the normal resting stage, show typical cyclic variations, or be of the stationary hyperplastic type.[28]

Underfunction.—The hormone tests have proved most instructive in the study of hypofunctional conditions. The two main complexes, roughly classified according to the most striking clinical symptom, include amenorrheas and sterilities. The hormone investigations have shown that these general groupings include a variety of conditions.

Amenorrhea: Among the amenorrheas, three main types can be recognized. The first consists of amenorrheas with a definite blood cycle which, however, never reaches normal levels and which, therefore, I have called a "subthreshold cycle."

(*a*) Subthreshold blood cycle. These patients at more or less regular intervals show an accumulation of hormone in the blood, which, however, rarely reaches beyond 2 +, which, in our studies, we consider the lower limit for positive reactions. Such patients usually also show a typical urine curve with increase of excretion at the time approximately coinciding with follicle ripening or ovulation, and another period which must be compared with the premenstrual time, although bleeding does not occur (fig. 5 *B*).

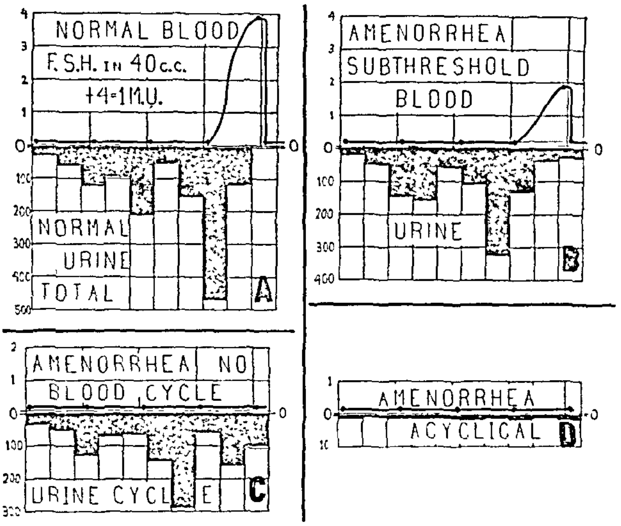

Fig. 5.—Graphs of specimens of blood and of urine showing curve of female sex hormone in the blood samples (40 cc.), as well as total mouse units excreted in the urine: *A*, normal fertile woman shown for comparison; *B*, amenorrhea (or sterility) with subthreshold blood cycle, and fairly normal urine cycle; *C*, amenorrhea without blood cycle but with urine cycle; *D*, acyclic amenorrhea.

(*b*) Negative blood cycle. In these patients frequent and long continued blood examinations fail to demonstrate accumulation of hormone with the amount of blood investigated (40 cc.). On the other hand, an excess of hormone is found in the urine over long periods of observation. We have been forced to explain this condition as due to an abnormal permeability of the kidney, in other words, a low renal hormone threshold, which contrasts sharply with some "premenstrual tensions" in which the renal threshold is abnormally high (fig. 5 *C*).

(*c*) Acyclic amenorrheas. In these, neither the blood nor the urine shows demonstrable quantities of female sex hormone (fig. 5 *D*).

Clinically these groups are indistinguishable, good subthreshold blood cycles having been demonstrated in patients with absent vaginas who have never menstruated. On the other hand, in acyclic individuals, the amenorrhea may have existed for only a short period, and yet the prognosis is poor.

Sterility: In every case of sterility spoken of in this connection, semen studies of the husband have shown potency, and mechanical (tubal stenosis) as well as inflammatory causes could be excluded. Among this group only a small number show normal hormonal conditions.

The majority of menstruating sterile women either show a subthreshold blood cycle (fig. 5 *B*), such as was described under amenorrheas, or negative blood conditions with urinary cycle present (fig. 5 *C*). Those cases in which sterility is combined with amenorrhea are explained by the hormonal changes accompanying the amenorrhea.

In the sterile types, also, the grouping and prognosis depends almost exclusively on the hormonal observations. However, as our experience has increased, stigmas noted in the individuals in whom these various hormonal changes have been studied enable us to predict with some degree of assurance what hormonal deviations may be expected. Lack of space prevents me from enlarging on this important phase of our investigations.

A generalization based on these hormone studies makes it evident that circulatory hormonal overcharge may result either from overproduction of the hormone or from hormonal underexcretion. In an analogous way, an undercharged circulation may be due to underproduction, overexcretion, or cessation of function.

Therapy.—With the preceding observations in mind, I feel justified in concluding that the present methods of therapy are not only illogical but in many instances scandalous. Some may be unaware of the widespread prevalence of dosing patients with inert commercial products. The point has been reached at which physicians, who in other disciplines of medicine are scrupulous, careful and sane, in this field prescribe ready made products solely characterized by number, containing heterogeneous mixtures of inert substances which include all but the hoof and hide of our domestic animals.

While such products as thyroid substance, insulin and parathyroid produce striking and concordant results in appropriate cases, the opposite applies even to the few potent extracts used in the genital sphere.

Our hopes have been dashed because of the fact that the potent female sex hormone does not cause the anticipated therapeutic results. This is fully explained since we recognize that this now purified substance acts solely on the tubular tract and, according to competent testimony,[29] when given in large doses over long periods, eventually causes sclerosis of the ovaries.

My investigations with all the supposedly potent anterior lobe preparations commercially obtainable have proved negative, as has also been found by Jannsen.[30] Attempts to utilize the high prepituitary hormone titer of pregnancy blood by means of transfusion appears nullified by the complete and rapid excretion noted by Erhardt.[31]

[31] Erhardt: Transfusion of Pregnancy Blood, Verhandl. d. Deutsch. Gesellsch. f. inn. Med. 42d congress, 1930, p. 87.

My associate, Dr. S. H. Geist, recently reported (at the last meeting of the American Gynecological Society) the negative results, as checked up by ovaries removed at operation, produced by as large a dosage as 1,500 rat units of the supposedly active prepituitary luteinizing factor.

My own efforts at therapy therefore have been directed toward influencing the underlying disturbances of the ovarian function by indirect means.

The Treatment of Overcharge (Hyperfunction): Our studies of puberty menorrhagia and metrorrhagia have convinced us that these conditions are usually self-limited or, as the older type of physician would have described it, are eventually outgrown. I therefore place these patients in the best surroundings available, at rest, with roborant diet, fresh air and sunlight. Not infrequently one or more curettages are necessary to relieve the bleeding temporarily. Transfusion may have to be practiced repeatedly. In several instances, two of my associates have resected the ovaries with good results, although at least two relapses have been noted. In two patients it has been necessary to give a reducing dose of x-rays almost to the point of amenorrhea. These two girls are now menstruating normally.

Injection of parathyroid, of insulin and of theelin, as well as large doses of calcium, have proved unavailing in our hands in this type of case.

The Bleedings of Maturity: The bleedings of maturity have likewise not responded to endocrine therapy. Here less hesitation has prevailed in employing the ordinary methods available to the gynecologist, such as curettage and roentgen therapy, as a majority of these patients have already borne numerous children.

In the preclimacterium, bleeding has been controlled by curettage, roentgen therapy or, in rare instances, the intra-uterine application of radium.

In the cases of "premenstrual tension" the overcharged circulation did not produce excessive bleeding. Renal (theobromine sodiosalicylate, caffeine) and intestinal elimination (salines) and limitations of fluids, combined with calcium therapy, has relieved a number of patients.

Undercharge (Hypofunction): A number of cases of amenorrhea have been found to be only secondarily due to ovarian disturbances. These include the symptomatic amenorrheas noted in tuberculosis, change of climate or secondary to other endocrine diseases, especially those of hypophyseal and thyroid origin. In these cases the underlying disease or condition, when amenable to treatment, has been attacked. Amenorrhea due to malnutrition, usually accompanied by moderate diminution in the basal metabolic rate and frequently mistaken as due to thyroid underfunction, responds in a gratifying fashion to a high protein diet.

I have been unable to influence the amenorrheas resulting from marked ovarian underactivity and in most instances have advised against the so-called stimulating dose of x-rays now advocated by some. The use of x-rays is never justified unless preliminary studies have demonstrated the presence of a subthreshold blood cycle, as otherwise already inert ovaries are completely destroyed from a functional standpoint. I have seen a number of cases in which irreparable damage has resulted from roentgen therapy applied for the relief of amenorrhea.

Taking for granted that the husband has been found potent and that inflammatory and mechanical causes, which so often coincide, have been fully excluded, the several varieties of sterility require different treatment. Most readily recognized among these groups are the constitutionally handicapped in which evidence of advanced infantilism, both local and general, proves that the genital organs have never been fully developed. When the thyroid function is markedly depressed, and unfortunately this group is small, thyroid medication is of sovereign value. We have reason to suspect that some of the sterilities are due to prepituitary functional disturbances, but the data at hand are as yet too scanty to be of convincing value. Great success is obtained by all, in the group of cases in which the sterility is transitory. Here wonderful and brilliant therapeutic results are recorded from every source. However, I have a large number of case histories available in which nothing whatever was done and fertility developed. In this group sex hygiene, dietary supervision (although I do not believe that the lack of vitamins plays any considerable rôle in the well fed human being), and reassurance of the patient are as effective as any therapy yet devised.

The climacteric symptoms, whether due to artificial or to the natural menopause, appear to result from a lack of female sex hormone in the circulation and an excess of prepituitary maturity factor as demonstrated by Zondek.[32] The results following the use of theelin—this appears to be its most useful field—have been too variable to be convincing. This product probably acts on the hypophysis by causing some regression of the pituitary castration changes. In my hands thorough elimination, in severe instances occasional venesection, and calcium in high dosage have proved as effective as female sex hormone therapy.

10 East Eighty-Fifth Street.

THE RÔLE OF PROGESTIN IN THE FEMALE REPRODUCTIVE CYCLE *

GEORGE VAN S. SMITH, M.D.
AND
O. WATKINS SMITH, PH.D.
BROOKLINE, MASS.

The term "progestin" was applied by Allen[1] and by Corner to the hormone of the corpus luteum, which maintains in a normal state of pregnancy rabbits castrated the day after mating. In experimental work, progestin has been found to produce most of the effects already known to be associated with the functioning corpus luteum. These functions are characteristic proliferation of the endometrium for the nourishment and implantation of ova, growth of the decidua, maintenance of pregnancy and inhibition of ovulation. Excess of progestin, by raising the threshold of uterine muscle by stimulation, has been shown to inhibit the delivery mechanism, with consequent death of pregnancy in utero. In addition, we have found[2] that progestin, through stimulation of the suprarenal glands, may have other functions, both metabolic and vasomotor. In the course of this paper another activity of progestin, in relation to the excretion of the ovarian follicle hormone, will be presented. Since the anterior portion of the hypophysis contains a hormone which stimulates growth of the corpus luteum, it is assumed with much supportive evidence that the production of progestin is conditioned by the presence of this luteinizing hormone.

* From the Fearing Research Laboratory, Free Hospital for Women.

* This work was facilitated by the aid of the Mrs. William Lowell Putnam Investigation of the Toxemias of Pregnancy, and the support also of Mr. Reginald W. Bird.

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 11, 1931.

* Through the hearty cooperation of Dr. John Rock, the Boston Lying-In Hospital and Dr. Frank A. Pemberton, the clinical application of the luteinizing hormone has been thus far made possible.

[1] Allen, W. M.: Am. J. Physiol. **92**:174 (Feb.) 1930.

[2] Smith, G. V., and Watkins, O.: Am. J. Physiol. **94**:586 (Sept.) 1930. Watkins, O., and Smith, G. V.: Am. J. Physiol. **96**:28 (Jan.) 1931.

In the human menstrual cycle the progestin secreted by the active corpus luteum following ovulation normally prevents further ovulation and brings about the characteristic premenstrual, secretory changes in the endometrium, the ovarian follicle hormone, estrin or folliculin, being a necessary factor in this process. The decrease in progestin toward the end of the cycle is followed by menstruation. To account for the rise and cadence of the corpus luteum and the concomitant variations in progestin, it is necessary, for the present, to postulate that when the graafian follicle reaches a certain stage in its growth under the influence of the gonad-stimulating hormone of the anterior hypophysis there takes place increased hypophyseal activity, with consequent ovulation and luteinization. Further, since progestin inhibits ovulation and also inhibits the action of pituitary transplants in causing maturity in rats,[3] it apparently depresses the pars anterior. It may be, therefore, that the regression of the corpus luteum is due to depression of the pars anterior by progestin.

Fertilization of the ovum is the normal occasion for survival of the corpus luteum and the continued action of progestin, which prevents menstruation and causes increased proliferation of the endometrium, sensitizing it for implantation of the ovum and decidual formation. This situation accompanies the appearance in the blood and urine of large amounts of the luteinizing hormone, the production of which is taken over from the anterior hypophysis by the trophoblast and later by the placenta. Although death of pregnancy in experimental animals follows the removal of progestin by ablation of the corpus luteum, in human beings pregnancy has been known to progress normally after early ovariectomy. Apparently, progestin is not a necessary factor for survival of pregnancy once placentation has occurred. This point is further borne out by the well known regression of the corpus luteum after the middle of gestation. In this connection some factor other than decrease of the luteinizing hormone must be sought to explain the regression of the corpus luteum in late pregnancy, for there is still much luteinizing hormone so long as the placenta survives. On the same basis, some factor other than progestin must account for the usual inhibition of ovulation in later pregnancy and lactation.

Although menstruation normally follows on the withdrawal of progestin, Hartman's[4] work on monkeys would indicate that the flowing is actually the positive effect of anterior pituitary activity in the presence of the folliculin accumulated during the previous cycle. It has already been stated that the follicle hormone is necessary for the endometrial proliferation caused by progestin. Thus folliculin, produced under the influence of the gonad-stimulating hormone of the anterior hypophysis, and progestin, produced under the influence of the luteinizing hormone of the same gland, are both synergistic and antagonistic. In their simplest form some abnormal conditions in the female reproductive phases are due to a lack of balance between these four factors. For example, insufficient gonad-stimulating activity by the pars anterior or inadequate ovarian response would make for amenorrhea or scanty menstruation and sterility. Evidence of this insufficiency is the genital hypoplasia so common in these cases, indicating too little follicle hormone, one of whose functions is to cause uterine and vaginal growth. Further, an abnormally persistent corpus luteum would also account for sterility and amenorrhea. This situation simulates the condition of pseudopregnancy as seen in animals. Administration of the gonad-stimulating hormone is indicated under these circumstances to override the corpus luteum, but as yet no potent preparation for clinical use has become available. The follicle hormone has been tried quite extensively, with only slightly encouraging results. We have used it in the form of theelin[5] and a crude but potent extract of urine from pregnant women, with partial and uncertain benefit. Giving this hormone alone would not be expected to remedy these conditions unless it activated the anterior hypophysis, but definite evidence of this is lacking. On the other hand, sterility might follow if the anterior hypophysis were too active, overriding progestin and causing menstruation before the fertilized ovum could become implanted.

By the same process of reasoning, abnormal menstruation may result from excessive activity of the gonad-stimulating hormone or excessive follicular response or from insufficient production of the luteinizing hormone or inadequate supply of progestin from the corpus luteum. Although, undoubtedly, other endocrine and constitutional factors are involved, administration of the luteinizing hormone or progestin is indicated. There is still no clinical preparation of progestin. We have given intramuscularly in various doses the luteinizing hormone, prepared from the urine of pregnant women by the method of Evans.[6] To date, eight patients with too frequent and excessive menstruation have been treated, causes for flowing other than endocrine having been eliminated. All were definitely relieved; one of these had dysmenorrhea also and was relieved. It is interesting that one patient complained of hot flushes following treatment. The luteinizing hormone failed to stop the flowing in a case of fibroids. Three other cases have been treated, with relief: a case presenting nausea and fainting spells at the time of menstruation, a case of pelvic inflammation with flowing, and a case of endometriosis with pain and flowing, unrelieved by previous conservative operation. It is still too soon to regard these early results as more than hopeful, but they indicate beneficial results following administration of the luteinizing hormone, either through a direct effect or through stimulation of progestin.

On the same basis, it was reasoned that insufficient progestin, by failing to maintain the decidua and thus impairing the vitality of the ovum, might be a factor in miscarriage. Seven other patients, from two to six months pregnant, were given the luteinizing hormone in total doses of from 50 to 100 cc. over periods ranging from five to twenty days. Of these, four were flowing, two were flowing and vomiting, and one was vomiting. All were managed clinically as cases of threatened miscarriage. In six, all flowing and vomiting ceased within ten days. The seventh patient had a marginal placenta praevia and was delivered. Three patients have since miscarried. The other three are getting along normally from two to six weeks after treatment. No conclusions can yet be made as to clinical results.

[5] The Doisy crystalline preparation supplied by Parke, Davis & Co.

[6] Parke, Davis & Co. and Dr. E. A. Sharp of that company cooperated in supplying us with this and other preparations.

For the present our chief interest centers in the change of endocrine balance in these pregnant patients following the administration of the luteinizing hormone. We have studied the folliculin of the blood and the urine by the Allen-Doisy rat test. A number of the patients had markedly high folliculin levels as compared with normal patients at the same stage of gestation. The blood regularly showed a decrease in folliculin, five or more days after the start of treatment. Having first satisfied ourselves that the amounts of folliculin in different specimens of urine can be compared satisfactorily in terms of urinary creatinine, we found that all these patients had definitely less folliculin in the urine when it was tested after from five to nineteen days of treatment. As a control, three of these patients were not given the luteinizing hormone until after a week of miscarriage routine, during which time there was no folliculin change.

This finding led us to study folliculin excretion in rabbits. We are using urinary creatinine again as a means for obtaining comparable results and are also measuring the twenty-four hour urine output for calculating total excretion. Preliminary experiments thus far indicate the following: Injection of large doses of theelin in normal and spayed doe rabbits results in only a little excretion, less than 10 per cent of the amount given. If luteinizing hormone is given before and with theelin, the normal rabbits show strikingly increased folliculin excretion, but the spayed rabbits do not show any increase. If progestin is given before and with theelin, there is a 50 to 75 per cent recovery in the urine in both normal and spayed animals.

These experiments show that progestin has another function; namely, that of promoting excretion of folliculin. Further evidence of this was found in one of the pregnancy cases mentioned in which the urinary folliculin was determined the day after the first injection. It was increased. By the tenth day it had decreased markedly. Since the folliculin in the urine as well as the blood of these patients decreased following continued administration of the luteinizing hormone, we have, in this, additional evidence of an inhibitory influence of progestin on the actual production of folliculin.

Although the clinical results of giving luteinizing hormone in early pregnancy are still too few to be used as a basis for any conclusions, we feel that the finding of marked drops in the folliculin level after treatment, together with the experimental discovery of the effect of progestin on folliculin excretion, indicates actual physiologic reactions which may in time have valuable clinical application.

SUMMARY

1. The functions of progestin and its rôle in the normal human menstrual cycle and in pregnancy have been briefly outlined within the limits of our present knowledge.

2. The luteinizing hormone which stimulates the production of progestin has been administered, with promising results, to nineteen patients whose chief symptom was abnormal flowing.

3. Early clinical and experimental evidence points to another function of progestin; namely, that of inhibiting the production of the follicle hormone and promoting its excretion.

THE HYPOPHYSEAL-OVARIAN RELATIONSHIP

QUANTITATIVE STUDIES WITH ESPECIAL REFERENCE TO HYPERPLASIA OF THE ENDOMETRIUM *

JOHN C. BURCH, M.D.

AND
R. S. CUNNINGHAM, M.D.
NASHVILLE, TENN.

Endometrial hyperplasia has long been one of the major problems of gynecology. Its exact etiology has been unknown, but its relationship to a disordered ovarian function has been recognized.

The material presented in this paper is taken from studies carried out on the etiology of endometrial hyperplasia [1] and on the functional relationship between the hypophysis and the ovary.[2] These studies suggest that certain disorders of the hypophyseal-ovarian relationship may have considerable importance in our understanding of endometrial hyperplasia.

In applying the results of animal experiments to the interpretation of conditions in human beings, much confusion has arisen on account of differences in terminology as applied to the estrual and the menstrual cycles.

Allen [3] has accurately described the estrual cycle of the mouse. The unmated mouse has a period of estrus every four to five days. This period is characterized by cornification of the vaginal epithelium. Ovulation takes place during the latter part of the estrual phase, but the corpus luteum remains inactive unless the animal is allowed to copulate. If copulation takes place with a vasectomized buck, a stage of pseudopregnancy results. This stage of pseudopregnancy corresponds to that phase of the human menstrual cycle lying between the fourteenth and the twenty-eighth days.

Two or three days before the onset of estrus in the mouse, the epithelium becomes markedly active, the gland cells multiply, and numerous mitotic figures are present. There is definite pseudostratification of the epithelium, and a fair amount of secretion is found in the glands. There is edema of the stroma. During pseudopregnancy the gland cells lose their pseudostratified appearance and become more regular. No mitoses are present, and there is some enlargement of the stroma cells. In the mouse, therefore, there are two distinct phases; one before ovulation and one after.

In the human being, following the cessation of the menstrual period, the uterine epithelium is of low columnar type. There are no mitoses and no secretion in the glands. The stroma is moderately edematous. After a few days the gland cells multiply, mitoses are present, and the mucosa increases in thickness. The edema becomes somewhat more prominent.

Following ovulation, the corpus luteum is formed. In the human being this structure functions irrespective of the act of copulation. In the uterus at this time (from sixteen to twenty-two days after the cessation of menstruation) numerous tufts or papillae project into the glands. The nuclei of the epithelial cells assume a more central position. There are no mitoses and there is no pseudostratification. The stroma cells increase in size and form a compact layer in the upper portion. Later, around the twenty-fifth day, the edema becomes quite marked. From this brief description it can readily be seen that the changes occurring in the human being are very similar to those found in the mouse.

The ovary has two known secretions, one first observed by Frank [4] and later studied more fully by Allen.[5] This has usually been called the "female sex hormone." In our opinion, it is more aptly designated as "estrin." Allen and Corner [6] have isolated another hormone, derived from the corpus luteum, which, when injected into rabbits, causes changes similar to those found in pseudopregnancy. By means of this extract of the corpus luteum, Allen and Corner have further been able to maintain pregnancy after the removal of the ovaries. Frank [4] has also shown that the estrus-producing hormone can be found in detectable amounts in the blood of human beings, beginning on the fourteenth day and increasing until menstruation.

It is fairly clear, then, that the changes preceding ovulation are the result of the estrous hormone and that the changes following ovulation are the result of the combined action of these two hormones. It is from this point of view that we have approached the problem of interpreting hyperplasias. These conditions have been thought to be the result of an ovarian dyscrasia, but it has not previously been possible to determine the type of this dyscrasia from the curettings.

Schroeder,[7] Shaw [8] and Graves [9] have all noted that, in their cases of Swiss cheese hyperplasias, no corpora lutea were found and that the ovaries were cystic. From this work the logical inference is that hyperplastic changes are the result of the unopposed action of estrin. We [1] have been able to confirm this hypothesis by comparing specimens of hyperplasia with the endometrium of spayed mice which had been injected with extracts of estrin and of corpus luteum and with a combination of the two. From these comparisons it was possible to demonstrate specific histologic pictures characteristic of each hormone.

Sections from twenty-eight cases of Swiss cheese hyperplasia were studied in the light of these comparisons and were found to be quite similar in many respects to the normal human endometrium of the sixth to the fourteenth day and to the endometrium of a mouse which had been injected with estrin. The Swiss cheese pattern is one of the most striking features of human hyperplasia but is not, in our opinion, of as great significance as the more minute changes of stroma edema, glandular pseudostratification and epithelial mitoses which are common in the estrin phase of the normal human cycle, in hyperplasia of the endometrium and in spayed mice injected with estrin. We have also observed two cases of typical Swiss cheese hyperplasia in which the ovaries contained no corpora lutea but did contain cysts of the graafian follicles. The fluid from these cysts was injected into spayed animals with the production of estrus. The endometrium of these experimental animals was quite similar to that seen in the respective human cases from which the fluid was obtained. From these observations we feel that it is legitimate to conclude that hyperplasia of the endometrium results from an unopposed action of the estrus-producing hormone.

The easiest and simplest explanation of an unopposed action of estrin is that the patient has failed to ovulate, since without ovulation there can normally be no corpora lutea. This failure to ovulate may be due to a breakdown in the inherent mechanism of ovulation or to simple mechanical conditions, such as inflammatory thickening of the tunica albuginea or to dense adhesions. These conditions prevent rupture of the follicles.

It has long been thought probable that some other organ played a part in the ovarian cycle. Experimental evidence of this was presented independently in 1927 by Smith and Engle [10] and by Zondek and Aschheim.[11] These changes have been confirmed repeatedly. Ovulation was a variable feature of the phenomena. Friedman [12] has shown by transplantation experiments that ovulation is the result of some humoral mechanism. Knauer [13] had previously come to the same conclusion. Fee and Parkes [14] hypophysectomized rabbits within one hour after copulation and found that ovulation did not occur. In connection with this experiment it should be borne in mind that the rabbit does not ovulate spontaneously but only after copulation. Smith and Engle [15] found that anterior hypophyseal tissue taken from guinea-pigs in the estrous period had relatively little capacity to increase the size of the ovary, while glands taken from animals in diestrus were more potent in this regard. These observations suggested that there might be a variation in the amount of the hormones secreted by the anterior lobe of the hypophysis during the different phases of the estrual cycle.

This contention was further strengthened by a series of experiments carried out in this laboratory.[16] Female rats were divided into experimental and control groups. The animals of both groups were spayed two weeks before the specific experiments were carried out. The animals in the experimental group received a series of six subcutaneous injections of an alcoholic extract of human placenta (given at twenty-four-hour intervals). The hypophyses of the animals of each group were transplanted into immature female mice as test animals. The ovaries of the mice receiving anterior lobe tissue from the injected rats were much larger than those receiving anterior lobe substance from the control group. The ratio was 5 to 2.

[16] Burch and Cunningham (footnote 2).

To further test this concept of a variation in the hormones produced in the hypophysis, concurrent with the normal estrual cycle, a large number of experiments have been carried out on the capacity of the anterior hypophysis of the sow to produce ovulation in the normal sexually mature rabbit.[17] The work of Corner [18] on the estrual cycle of the sow was used as a basis for the selection of the donors. The material was selected on the killing floor of a local abattoir and brought immediately to the laboratory. The hypophysis was removed and the anterior lobe dissected out and carefully weighed. It was then crushed in physiologic solution of sodium chloride and ground up with sterile sand. The mixture was centrifugated for thirty minutes and the supernatant fluid drawn off. This was diluted to the point at which 1 cc. represented 5 mg. of the fresh tissue. This fluid was injected in varying amounts into the marginal ear vein of sexually mature female rabbits. It is obvious that the fluid did not contain as much tissue as we have calculated, but a constant technic has been used and whatever error was present has been the same in all experiments. The rabbits injected either were killed or had the ovaries examined by laparotomy within from twenty-four to thirty hours after the injection. When the hypophysis was taken from a sow in proestrus, an amount of the suspension representing 1 mg. induced ovulation in a rabbit. Ten milligrams of anterior lobe tissue was necessary to induce ovulation when the donor sows were in heat. Forty milligrams was required to induce ovulation when the ovaries of donor sows contained active corpora lutea. These results indicate a definite cyclic variation in the capacity of the anterior lobe to produce ovulation.

The evidence reviewed in the foregoing indicates that estrin is probably the direct etiologic factor in the production of endometrial hyperplasia. This effect could result either from the presence of an excessive amount of their hormone or from the absence of some substance or mechanism which normally holds its action in check. It seems to us that the hormone produced by the corpus luteum is the agent which is most likely to be responsible for this action; this seems especially pertinent since the ovaries from cases of hyperplasia have been found to be uniformly lacking in corpora lutea. It should further be noted that the failure in ovulation (which obviously results in absence of corpora lutea) could well be due to some interference with the normal activity of the hypophysis. This could be either a deficiency in the substance producing ovulation or a failure in its release or utilization.

SUMMARY

Our experiments tend to show that endometrial hyperplasia is due to a relative excess of estrin. This of course can result from either an actual excess or a relative excess. The latter seems more probable. The ovary and the hypophysis are closely associated and each affects the other. There is a definite cyclic variation in the capacity of the anterior hypophysis to produce ovulation. Variations and deficiencies in the ovulation cycle might easily cause alterations in the menstrual cycle with idiopathic bleeding as a symptom.

THE EFFECT OF HYPOPHYSECTOMY ON OVULATION AND CORPUS LUTEUM FORMATION IN THE RABBIT *

PHILIP E. SMITH, Ph.D.
AND
W. E. WHITE, M.A.
NEW YORK

That the secretion of the anterior pituitary is essential to gonadal function seems to be one of the most firmly established facts in the physiology of the reproductive system. With ablation of the anterior pituitary, follicles cease to develop and those with cavity formation undergo atresia. The uterus and vagina decrease in size and their cyclic changes cease. In the male the effects are equally pronounced. Pituitary implants restore gonad activity. In immature rats and mice, pituitary administration precociously develops the reproductive system, and in adults past the menopause it will induce estrus.

Some recent work has shown that the pituitary sex hormone (or hormones) is secreted into the body fluids with almost amazing rapidity. This work at the same time has raised a question regarding the essentiality of the anterior pituitary in stimulating the growth of the corpus luteum. These results are so striking that we deemed it worth while to repeat and extend the experiments, with a somewhat altered technic. The results obtained form the basis for this paper.

The work to which we refer is that reported in a series of papers by Fee and Parkes [1] in rabbits. This form, as first shown by Heape,[2] a finding which has been repeatedly confirmed, does not ovulate spontaneously but only after mating or other sexual excitement and then within a period of from ten to twelve hours. Fee and Parkes, with a technic which they have ventured to characterize as hypophysectomy, decerebrated a series of rabbits at varying periods after mating, dissected out the pituitary in part of the animals and left it in situ in others. Ovulation took place only if the pituitary was left in place for a period of an hour (approximately) or longer. According to these findings, then, the pituitary, which had been secreting at a rate only sufficient to bring about a development of the follicles to the condition obtained in the nonmated estrus rabbit, by coitus was stimulated to secrete within the period of one hour sufficient gonad-stimulating hormone to bring about the maturation of the follicles. More surprising still was the observation that in the animals the development of the corpora, although somewhat slowed, nevertheless was normal in character for a period of thirty-six hours after copulation. Longer periods of observation were not reliable and seldom possible because of the severe general effects of the decerebration. These investigators carefully stated that this period of growth of the corpora did not show that their further development could take place independently of the pituitary; nevertheless the results suggest this possibility.

[2] Heape, W.: *Ovulation and Degeneration of the Ova in the Rabbit*, Proc. Roy. Soc. **76**: 263-267, 1905.

In our hypophysectomies we have not used a technic which subjects the animals to a severe trauma, such as does decerebration, but one which leaves them in an essentially healthy condition. It seems unnecessary to describe the operative procedure in detail. It will suffice to state that an oral approach through the soft palate is used. The capacious blood sinus in which the pituitary lies, surrounded by its dense capsule, is injected with warm bone wax. The capsule is then exposed and opened, and both lobes of the pituitary are removed with a cannula and negative pressure. It is not a blind operation, all essential structures being visible. There is little bleeding. The animals show a good recovery and usually remain in excellent condition. Ten successful operations have been performed and the total removal of the anterior and posterior pituitary confirmed by a study of serial sections of the contents of the sella. Periods of from one and a quarter to seventeen hours elapsed between mating and the actual removal of the pituitary. In each of seven of the animals, both ovaries were inspected and one of them was removed for sectioning about twenty-four hours after hypophysectomy, the second ovary being removed twenty-four hours later. In each of two of the animals, one ovary was removed four days and the other eight days after the hypophysectomy. In every case, ovulation occurred, even though the pituitary was removed within an hour and a quarter after the mating. Since follicular growth and maturation will not take place in the absence of the pituitary gonad-stimulating hormone, it is evident that the stimulus afforded by copulation has caused, by some at present unknown mechanism, an immediate and considerable discharge of this hormone. This response is striking and gives a conception of the anterior pituitary as a secretory-labile and responsive structure, which in spontaneously ovulating forms, prior to ovulation, may pour out its stored secretion by some releasing mechanism.

The second phase of our study concerns the essentiality of a pituitary secretion for the complete development and function of the corpus luteum. Our work confirms the observation of Deanesly, Fee and Parkes that corpus luteum formation takes place in rabbits even though the pituitary has been removed but a short time after mating and, consequently, several hours before ovulation has taken place. The corpora in such animals twenty-four hours after hypophysectomy (from fifteen to thirty hours after ovulation) appear to be normal, nor is there a slowing in the rate of development compared with unoperated controls, as noted by the previously named investigators. This is probably due to the fact that our operation left the animals in excellent condition, whereas their procedure led to the death of the animal within a period of from one to two days. Even in the ovaries removed at the end of the second day after hypophysectomy, or from fifty to fifty-five hours after mating, the corpora show no striking developmental failure as compared with the normal controls.

The lutein cells are large and typical in appearance, though apparently not quite as numerous as in the controls. The corpora have consequently a somewhat larger central cavity.

In the two animals in which the left and right ovaries were removed four and eight days, respectively, after hypophysectomy, the corpora show, however, a contrast with the normal. In those removed after a period of four days it is evident that little growth beyond that of the second day has taken place. Although there are many normal appearing lutein cells present, they are not as numerous as in the controls, and the central cavity is consequently much larger. The number of connective tissue cells in proportion to the lutein cells is much greater than normal. In the ovaries removed eight days after hypophysectomy the corpora have regressed. They appear avascular and small. They contrast markedly with the normal, which is larger and highly vascular and in which there remains but a remnant of the central cavity.

It is thus evident that after hypophysectomy the corpora will develop with little or no deviation from the normal for a period of approximately two days. They undergo this development without any postovulatory secretion of the hypophysis. Furthermore, since most of the animals were virgins, there is no possibility of any postovulatory pituitary secretion being still present from previous ovulation. That they will not undergo complete development under these conditions, however, is evident from the ovaries removed at four and eight day periods.

In order to see the effect on the completely formed corpora, a twenty-two day pregnant rabbit was hypophysectomized, one ovary being removed four days and the other eight days later. This animal aborted some of the fetuses on the third to the fourth days. When a laparotomy was performed on the fourth day, there were three dead fetuses in the uterus. The corpora, which have been shown to be essential to gestation in experimental animals, in this rabbit showed avascularity and regression when the animal was opened on the fourth day. So far as can be demonstrated by a single experiment, it is apparent then that the secretion of the anterior pituitary is essential for the functional maintenance of the corpora. Their regression may be primarily responsible for abortion which follows pituitary ablation.

COMMENT

In view of the well known effect of certain extracts (alkaline) of the hypophysis on the formation and maintenance of corpora lutea,[3] it is not surprising that complete development of the corpora failed in the absence of the hypophysis. The finding that they would develop for a period in excess of two days in the absence of any postovulatory secretion of the hypophysis was unexpected. That such is the case would seem to have some bearing on the problem of whether the anterior pituitary secretes only one or more than one hormone which act on the ovarian constituents. This problem has invariably been considered and its experimental solution attempted by noting the effects of the administration of pituitary implants or of extracts which have been made in different ways. Some of this work will be briefly mentioned. In work reported earlier by one of us,[4] it was found that injections of a saline supension of beef hypophyses prevented the restorative effects of implants on the ovaries and testes of hypophysectomized rats. Later, Evans and Simpson[5] reported that such injections prevented the stimulating effects of implants in immature rats. The latter investigators, because of these findings, postulated an antagonism between the gonad-stimulating and the growth hormones. The latter, they believed, carried the luteinizing factor. Engle [6] has shown that there are characteristic differences between the effects of injection of the urine of pregnancy with its anterior pituitary-like principle and of implants. Work on the purification of extracts has strengthened the idea of the duality of the pituitary sex hormone, especially the recent paper by Fevold, Hisaw and Leonard [7] and the work of Zondek.[8]

[5] Evans, H. M., and Simpson, Miriam E.: Antagonism of Growth and Sex Hormones of the Anterior Hypophysis, J. A. M. A. **91**: 1337 (Nov. 3) 1928.

Although the data up to the present seem insufficient and the field not thoroughly enough explored to justify dogmatizing on the question of the unity or duality of the pituitary sex hormone, nevertheless there appears to be a definite trend toward the belief that there are two sex hormones secreted by the anterior hypophysis, one stimulating follicular growth, the other luteinization. The skeptics have been as yet satisfied to express their doubts in other ways than by publication. The purpose of introducing the subject here is to emphasize another angle of the question; namely, the conditions obtaining in a sexually mature female when no extracts are injected. Earlier in the paper it has been shown that, although the pituitary was removed shortly after mating, ovulation was followed by a normal growth of the corpus luteum for a two day period. It is evident that, if the granulosa is acted on by two hormones, one causing growth of the granulosa, the other luteinization, the two must be present in these animals at the same time. There must be a "selective utilization" of these hormones by the granulosa before and after follicular rupture. The follicular growth followed by ovulation and the lutein transformation cannot under these conditions be due to the successive secretion by the pituitary of a follicle or gonad-stimulating hormone and of a luteinizing hormone.

In the intact animal a similar condition exists, at least in some forms. In the pregnant rabbit the follicles grow and reach the size that is attained in the nonpregnant estrus animal. These animals will mate. Ovulation is induced by the injection of the urine of pregnancy.[9] The confirmation of this and even ovulation after injection of a saline suspension of anterior hypophysis has been recently reported by Wolfe.[10] In the rat during gestation, mating [11] may occur. Even the cyclic formation of normal follicles followed by luteinization [12] has been reported. If there are two pituitary sex hormones, it is evident that in these cases both are present throughout pregnancy and that here as well as in rabbits hypophysectomized shortly after mating there must be a selective utilization of them by the ovarian elements. Follicular growth and luteinization under physiologic conditions thus cannot be explained by the successive secretion by the pituitary of two hormones. The luteinizing hormone, if it is a specific hormone, is present throughout, for the corpora lutea of pregnancy are being maintained. In its presence, follicular growth and maturation take place. Factors such as toxicity of extracts or nonphysiologic rates of growth of the granulosa, leading to its premature entrance on the second phase of its cycle, namely, luteinization, may be responsible for the luteinization effects of extracts, rather than the fact that they contain a specific luteinizing hormone.

SUMMARY

Rabbits have been hypophysectomized by a procedure that permits prolonged survival.

Ovulation will take place although the pituitary is removed after a postmating period but slightly over an hour in length, thus confirming the report of Fee and Parkes. In such animals the corpora lutea develop normally for approximately a two day period. Further changes are atypical.

The development of the corpora in the absence of any postovulatory pituitary secretion is discussed in regard to its bearing on the question of the unity or the duality of the pituitary sex hormones.

THE PHYLOGENY OF MENSTRUATION *

CARL G. HARTMAN, Ph.D.
BALTIMORE

A little over a hundred years ago the medical world experienced a flurry when the French anatomist Cuvier announced that menstruation could no longer be considered a distinctly human characteristic, since he had found (as had indeed a few forgotten authors before him) that female apes and monkeys share with women this periodic bleeding phenomenon. The menstrual process was therefore set down as a primate character, particularly since, as Heape first pointed out, the menstrual cycle in both monkeys and women involves identical changes of the reproductive organs.

The general biologist may concede that in its spectacular manifestations menstruation is a "primate character." But if one searches for fundamental or even for the more superficial physiologic causes, and if one investigates other mammals and even the lower vertebrates and attempts to discover what they have in common with man, anthropocentric ideas receive jolt after jolt. I propose to show the universality of uterine bleeding in the vertebrate series and to offer this generalization as another example of the kinship of man with the whole of creation. Perhaps, eventually, the traditional attitude of the medical man who considers the human body as something apart from brute creation will eventually disappear entirely, leading to a better understanding of the body which it is attempted to improve or cure. There is nothing essential or physiologically important about the human body that is not already present or clearly foreshadowed in the lower forms. To illustrate this by examples nearer to my theme, fact on fact is accumulating to demonstrate the generalized character of the reproductive process, and I propose to show that uterine bleeding is no exception.

* From the Carnegie Laboratory of Embryology, Johns Hopkins Medical School.

* Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 11, 1931.

Sixty years ago it was still held that menstruation constitutes a preparation for the reception of the egg, which, it was held, was discharged at or about the menstrual period. The entire theory of menstruation started with this assumption. After much painstaking labor on the part of the gynecologist it is now known that ovulation occurs almost exactly in the middle of the cycle. On this fact there was immediately elaborated another far-reaching theory of menstruation which emphasizes the ovarian factor, the corpus luteum, or rather its degeneration, as the cause of menstruation, a *post hoc, propter hoc* theory which in its turn is quite devoid of any experimental proof. The theory is still in vogue, however, despite the fact that the work of Heape, van Herwerden, Corner and Allen has shown that the corpus luteum is unessential to the menstrual rhythm. A large mass of material from the Carnegie monkey colony, shortly to be published, involving hundreds of menstrual cycles, precisely diagnosed as to whether ovulatory or nonovulatory, should finally convince the student of the problem that an extra-ovarian factor is involved in the menstrual flow. Clinically the uterine bleeding is undifferentiable whether it occurs from a 12 mm. hard, interval type of uterus, accompanied by a "resting" ovary, or from a 22 mm. soft, succulent, vascular organ produced under the stimulus of a corpus luteum.

The challenge to point out the extra-ovarian factor concerned in bleeding was met by the Carnegie Laboratory through a cooperative piece of work (Hartman, Firor and Geiling), in which the possible rôle of the anterior pituitary was analyzed. It was found that uterine bleeding which the ovarian hormone produced when injected into monkeys (Allen) was ineffective when injected into the hypophysectomized animal, whereas in such, as in normal animals, anterior lobe substance in any form always caused bleeding. These experiments mark a beginning in the analysis of the process.

But the problem is not a simple one. To the biologist it has broad ramifications. He thinks of menstruation as just one more form of uterine bleeding which begins, as shall be shown, with the cartilaginous fishes and therefore goes back far into geological time. Perhaps the essential physiology of menstruation has a more venerable history than has been imagined.

In the monkey there are many types of uterine bleeding. Aside from the postpartum hemorrhage, the bleeding presaging abortion, and different types of pathologic bleeding, there are as regular or frequent occurrence: (1) menstruation with ovulation; (2) menstruation without ovulation; (3) the placental sign or bleeding of implantation, and (4) the intermenstrual or mittelschmerz bleeding. Leaving out the last as the more obscure (the probable homologue of the estrous bleeding of dogs and cows), I am tentatively considering menstruation and the placental bleeding as homologous; that is, conditioned by the same physiologic factors. The close connection between menstruation and reproduction, on which three profound students of the problem, Robert Meyer, Robert Schröder and Emil Novak, have insisted, thus attains a new significance. The fact is that throughout the vertebrate series, wherever the embryo lives in a brood chamber at the expense of the parent beyond the point to which the stored yolk of the egg carries it, there one finds bleeding into the brood chamber. This is true of man and of monkey, the "menstruating" forms that have a particularly hemorrhagic type of implantation; it is true of other forms having a burrowing type of placentation, such as lemurs, carnivores and rodents; and it is equally true of the nondeciduates, like the sheep and the cow. In many of these the bleeding into the uterine cavity has been described and the erythrocyte content of the "uterine milk" studied (Bonnet, Kolster). Because of the widespread nature of the phenomenon, its students have ascribed to the hemoglobin and its derivatives a nutritive function, probably most often a means of conveying iron, perhaps at times conveyance of oxygen itself.

Passing to the predominantly egg laying classes of vertebrates (fishes, amphibia, reptiles, birds) one finds that, in all except the birds here and there, in species, genera or even whole families, life habits have become associated with viviparity, intra-uterine or intra-ovarian development, even to the extent of yolk sac or allantoic implantation. Here one encounters the same story over and over again: where the embryo depends for development beyond the egg stage on the mother's (or the father's) body substance, there one may find in the brood chamber red blood cells mingled with the pabulum provided by the nutritional organ.

With the exception of certain brood pouches as the back of the Surinam toad, the gular pouch of Darwin's toad, the pouch of the male sea-horse and pipe-fish, the nutritive organs are the derivatives of the müllerian duct. This is practically the only mucous membrane in the body through which the passage of red blood cells is a physiologic process. Is this under the control of the anterior lobe? If so, this gland already shows a difference of function in the pregnant and in the nonpregnant shark. This principle is susceptible of test by experiment on the appropriate species.

From among the great variety of conditions under which the embryonic nutrition is effected in the various truly viviparous fishes and amphibia, let us select three:

1. Many eggs of *Salamandra atra* are shed into the oviduct, but only one or at most two embryos are destined to develop and to be born; the survivor lives at the expense of the abortive eggs, swallowing them bodily as it floats in the embryotrophic "soup" provided by the oviduct. This semifluid mass is laden with red blood cells, according to Wiederscheim to provide oxygen directly to the embryo.

2. In the stingray *Pteroplatea* there grow out from the uterine wall long slender threads (trophonemata) which are highly vascular and covered with secreting glands. These strands enter the gill-slits of the embryo, hang into the gut and become not stomach tubes but secretory stomach villi. Their secretion feeds the embryos. Red blood cells find their way into the uterine cavity and the embryonic intestines.

3. *Zoarces*, a bony fish, has an intra-ovarian method of reproduction in which the spent follicles or corpora lutea literally and directly feed the developing embryo. The phenomenon is a kind of diagrammatic representation of the so-called trophic function of the corpus luteum of pregnancy, postulated by some writers on the corpus luteum. The shed eggs of *Zoarces* remain within the ovary, held in place by the emptied follicles, which metamorphose into corpora lutea in the form of secretory villi. They become greatly injected by capillaries, which form veritable retia mirabilia. Secretion increases according to the needs of the growing embryos, which remain within the ovarian chamber until birth. In the embryotrophic substance of the ovarian chamber and in the gut of the embryo, red and white blood cells are found in numbers. Stuhlmann thinks

that the blood serves the purpose of oxygenation directly. How blood gets into the ovarian cavity this author is at a loss to say, since he finds the blood vessels intact. With his failure to analyze the mechanism of bleeding in *Zoarces,* I have a sympathy, as the same difficulty is encountered in explaining the blood loss of the bitch and the cow at heat and the monkey during the intermenstrual bleeding.

Sufficient has been said to introduce those who have not thought of the matter to the widespread occurrence of bleeding into the müllerian derivatives. The study of the control of the bleeding has not yet begun, so far as the lower vertebrates is concerned. The suggestion of Hartman, Firor and Geiling that a hypophyseal factor may be generally involved seems to me to be worth following up. The common denominator in the physiologic control of the various types of bleeding is likely to be the fundamental principle involved. Menstruation according to this view begins with the Salachian fishes—and there is again "nothing new under the sun."

Wolfe and Madison streets.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. FRANK, DRS. G. V. S. AND O. W. SMITH,
DRS. BURCH, WILLIAMS, WOLFE AND CUNNINGHAM,
DR. SMITH AND MR. WHITE,
AND DR. HARTMAN

DR. EDGAR ALLEN, Columbia, Mo.: Dr. Frank finds that the amount of theelin in the blood and that excreted in the urine increase before menstruation. In quantitative analyses of the theelin content of human ovarian tissues, Drs. Pratt and Newell and I found greater amounts of theelin at the time of ovulation; i. e., in the interval of the menstrual cycle. Perhaps the suggestion made by Drs. G. V. S. and O. W. Smith that there is a change in the threshold of excretion will be the answer to these differences. The matter of a name for follicular hormone is urgent. Five different names are now in use: "follicular hormone," "estrin," "amniotin," "female sex hormone" and "theelin." Dr. Doisy's name for the crystalline material which he has isolated is "theelin." I propose its more general use. The paper by Dr. Smith and Mr. White presents one of the outstanding achievements of recent years. I have noted in the clinical literature that Zondek and Aschheim have obtained priority in some citations for this work. Dr. Smith has concerned himself little with discussion of priority. Careful scrutiny of the literature will determine that publication by Smith and Engle preceded that of Zondek and Aschheim. I was greatly interested in the discussion of mitosis by Drs. Burch, Williams, Wolfe and Cunningham. The action of theelin is principally to cause division of cells of the accessory genital tissues. Their suggestion that progestin may in some way stop growth of the tissues after ovulation is interesting. I wish that Dr. Hartman might have talked further about the matter of anterior hypophysis stimulation of menstruation. With the anterior lobe intact in castrated animals, enough growth can be induced in the endometrium by injections of theelin so that, when injections are discontinued, menstruation begins. To just what extent the anterior lobe can work independently of the ovary should be studied further. Dr. Hartman's negative results in a castrate of eight months might give an indication, at least, that some growth in the endometrium from the action of theelin is required before menstruation can be produced.

DR. FREDERICK L. HISAW, Madison, Wis.: I propose to limit my remarks to the physiology of the corpus luteum. At present it is known that the corpus luteum of the sow secretes not one hormone but three, in addition to estrin. Progestin, then, or corporin, as we speak of it in our laboratory, is only one of the three. Corporin acts on the uterus and perhaps produces other physiologic changes. Another hormone, relaxin, acts on the pelvic ligaments; it does nothing else, so far as is known. A third hormone acts on the vaginal mucosa of rodents, producing mucigenation typical of the condition found during pregnancy. I wish to speak about the action of corporin on the endometrium. Dr. Allen has shown that theelin stimulates endometrial growth in monkeys, and its discontinuance is followed by menstruation. We have found that theelin at a given dosage (40 rat units daily) can be continued presumably indefinitely (forty days at least) without signs of menstruation, but if this dosage is lowered (20 rat units daily), menstruation occurs. A decrease of the dosage, then, or a discontinuance of theelin treatment is followed by menstruation. The endometrium is characterized by numerous mitoses, low glandular mucosa (from 35 to 40 microns), only slight coiling of the glands, and, at the time of menstruation, no premenstrual swelling of the gland cells and little or no fraying of the mucosa. When these conditions are produced in a castrated monkey, and the theelin treatment is replaced by injections of corporin, a typical premenstrual condition is developed. The uterine glands are coiled and dilated, the glandular mucosa is high (from 70 to 80 microns), mitoses are very few or absent, and just previous to menstruation there is a pronounced fraying of the mucosa. Corporin, then, modifies the theelin type of endometrium into the premenstrual type normally associated with a corpus luteum. When theelin in large doses is given simultaneously with corporin, only the theelin effects are seen; that is, theelin overrides corporin. This reaction, then, is one in which theelin must act first, followed by corporin, as corporin cannot modify the uterus of an untreated castrate. Neither does corporin seem to postpone the time of bleeding following discontinuance of theelin treatment or postoperative bleeding following ovariectomy.

DR. CARL R. MOORE, Chicago: This symposium has been intensely interesting, to a certain extent enlightening, and also to an extent confusing, because of the various aspects presented and the differences occurring among animals of different species. I have sympathy for the clinician who is presented with problems of hormonal administration, for even in the laboratory, with experimental animals, it is often difficult to bring a creditable interpretation to bear on repeatable results. The phase of these problems of most interest to me is the demonstrable links between the different gland activities and their influence on one another. In my experimental work I have recently offered certain suggestions regarding the nature of these interlinkings, and the present discussions have contributed materially to this conception. The chief aspect that the clinician should bear in mind is that the administration of sex hormones (theelin, estrin, testis hormone and the like) so acts on the anterior lobe of the hypophysis as to diminish the gonad-stimulating hormones available and, as a result, injury to the gonads occurs. Perhaps the clinician has often attempted a stimulation of a so-called hypogonadal state, ephemeral as this may be, by administration of preparations of the female or the male hormone. In actual laboratory observations, however, instead of a stimulation there is really an injury to the intact gonads. Substances produced by the ovary do not stimulate its activity, nor do substances produced by the testis stimulate this organ. The injury produced on both appears to be due to the hypophyseal depression from the gonad hormones. This reciprocal relation has been indicated in many of the papers presented today and by the remarks of other speakers. How many other endocrine glands will prove to have a place in the chain of events is impossible to predict at present. The report of Drs. Burch, Williams, Wolfe and Cunningham, in which it is shown that the activity of the hypophysis varies with the amount of the female hormone present, substantiates the reciprocal nature of the interactions between the hypophysis and the ovary.

DR. JEAN PAUL PRATT, Detroit: This symposium suggests to the clinician many possibilities for diagnosis and treatment, but a word of caution is necessary, not to draw conclusions too hastily from the results of animal experiments. Estrus of animals must not be confused with menstruation, for the conditions are not identical. Disturbance of menstruation is one of the best indicators of abnormality of sexual organs and therefore it is natural that one should look for some regulator of menstruation. Even the fact that monkeys menstruate must not lead one to conclude that their menstruation is similar to human menstruation, or that the two primates will necessarily respond in a similar way to glandular products. In 1926, in this section at the Dallas meeting, I reported the injection of the follicular hormone in women and noted at that time that one could get definite evidence of growth of the uterus. I had hoped to be able also to report bleeding, but in many attempts there has been no evidence of menstruation being reproduced by the injection of theelin; in many observations, however, the evidence of growth has been repeated. So far as I can see clinically, the only thing that one can expect to get from theelin is growth of the uterus. There have appeared in the literature reports ascribing beneficial results from the use of theelin in dysmenorrhea and in combating symptoms of the menopause. In my experience this conclusion is not justified, for equally good results may be obtained by injection of sterile water, or by other psychotherapeutic measures. For, after all, the symptoms of most dysmenorrheas and the menopause are largely psychic. The suggestions in the symposium give great hope for future therapy, but a great deal of work is necessary to translate the results of animal experiments into terms of human therapy.

Dr. M. A. Goldberger, New York: Our interest has been mainly in studying the occurrence of the female sex hormone, as we call it and the anterior pituitary hormone, in the human female. The first chart that Dr. Frank showed might be emphasized; in this the method of extraction of the female sex hormone was graphically produced. Whereas previously we used to throw the blood sludge away after the female sex hormone was extracted, we are now able to use that sludge and extract the anterior pituitary hormone.

Dr. Charles Mazer, Philadelphia: The degree of uterine development should be the main guide in the administration of female sex hormone or estrin. The product does not exert any action on the ovaries. It does, however, produce growth and vascularity of the uterus. If the uterus is normal in size, the existing condition is usually due to failure of the second phase of the ovarian cycle, luteinization, for which the luteinizing hormone of the anterior lobe of the pituitary gland should be administered. In my experience, low voltage irradiation of the ovaries and pituitary gland is the most effective agent in restoring menstrual periodicity. The functional menorrhagias and metrorrhagias likewise respond to this treatment.

Dr. Robert T. Frank, New York: I pity the clinician—and I am one—if he attempts to translate into clinical medicine what the advance guard is feeling out in physiology. We have had a great disappointment in that theelin (I think that it is time to adopt one name and, in deference to Dr. Doisy's epochmaking discovery of crystallization of this product, I think we might use that name) works harmfully on the ovary. I cannot see how it can act in a stimulating fashion, and I predict that we shall meet with similar disappointments when we have a commercially active product to use on the human being. Dr. Smith and Mr. White brought out that the amount of a hormone that one finds in a gland is no indication whatever of the amount that it is secreting into the circulation. Dr. Allen mentioned or referred to a change in threshold of the kidney toward the excretion of theelin. The work in our laboratory has definitely shown such a change in threshold, as we reported last year in several papers. Whether any other explanation can be found is yet to be seen. The time has also arrived to call a halt in ascribing every part action of a hormone to a special hormone. For instance, to have collected eleven factors for the prepituitary is carrying the thing to an extreme. Further study will probably show that simplification is possible. Our old concept, at least our old histologic concept, of menstruation should be kept up for the time being until we have a more definite conception of what the exact mechanism of the menstrual bleeding is. Finally, I want to call attention to a clinical application. The physician who would not think of treating a patient with thyroid extract in a thyroid disturbance or in any disturbance of metabolism, without making a basal metabolism determination, the physician who insists on taking frequent samples of blood to note the sugar level in a case of diabetes or suspected diabetes, or the physician who insists on electrocardiograms in every case of organic and functional heart disease still seems to balk and hesitate in applying these blood and urine hormone tests, which are available and which are comparatively simple, in clinical and in functional disturbances of the genital system, otherwise entirely indistinguishable and readily confused with one another.

Dr. Philip Edward Smith, New York: I want to say a word about the proposal of Dr. Allen that the female sex hormone or follicular hormone be called "theelin." This is a patented product and it appears to me improper to use in our scientific papers a patented name to designate an active principle. The matter of patents affects the investigator, the practitioner and the public. There is at present a general and unfortunate tendency to patent all products discovered in the laboratory. The assurance that pharmaceutic houses will place on the market properly standardized products is important, but is it getting at the problem in the proper way for the investigator to patent his discoveries? I am not referring particularly to theelin, which is the least objectionable of the examples. Should the investigator or the laboratory or the university levy tribute from the public for these discoveries? There is enough wealth in this country to support investigation, and this wealth will be more freely given if there are not any royalties. I think that the American Medical Association could well sponsor the setting up of a national body for the standardization of these products. The investigator would then have no reason for patenting his discoveries and the element of commercialism need then not enter into his research work. In connection with Dr. Frank's paper, I believe that the assays which he is making of the content in the blood of the anterior pituitary hormone are giving invaluable information. It is the hormone that is secreted into the blood that counts; it is not the hormone that is stored in the gland. The assay of pituitary activity by implants gives an indication of the stored hormone of that gland; it may not give any information in regard to the amount of the hormone being supplied to the animal. Implants of the thyroid, for instance, would give an entirely erroneous picture of the amount of secretion which goes into the circulation in exophthalmic goiter and in colloid goiter. It is by using the blood assay method in which Dr. Frank is pioneering that we shall get information of the greatest value.

Dr. John C. Burch, Nashville, Tenn.: One of the most interesting phases of this work is the different action of the various hormones in varying concentrations. This is well shown by Friedman's work on the rabbit. It is important to remember that the amount of hormone circulating in the blood and at the point of action is the essential thing. In regard to the apparent contradiction between the work of Dr. Hisaw and his co-workers and that of Dr. Cunningham and myself, I wish to state that our donor rats were injected with large amounts of an alcoholic extract of human placenta over a short period of time. Following this method we got an increase of the ovarian-stimulating power of the anterior hypophysis. Dr. Hisaw found that when estrin was injected over a long period of time the reverse was true and there was no stimulation. It is possible, therefore, that these two sets of experiments were different in the type of substance injected (because placental extracts may contain some factor other than estrin) as well as in the duration of the injections. Variations in either of these two factors may have been responsible for the difference in the results.

Dr. George van S. Smith, Brookline, Mass.: The term "luteinizing hormone" for the substance prepared from the urine of pregnant women may be incorrect, for, when given intravenously, it produces ovulation as well as luteinization. The recent work of Evans indicates that this hormone is active on the ovaries only if the anterior hypophysis is present. Hence the ovarian effects may be due entirely to its stimulation of the anterior hypophysis. I was glad to hear Dr. Hisaw bring up the subject of quantitative endocrine relationships; e. g., small amounts of theelin are necessary for the progestational proliferation of the endometrium caused by progestin, but large amounts inhibit the action of progestin. This situation seems to be true also in the matter of lactation. Some of the experimental discrepancies may be found due to incorrect dosage. Dr. Ernst Philipp of Berlin implanted portions of the anterior lobes of the pituitary glands of three patients who died shortly after delivery and found the ovaries of the test animals unaffected. This observation indicates again that the sex hormones of the anterior hypophysis are depressed after the middle of pregnancy and during lactation, as gaged by the regression of the corpus luteum and the absence of ovulation. I feel that enlightenment in these matters will depend on the studies of lactation that are now being pursued.

Dr. Carl G. Hartman, Baltimore: I wish to thank Dr. Novak for giving others the chance to criticize my views, and I will take to heart Dr. Frank's suggestion as to the name, although I must say that names will not get one anywhere in studying physiologic causes. I am sorry that Dr. Hisaw did not discuss further the relaxing hormone, because Dr. W. L. Straus, one of my colleagues, has found that in the monkey there is a definite relaxation of the symphysis, so much so that one can put one's finger into the slit formed by spreading the ischial tuberosities. This takes place within the last three weeks of gestation, and the ligaments are again thoroughly knit up within ten days after parturition. No matter how hard one pulls, one can't get a spread of over 3 mm. in the normal animal, whereas it is easy to get a spread of 15 mm. with rather moderate pressure at which the puerperal monkey flinches with pain. Lastly, one other warning as to the gaging of results: Dr. Friedman has obtained most variable results with the study of his method of causing ovulation not only by the route of administration, namely, whether intravenous, intraperitoneal or subcutaneous, but also by the distribution of the dosage over a period of time.

SLIPPING OF THE UPPER FEMORAL EPIPHYSIS

A STUDY OF SEVENTY CASES *

ALBERT B. FERGUSON, M.D.
AND
M. BECKETT HOWORTH, M.D.
Fellow of New York Orthopaedic Dispensary and Hospital
NEW YORK

A condition occurring between the ages of 8 and 17 years is described in the literature as epiphyseal fracture, separation, or slipping, epiphyseal coxa vara, adolescent rickets, pathologic fracture, and femoral osteochondritis of adolescence. It is a disease characterized by weakening of the epiphyseal disk at the femoral head, permitting subsequent displacement of the head on the neck.

We are presenting a study of seventy cases of this disease from the New York Orthopaedic Dispensary and Hospital. Sixty-three were seen in adolescence; seven were adult residuals. Thirty-nine were in males, thirty-one in females. In thirty-one cases only the left hip was affected; in twenty-four the right, and fifteen were bilateral. Bilateralism is about as common as in coxa plana and only slightly more common than in frank infections.

Of fifty-five patients, 65 per cent were overweight, half of them having endocrine imbalance. Many of the overgrown children were of the type described by Mikulicz—a large child with flabby, weak musculature and more than the usual subcutaneous fat. Often a patient, obese in adolescence, was normal or even slender five or ten years later. In four cases endocrine therapy was tried with no effect on the epiphyseal disk, although weight was reduced. Many grew rapidly in height or weight just before the onset. A number of slender patients were tall for their age, thus having more than the usual weight on their hips.

Premature union of growth centers, as compared with the normal side, is usual at the affected hip in the trochanters, head and acetabulum. It was noted at 12 years in one girl. The same thing may be noted in other inflammations at the hip. It is therefore considered as evidence of the wide extent of circulatory disturbance in the region. It does not indicate endocrine imbalance, as it is not seen in the unaffected hip or in other regions of the body.

At or shortly before the onset, twenty-four patients out of forty-five (53 per cent) had tonsils diseased or removed, five (11 per cent) had appendicitis, and five had other infections. Seventy-five per cent had some definite infection, which suggests that infection elsewhere may be an etiologic factor.

THE RÔLE OF TRAUMA

Trauma hastens the onset of symptoms and initiates or increases displacement. The trauma is usually trivial and rarely more than occurs in the normal activity of the average child. Greater displacements are more common with trauma which might have been severe. Displacement may be gradual with no trauma. One case showed displacement of two-eighths, three-eighths, four-eighths and five-eighths inch at successive examinations with no injuries and with no aggravation of symptoms. Trauma may aggravate the displacement at any time. We have found no differentiation into traumatic and nontraumatic types.

CHARACTERISTICS OF ONSET

The age at onset in thirty-six boys was from 9 to 16 years with 75 per cent between the twelfth and fifteenth birthdays. In the cases beginning before the age of 12 years there was unusual stress on the epiphyseal line by reason of severe trauma or excessive overweight. Uninfluenced by these factors, the age at onset was from 12 to 16 years for boys.

Symptoms were present before displacement in seventeen hips in thirteen boys. Those younger than 13 reached that age before slipping occurred, the preslipping stage averaging thirteen months. Preslipping stages beginning after 13 averaged only five months. Prompt displacement is apt to occur at the age when epiphyseal cartilage is forming bone rapidly.

Displacement occurred in thirty-three of the adolescent boys; 66 per cent slipped between the thirteenth and fifteenth birthdays. This is the age of slipping for boys. The six younger boys (aged from 9 to 12 years) were subject to unusual stress in the form of severe trauma or excessive overweight. Unusual stress may be regarded as the cause of displacement before the slipping age period. Conversely, the five boys whose first displacement occurred after the fifteenth birthday were not materially overweight or remembered no trauma up to the day of slipping.

In the five months from July to November, 66 per cent of the boys had onset of the disease and 70 per cent had onset of the displacement. This incidence expresses the seasonal activity of the boy—the period of vacation and of football playing.

Analysis of the years of onset showed no epidemic features.

The age of onset of symptoms in girls was from 8 to 13 years, with 89 per cent occurring between the tenth and fourteenth birthdays. Displacement occurred at the tenth to fourteenth year, with 87 per cent between the eleventh and fourteenth birthdays. The seasonal incidence was one month earlier for girls; their period of activity was not prolonged by football. The girls outside the usual age period and the female preslipping cases showed the same relations to trauma, excess weight and duration of the preslipping stage as have been noted for boys.

---

* Read before the Section on Orthopedic Surgery at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 11, 1931.

PATHOLOGY

Twelve hips have been opened at operation. In the specimens examined, the bone and epiphyseal line showed no evidence of rickets, infection or osteomalacia. The capsule and periosteum about the neck were thickened, sclerosed and avascular. These changes were present in the hip operated on in the preslipping stage (fig. 1).

CLINICAL FEATURES

There are four stages of the disease—preslipping, slipping, quiescent and residual. When there are no acute signs and no spasm, the lesion is quiescent. When the lesion is quiescent and the epiphyseal line is united, it is residual.

In these cases we have found the following: In the preslipping stage limp and pain are usual; fatigue, stiffness and disability are frequent (table 1). Examination reveals limp, pain on motion, and often spasm or atrophy. All motions except extension tend to be limited, internal rotation being most commonly affected. When the hip is flexed it tends to abduct and rotate externally, allowing further flexion. After slipping has occurred, the symptoms and signs are more pronounced. Complete disability is often present but is not dependent on the amount of displacement. Shortening, tenderness and, occasionally, crepitus and swelling may appear. When the femur is rotated, the head may be palpable under the gluteal muscles—a sign almost pathognomonic of slipped epiphysis. In the quiescent stage, the signs and symptoms have subsided and may be less than in the preslipping stage; spasm has disappeared. Limp, pain, fatigue and limitation of motion often persist into the residual stage.

Table 1.—*Clinical Features*

	Before Slipping, Per Cent	After Slipping, Per Cent
Symptoms:		
Limp	93	96
Pain	100	93
Fatigue	83	78
Stiffness	90	94
Disability in athletics	67	93
Physical Signs:		
Limp	88	84
Pain on motion	71	92
Spasm	67	84
Tenderness	33	98
Shortening	17	85
Atrophy	45	71
Limitation of Motion:		
Flexion	67	84
Abduction	64	92
Adduction	44	84
Internal rotation	86	98
External rotation	77	85
All motions	..	71
Deformity:		
Flexion	0	*
External rotation	11	67
Adduction	..	27

* As the absence of flexion deformity was not apt to be recorded, its incidence is indefinite. Flexion deformity, when present, was slight.

ROENTGENOGRAPHIC OBSERVATIONS

In the preslipping stage the epiphyseal line is abnormally wide; the end of the neck may be irregular and somewhat decalcified. Thickening of the capsule may be recognizable at the margins of the joint. Most of the other epiphyseal lines in the region are somewhat closer to union than on the normal side.

In the slipping stage the same changes are present, and there is a varying degree of upward displacement, external rotation and adduction of the neck on the head. The displacement of the head uncovers the end of the neck superiorly and anteriorly. Callus may be present in the angle between the head and neck inferiorly; as it matures it may obscure the original outline of the neck and give the appearance of an epiphyseal line in a plane more vertical than usual. Examination with the femur rotated internally causes the shadows of the head and neck to superimpose, simulating reduction of displacement.

Table 2.—*Example of Index of Motion*

	Motion	Factor	Product
Flexion	145	0.4	58
Abduction	45	0.4	18
Adduction	30	0.2	6
Internal rotation	30	0.2	6
External rotation	60	0.1	6
Extension	10	0.1	1
Index of function			95

Hypermobile	over 110
Normal	90 to 110
Good	60 to 90
Fair	50 to 60
Indifferent	40 to 50
Poor	30 to 40
Bad	under 30

After quiescence, the callus is mature, there is no decalcification unless there has been confinement in plaster, the end of the neck is less irregular, and the epiphyseal line is narrow.

In the residual stage, ossification of the epiphyseal line is completed and slight calcareous deposits indicating arthritis may appear at the articular margins. Arthritic changes are more extensive and more definite several years later.

Marked lumbosacral anomalies, such as a transitional type of vertebra, were present in 43 per cent of the cases.

DIAGNOSIS

A child between 8 and 18 years of age complaining of a limp, or pain in the hip, thigh or knee may have a preslipping or slipped upper femoral epiphysis. The hip should be carefully examined for limitation of motion, particularly internal rotation and abduction, and for spasm at the limits of motion. The presence of these physical conditions necessitates roentgenographic examination, by which the diagnosis can almost always be established. Questionable cases should have careful observation, limitation of activities, and repeated roentgenographic examinations.

The roentgenographic and other features of this condition are so different from those of other conditions occurring in this age period, such as tuberculosis, fracture, dislocation, residuals of coxa plana, osteomyelitis and suppurative arthritis, that discussion of differential features is superfluous. The active stage of coxa plana is usually confined to children under 10 years of age. The absence of changes in the epiphyseal line distinguishes nonsuppurative arthritis.

METHODS OF EVALUATION OF RESULTS

If operative procedure does not correct displacement, the operation has failed. Since upward displacement of the neck is the most important deformity to correct, is the easiest to measure, and is usually corrected when anything is accomplished, this may be used for convenience as the measure of the success of the operative procedure. Judging displacement requires great care. Rotation and callus formation obscure the relation of the head to the neck. To check the interpretation, additional measurements may be used—the distance from the head to the lesser trochanter, the adduction of the neck relative to the axis of the head, the amount of the end of the neck uncovered by the head superiorly.

The function of the hip may be expressed by means of an index. If each motion of the hip is arbitrarily evaluated for its importance in function, the index will be obtained by multiplying the degrees of each motion by the constant of value and adding these sums. The constants we have used are:

For flexion and for abduction........... 0.4.
For adduction and for internal rotation... 0.2.
For external rotation and for extension 0.1 (table 2).

We shall use this index to express the functional result in these hips. As improvement in symptoms accompanies improvement in function, the index offers a fair statement of the outcome of the case. A normal hip has an index of between 90 and 110.

RESULTS

In judging the results of operative procedures, comparisons must be made with the results in cases in which operation was not performed. Fifteen hips were given no operative treatment. Their displacement varied from zero to five-eighths inch; in four it was three-eighths inch or more. Twelve had treatment by bed or caliper brace; three had no treatment. All with good function improved; all with impaired function improved greatly; in all, the symptoms were much improved or eradicated. This record was not approached by most operative procedures that we have used.

There are thirty cases that were followed to the residual stage. At the last examination the ages of the patients varied from 12 to 27, with an average of 17 years. The time since the last orthopedic treatment varied from five months to fourteen years, with an average of three and a half years and a mean of three years. The age at operation had no detectable influence on the result, although with closed reduction in a young patient it is possible that further slipping might occur.

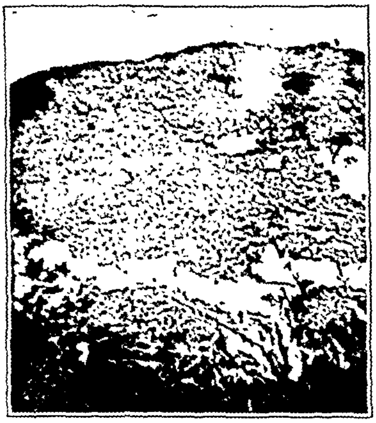

Fig. 1.—Sclerosis and avascularity of the tissues about the femoral neck. The specimen is from a patient operated on in the preslipping stage.

CLOSED REDUCTIONS

Closed reductions were usually forceful abductions followed by forced internal rotation. In twenty-one cases, closed reductions of this type were utilized. Eighteen closed reductions failed, six patients having subsequent open operations. Two were about 50 per cent successful; one was almost completely successful but displacement was slight in these three. Operations were performed within one month of the onset of symptoms and within three and a half weeks after displacement.

The functional results following abduction manipulation are judged in the eighteen cases which we have seen in the residual stage. Two of these had partial correction; one was improved from an index of 20 and displacement of 1⅛ inches to a final index of 96 with displacement of five-eighths inch; another was improved from an index of 12, displacement of seven-eighths to an index of 34, displacement of five-eighths. Of the remaining sixteen patients, all unimproved anatomically, twelve had a final index of below 50; four had hips which were good functionally, but one was worse than before manipulation. All but one of the unsuccessful attempts at reduction were performed more than four months after the onset of symptoms and more than one month after slipping, and callus was present in each case. The three displaced hips having no attempt at reduction show results as good as manipulated hips with similar displacements.

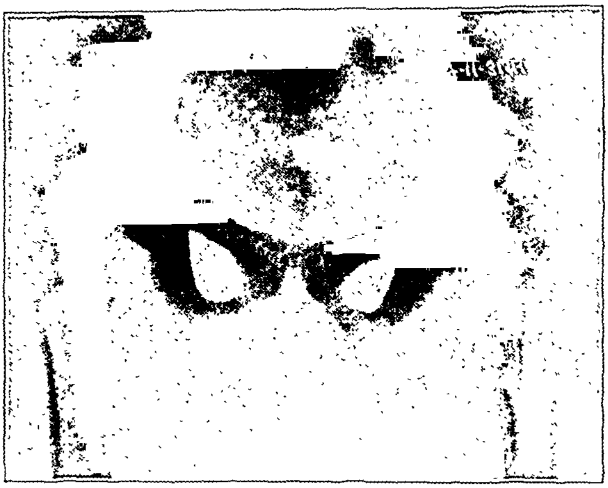

Fig. 2.—Result of manipulation in hips with similar displacements. On the left the abduction method was used unsuccessfully. The right was reduced by traction four weeks after slipping. Callus projects inferiorly at the end of the neck on the right.

We have tried reduction by traction in seven cases this year, with some success anatomically (fig. 2), but we have as yet only limited knowledge of the functional result. Manual traction of from 300 to 600 pounds is gradually applied with the aid of stirrups at the ankle and knee, the leg being adducted. When it is believed that reduction has occurred, the leg is rotated internally, force being used if necessary. It is then roentgenographed and, if reduced, a double spica is applied in abduction and internal rotation.

Traction was also used in 1922 in two cases. Each was successful anatomically. Each operation was done five days after slipping and within two months of the onset of symptoms. The indexes of function in the residual stage were 70 and 100. They were symptomless except that one patient had some pain in wet weather or when fatigued.

OPEN OPERATIONS

Open reductions were attempted in eleven cases, with fair anatomic success in three. The Smith-Petersen approach was used. Five of the eleven hips had the head freed at the epiphyseal line; six had cuneiform osteotomy near the line. Visible epiphyseal cartilage was removed and the displacement corrected. The leg was immobilized, usually in abduction, internal rotation and extension. Seven of these—five of which had attempts at closed reduction—were followed to the quiescent or residual stage. Only three showed any notable improvement anatomically; these were improved functionally but still had low indexes, 51, 47 and 33. Of the four that were not materially improved anatomically, one was functionally slightly better, one was slightly worse, and two were much worse. These results do not compare favorably with cases in which no attempt at reduction was made. Probably a bar to successful reduction in these operations was callus formation on the neck inferiorly which would catch in the margin of the head. This suggests the need of exposing this area at operation so that the callus can be removed and the head pushed up. All these open operations were in cases of long standing, with marked callus formation. It is quite possible that open operations done in fresh cases might show much better results.

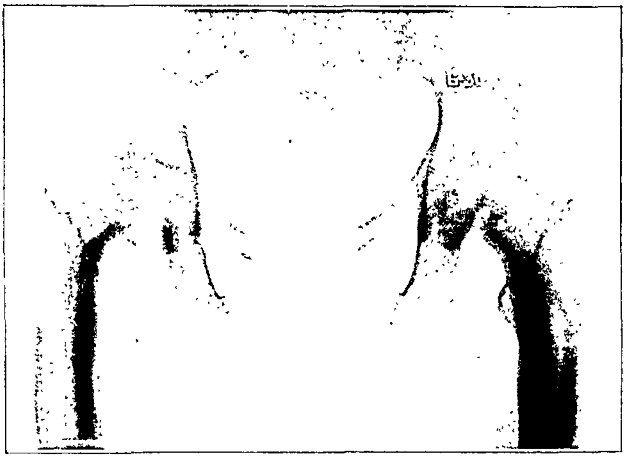

Fig. 3.—Marked bilateral displacement with good function. On the left the index of function was 73; on the right it was 83. There was no operation.

Subtrochanteric osteotomy was done in four cases with displacement from five-eighths to seven-eighths inch. One was a stiff hip in adduction deformity which was relieved. The others showed flexion or extension of the upper fragment after operation. In one case this added 2 inches (5 cm.) to the shortening. This case was not improved functionally. The remaining two cases were materially improved and attained indexes of 80 and 70.

Two patients eventually had reconstruction operations, one after four attempts at reduction, including an open operation; the other after an attempt to hold the head in place with a spike which penetrated the joint.

RELATION OF DEFORMITY AND OF REST TO FUNCTION

In the final examination in the residual cases and in the initial examination in all cases we found instances of marked deformity with good function (fig. 3) and of slight deformity with impaired function (fig. 4). There is no constant relation between deformity and function. The average function is less with greater displacement, but this is partly accounted for by greater traumatism in treating them.

Seven patients had two or more months in bed before operation. Their average functional index went up from 30 to 56 before operation and was only 60 in the residual stage. Three were worse after operation. Rest accomplished more in restoring function than did attempts to improve the deformity. One third of the cases in which two and a half or more months were spent in bed became quiescent within four months. All cases with less rest period took longer than this, averaging ten months. These improvements with rest indicate that impairment of function is due in part to inflammation. We believe that it is as important to treat this inflammation as to treat the deformity.

AN OPERATION FOR YOUNG PATIENTS

The seven cases which did not slip were followed to the quiescent or residual stage. None of the four cases relieved of weight bearing during the preslipping stage developed any displacement; of the remaining sixty-six cases, in thirty-one of which a preslipping stage was definitely recognized, only three reached the residual stage without slipping; thus the chance of slipping is great, and two or even three slippings are not infrequent. All cases in which slipping did not occur became symptomless, with normal function. In cases with displacement followed to the residual stage, the index was 46 or less in 50 per cent. To allow displacement to occur is to exchange a potentially normal hip for a 50 per cent chance of having less than 50 per cent function.

In the preslipping cases, slipping must not be allowed to occur. Displacement may be prevented by confinement to bed or possibly by a caliper brace. A brace with weight bearing is of no value in these cases. Such treatment is satisfactory if the patient is old enough to attain ossification of the epiphyseal line in a short while. When the patient is young, an operation to hasten ossification of the epiphyseal disk is better and safer than long periods of bed or brace treatment. Such an operation, used in one case,[1] is as follows: The capsule is opened through a Smith-Petersen incision, and several holes are drilled through the neck and epiphyseal line into the head. Bone slivers may be inserted in the drill holes. When the patient operated on, a girl, aged 11 years, was up after three months in bed she had an index of 79 and the head was united to the neck (figs. 5 and 6). This was a twenty-point

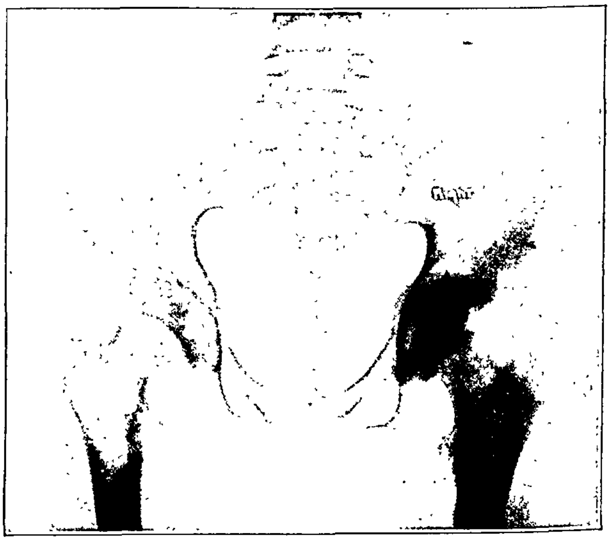

Fig. 4.—Slight displacement at the left hip with poor function. The index of function was 21.

---

[1] The operation has been used in two more cases since June, 1931, with excellent results to date.

loss in the index representing the effect of operative trauma. We expect this to improve, but a good hip is assured.

That this operation will not cause noteworthy growth disturbance has been demonstrated in cases of coxa plana. For example the earliest of these, done in 1928, shows, in 1931, growth of the neck equal to the normal side. The operation has been done in coxa plana fifteen times.

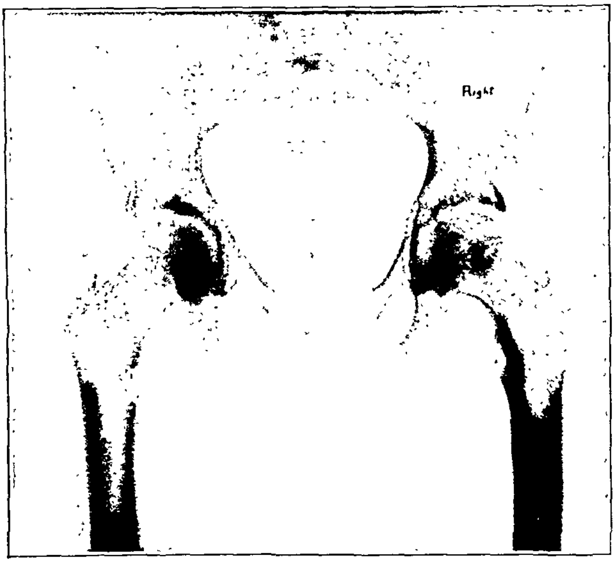

Fig. 5.—Preslipping right hip before drilling was done. The epiphyseal line is wide, the end of the neck is irregular, and the other epiphyseal lines in the region are narrower than on the left.

SEQUELAE

Thirty cases that have reached the residual stage were examined roentgenographically for arthritis. None was found in fourteen patients, aged from 12 to 17. Sixteen patients aged from 15 to 27 showed arthritic calcification, most commonly at the margin of the acetabulum; these cases had displacement of from one-fourth to 1½ inches, the average being five-eighths inch. The seven adults showing the late residual of slipped epiphysis all showed arthritic changes. In six it was marked. In unilateral cases the unaffected hip showed no evidence of arthritis.

As all patients over 17 years of age showed evidence of arthritis, we cannot say what will prevent it. It is likely that more attention to rest treatment for the inflammation, treatment of focal infections, general hygienic measures, more efficient reduction of displacement, and prevention of slipping in preslipping cases would improve the results as regards arthritis.

CHOICE OF TREATMENT

Our impressions of the selection of methods of treatment are as follows:

General treatment should include a weight-reducing diet and elimination of foci of infection.

The preslipping case is an emergency case. Weight bearing should be stopped until the disease is quiescent and the epiphyseal line ossified or close to union. If this entails a long period of confinement, it may be better and safer to use the drilling operation.

In the slipping stage, displacements of less than three-eighths inch should be treated as preslipping cases unless very recent, in which case closed reduction might be considered. With more displacement the reduction should be attempted if it is less than two months since the onset of symptoms, less than three weeks since the last displacement, and if callus is very slight in amount. However, if the patient is young there will be danger of recurrence of slipping before the epiphyseal line ossifies, and open reduction with eradication of the epiphyseal cartilage would seem preferable. When cases are not recent, as previously described, open reduction may be attempted if the operator has been successful in obtaining reduction in this way. Otherwise it is best to treat the case by rest until quiescent and then do a subtrochanteric osteotomy, with particular attention to preventing flexion or extension of the proximal fragment. This operation is also the treatment of choice in cases that have reached the residual stage with deformity that interferes with function or predisposes unduly to arthritis.

In all operative procedures, rest from weight bearing should be emphasized. A spica should not be left on more than two and a half months, but there should be no weight bearing for at least three months after operation nor until there is a good range of motion with no spasm except on forced motion. Double spicas are much more apt to maintain reduction than single spicas.

ETIOLOGY

It has been suggested that this disease is due to trauma, static forces, rickets, osteomalacia, infection and endocrine imbalance. In 1926, Key reviewed the literature and did much to refute these theories. The features that we have reported and the cases described in the literature bring us to a conception of this disease which we find helpful as a working hypothesis and guide to treatment. This hypothesis is that weakening at the epiphyseal disk is due to vascular stasis about it secondary to sclerotic changes in the soft tissues about the femoral neck. The most probable cause of the sclerotic changes is a previous, or occasionally concurrent, infection—a subacute arthritis or, rarely, infection in the neck. Such infection may be metastatic from infection elsewhere.

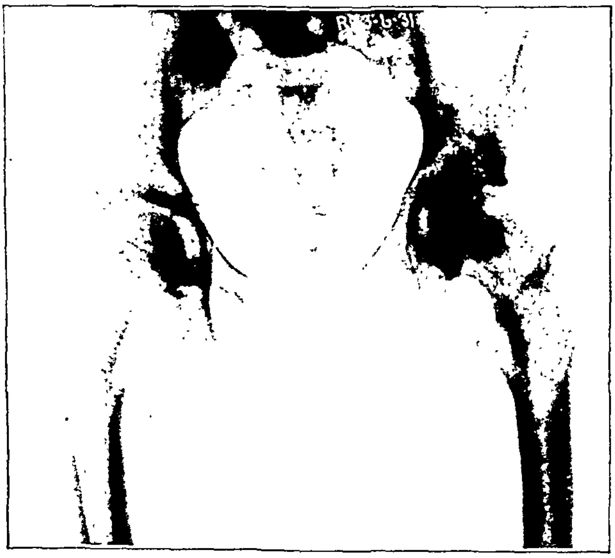

Fig. 6.—Same case as in figure 5 four months after drilling.

Stasis may also be produced in other ways and other ages, which may account for some related

ditions such as coxa plana and osteochondritis dissecans. Transitional cases showing the relation to these other conditions have been excluded from the present report.

This disease is far more common than is generally supposed. Every adolescent child with a hip limp should be examined for it, especially if the child is overweight. If the condition is recognized in the preslipping stage it should be considered an emergency case. Displacement must be prevented. In selecting the treatment to be applied to the given case there must be careful consideration of the age of the patient, the stage of the disease, the presence of callus, and the time since the onset of symptoms and since displacement.

SUMMARY AND CONCLUSIONS

1. Seventy cases of slipping of the upper femoral epiphysis are reviewed.
2. Bilateral occurrence is not infrequent and should always be looked for.
3. Overweight children, whether tall or fat, are more susceptible to the condition. This appears to be due to the greater stress on the hip rather than to any physiologic factor such as endocrine imbalance.
4. Trauma appears to be of importance merely in hastening the onset of symptoms or displacement in a hip which is already diseased.
5. Seasonal variations in onset are accounted for by the seasonal activity of children.
6. The onset of symptoms and of displacement occurs usually during the rapid growth period of adolescence. Exceptions are explained by the factors of weight and trauma.
7. The pathologic features are sclerosis, thickening and avascularity of the soft tissues about the neck, with absence of any primary disease of the bone or cartilage.
8. Sclerotic changes about the neck are followed by a vascular disturbance, resulting in weakening at the epiphyseal disk, which frequently eventuates in slipping.
9. Four stages are described: preslipping, slipping, quiescent and residual.
10. Definite symptoms, physical signs and roentgenographic evidence of the disease are always present in the preslipping stage, and early diagnosis is essential for the best results.
11. After slipping there may be complete incapacitation of the hip or only slight disability, but definite evidence of the condition is always present.
12. Final function is not proportional to deformity.
13. Adequate rest for the hip is the most important factor in obtaining a good result.
14. In hips that have slipped less than three-eighths inch, and in the preslipping cases, rest alone is sufficient treatment. If the period before expected epiphyseal union is longer than six months, drilling across the epiphyseal line will hasten union.
15. (*a*) In hips that have slipped more than three-eighths inch early in the disease and recently, reduction is recommended. (*b*) In later cases with as much displacement, open reduction or subtrochanteric osteotomy after quiescence is advised.
16. In all cases, weight reduction and eradication of foci are indicated.
17. The well developed callus and early union occurring in this condition should be mentioned because of the frequently accepted view that joint fluid interferes with the healing of bone.
18. Arthritis is the usual sequel in adults.

420 East Fifty-Ninth Street.

ABSTRACT OF DISCUSSION

Dr. Irvin Balensweig, New York: I first called attention to this condition in 1926 when, in reviewing a series of cases, I also observed that the end-results were unsatisfactory in patients who were treated by the closed method of reduction. Since that time, further study has led me to believe that this condition, as one sees it in the clinics, has been present anywhere from one to two years prior to the time of observation and that the slipping of the epiphysis is therefore a gradual process except when it is caused by traumatisms, when the head may be grossly displaced. Every attempt should be made to recognize the lesion prior to the slipping; this can be done by subjecting children between the ages of 10 and 12 years to roentgen examination when they present themselves with a history of so-called growing pains in the thighs and an occasional limp. The movements of the hip will be found to be free except those of internal rotation and flexion with the limb in a neutral position; whereas flexion with the limb in external rotation is freer. This sign, to my knowledge, has never been described before. Roentgen examination in these cases reveals a widening of the epiphyseal line, and some fragmentation and areas of absorption in the diaphyseal region. The patients should be treated either by the conservative method of using a Thomas caliper brace or, far better, by a fusion of the epiphyseal line. I am pleased to learn that this type of operation has been carried out at the New York Orthopedic Hospital. It is also wise to roentgenograph hips before and after attempts at reduction in both internal and external rotation. It is only by such a procedure that one can determine the accuracy of the reduction. It is my conviction that when the condition is of long standing reduction cannot be accomplished by manipulative measures.

Dr. Albert B. Ferguson, New York: As to the relation to coxa plana, we have a number of cases that we might consider as transitional between coxa plana and slipping epiphysis. Some of these cases resemble, for example, the preslipping stage of slipping epiphysis, but at such an early age we are not sure whether a coxa plana or a slipping epiphysis will develop, and in some, as we followed them, coxa plana has developed, and in others slipping epiphysis has developed. In the paper we have excluded all transitional cases, both those that show a relation to coxa plana and those that show a relation to osteochondritis dissecans. The same applies to cavitation in the neck of the femur. We have a few cases in which actual cavities have been present in the neck and one case in which there was an actual abscess in the neck, which also showed a slipping epiphysis. We consider the latter as a transitional case and have not included it in the report, which is limited to typical cases of slipping epiphysis. The examination of the hip roentgenographically in internal and in external rotation needs to be emphasized, as Dr. Balensweig has brought out. In these closed reductions in which we have reported a very small percentage of success, most of the reductions have been considered good reductions when roentgenographed after the operation. They were found to be anything but good reductions by examination in positions other than the usual anteroposterior position. The patient could be turned on the face in plaster and rotated until the femur was brought into a neutral anteroposterior position or into an externally rotated position, and the displacement would then be visible just as it was before reduction, and, on the other hand, we have made such films, films in internal rotation, which would be the position after reduction. We have made such films before the operation and then had a picture which was exactly the same as the film after reduction. If one wishes to be sure as to the presence or absence of reduction, one must examine these patients very carefully and in several positions. With regard to traction reduction, on the operating table it is, I think, impossible to use the amount of traction which we have used in accomplishing this reduction. It has been demonstrated in these cases that traction of from 300 to 600 pounds (136 to 272 Kg.) in adduction in cases sufficiently recent will reduce the displacement. We have several cases in which the reduction was practically complete and confirmed by views in several directions. We have, however, had considerable difficulty in maintaining that reduction. At least a third and possibly half of the cases in which we have used traction have later showed some displacement, so that we are not yet ready to report on the final result, either anatomically or functionally.

THE NATURE AND ORIGIN OF THE PIGMENTED STREAKS CAUSED BY SEPARATION OF THE CHOROID[*]

F. H. VERHOEFF, M.D.
BOSTON

It is well known that on ophthalmoscopic examination pigmented streaks are sometimes seen in the fundus in cases in which there has been postoperative separation of the choroid. The streaks are black, have a granular appearance, and may show breaks in continuity. They may be straight or slightly wavy, of various lengths, and quite numerous. Not infrequently they branch. The largest may have about twice the width of a large retinal vein. They are most abundant at the periphery of the fundus, and many of them extend to the limit of the ophthalmoscopic field. Seldom do they reach as near as 2 or 3 mm. to the optic disk. Most of them are more or less meridional in direction and tend to be parallel to one another, but some run in a circular course. In the region of the streaks the fundus may show pale areas and scattered pigment dots. As far as is known, the streaks are permanent. They cause no demonstrable impairment of vision.

The streaks were first described in two clinical cases by Schur[1] in 1913; later Lindner[2] recorded two cases, and Plocher,[3] one case. Schur suggested that folds in the choroid played a rôle in causing them, Lindner that they were due to proliferation of the pigment epithelium such as sometimes occurs after separation of the retina, while Plocher offered no explanation. Fuchs[4] examined microscopically an eye in which separation of the choroid was still present after a perforating ulcer of the cornea. In the choroid he found creases in which the pigment epithelium on one side was in contact with that on the other and assumed that, in cases in which the choroid became replaced, such creases remained and thus explained the black streaks seen ophthalmoscopically. As will be seen later, this explanation was incorrect.

As Fuchs pointed out, these streaks, as seen ophthalmoscopically, differ in important respects from those known as angioid streaks. Especially do they differ in appearance and in the fact that they do not radiate from the optic disk. In spite of these facts, Guist[5] has advanced the view that angioid streaks are due to folds in the choroid, resulting from flat separation of the latter dependent on exudation.

Hitherto the microscopic appearance of the streaks has never been described. Recently I had an opportunity to examine microscopically two eyes in which such streaks were present and five eyes in which separation of the choroid still existed, and I was able to ascertain the exact nature and origin of the streaks. The important features of the cases in which the streaks were found are described herewith. Full details of the other cases are not essential for the purposes at hand and will be omitted.

REPORT OF CASES

Case 1.—A man, aged 68, was admitted to the Massachusetts Eye and Ear Infirmary, Feb. 23, 1928, with the diagnosis of chronic congestive glaucoma and bullous keratitis of the right eye. The tension of the eye was 50 mm. Schiötz and its vision was reduced to light perception with faulty projection. The left eye was normal and had normal vision without a glass.

February 24, an iridectomy was performed on the right eye. April 29, the lens was cataractous. July 6, the tension was 45 mm. (Schiötz). The anterior chamber was obliterated. Cataract operation was attempted, but vitreous was lost and the cataract was not removed. Feb. 23, 1929, light perception was still present. The right eye was enucleated.

Pathologic Examination of Right Eye.—The eye was fixed in a diluted "solution of formaldehyde-U. S. P." (1:10) for forty-eight hours, followed by 2.5 per cent hydrochloric acid in a 70 per cent alcohol for twenty-four hours.

The cornea showed pannus degenerativus and marked changes characteristic of old bullous keratitis. The iris below showed marked fibrosis and was adherent to the cornea from its root to the pupil. The capsule of the lens was ruptured and lens matter was bulging the operative wound, which was covered by conjunctiva and a slight amount of connective tissue. The clefts within the lens were invaded by pus cells, many of which were necrotic, and there was a fairly large mass of macrophages with some pus cells between the lens and the cornea—phacoanaphylactic reaction. The anterior part of the vitreous contained a considerable number of swollen cells, apparently chiefly macrophages. Otherwise the posterior part of the eye was free from evidences of inflammatory reaction, except for a few macrophages here and there on the surface of the retina.

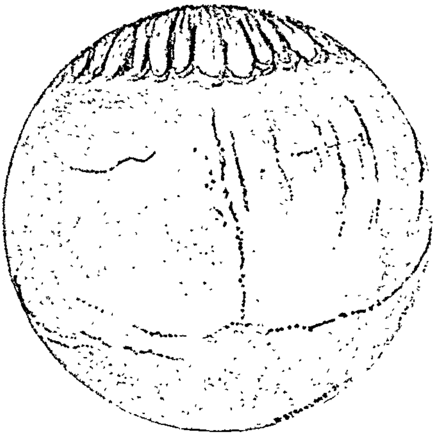

Fig. 1 (case 1).—Temporal quadrant of fundus, after fixation and immersion in glycerin, showing typical pigmented streaks. The retina is in situ.

The optic disk was deeply cupped. The retina and choroid were everywhere in situ. Ganglion cells were still present in considerable numbers in the macular region but were absent elsewhere. The choroid was everywhere smoothly applied to the sclera. Colloid excrescences were very few in number.

When the eye was opened after fixation, the vitreous was found separated from the fundus by fluid. The fundus showed on each side numerous pigmented streaks identical in appearance with those seen ophthalmoscopically after separation of the choroid (fig. 1). Ten of these were large; eight on one side, two on the other. All except two of these large streaks began near the ora serrata and ran in the direction of the disk, more or less parallel to one another. The largest of these was 9 mm. in length and about 0.2 mm. in greatest thickness. At the posterior end of this was a streak about 13 mm. long running equatorially. Two mm. behind the ora, there was another streak about 5 mm. long, which also ran circularly. The smaller streaks ran in various directions, but mostly either circularly or meridionally. The streaks appeared to consist of coarse pigment dots and showed small breaks in continuity. In the vicinity of the streaks the fundus often was paler than elsewhere and showed scattered dots.

ditions such as coxa plana and osteochondritis dissecans. Transitional cases showing the relation to these other conditions have been excluded from the present report.

This disease is far more common than is generally supposed. Every adolescent child with a hip limp should be examined for it, especially if the child is overweight. If the condition is recognized in the preslipping stage it should be considered an emergency case. Displacement must be prevented. In selecting the treatment to be applied to the given case there must be careful consideration of the age of the patient, the stage of the disease, the presence of callus, and the time since the onset of symptoms and since displacement.

SUMMARY AND CONCLUSIONS

1. Seventy cases of slipping of the upper femoral epiphysis are reviewed.
2. Bilateral occurrence is not infrequent and should always be looked for.
3. Overweight children, whether tall or fat, are more susceptible to the condition. This appears to be due to the greater stress on the hip rather than to any physiologic factor such as endocrine imbalance.
4. Trauma appears to be of importance merely in hastening the onset of symptoms or displacement in a hip which is already diseased.
5. Seasonal variations in onset are accounted for by the seasonal activity of children.
6. The onset of symptoms and of displacement occurs usually during the rapid growth period of adolescence. Exceptions are explained by the factors of weight and trauma.
7. The pathologic features are sclerosis, thickening and avascularity of the soft tissues about the neck, with absence of any primary disease of the bone or cartilage.
8. Sclerotic changes about the neck are followed by a vascular disturbance, resulting in weakening at the epiphyseal disk, which frequently eventuates in slipping.
9. Four stages are described: preslipping, slipping, quiescent and residual.
10. Definite symptoms, physical signs and roentgenographic evidence of the disease are always present in the preslipping stage, and early diagnosis is essential for the best results.
11. After slipping there may be complete incapacitation of the hip or only slight disability, but definite evidence of the condition is always present.
12. Final function is not proportional to deformity.
13. Adequate rest for the hip is the most important factor in obtaining a good result.
14. In hips that have slipped less than three-eighths inch, and in the preslipping cases, rest alone is sufficient treatment. If the period before expected epiphyseal union is longer than six months, drilling across the epiphyseal line will hasten union.
15. (*a*) In hips that have slipped more than three-eighths inch early in the disease and recently, reduction is recommended. (*b*) In later cases with as much displacement, open reduction or subtrochanteric osteotomy after quiescence is advised.
16. In all cases, weight reduction and eradication of foci are indicated.
17. The well developed callus and early union occurring in this condition should be mentioned because of the frequently accepted view that joint fluid interferes with the healing of bone.
18. Arthritis is the usual sequel in adults.

420 East Fifty-Ninth Street.

ABSTRACT OF DISCUSSION

Dr. Irvin Balensweig, New York: I first called attention to this condition in 1926 when, in reviewing a series of cases, I also observed that the end-results were unsatisfactory in patients who were treated by the closed method of reduction. Since that time, further study has led me to believe that this condition, as one sees it in the clinics, has been present anywhere from one to two years prior to the time of observation and that the slipping of the epiphysis is therefore a gradual process except when it is caused by traumatisms, when the head may be grossly displaced. Every attempt should be made to recognize the lesion prior to the slipping; this can be done by subjecting children between the ages of 10 and 12 years to roentgen examination when they present themselves with a history of so-called growing pains in the thighs and an occasional limp. The movements of the hip will be found to be free except those of internal rotation and flexion with the limb in a neutral position; whereas flexion with the limb in external rotation is freer. This sign, to my knowledge, has never been described before. Roentgen examination in these cases reveals a widening of the epiphyseal line, and some fragmentation and areas of absorption in the diaphyseal region. The patients should be treated either by the conservative method of using a Thomas caliper brace or, far better, by a fusion of the epiphyseal line. I am pleased to learn that this type of operation has been carried out at the New York Orthopedic Hospital. It is also wise to roentgenograph hips before and after attempts at reduction in both internal and external rotation. It is only by such a procedure that one can determine the accuracy of the reduction. It is my conviction that when the condition is of long standing reduction cannot be accomplished by manipulative measures.

Dr. Albert B. Ferguson, New York: As to the relation to coxa plana, we have a number of cases that we might consider as transitional between coxa plana and slipping epiphysis. Some of these cases resemble, for example, the preslipping stage of slipping epiphysis, but at such an early age we are not sure whether a coxa plana or a slipping epiphysis will develop, and in some, as we followed them, coxa plana has developed, and in others slipping epiphysis has developed. In the paper we have excluded all transitional cases, both those that show a relation to coxa plana and those that show a relation to osteochondritis dissecans. The same applies to cavitation in the neck of the femur. We have a few cases in which actual cavities have been present in the neck and one case in which there was an actual abscess in the neck, which also showed a slipping epiphysis. We consider the latter as a transitional case and have not included it in the report, which is limited to typical cases of slipping epiphysis. The examination of the hip roentgenographically in internal and in external rotation needs to be emphasized, as Dr. Balensweig has brought out. In these closed reductions in which we have reported a very small percentage of success, most of the reductions have been considered good reductions when roentgenographed after the operation. They were found to be anything but good reductions by examination in positions other than the usual anteroposterior position. The patient could be turned on the face in plaster and rotated until the femur was brought into a neutral anteroposterior position or into an externally rotated position, and the displacement would then be visible just as it was before reduction, and, on the other hand, we have made such films, films in internal rotation, which would be the position after reduction. We have made such films before the operation and then had a picture which was exactly the same as the film after reduction. If one wishes to be sure as to the presence or absence of reduction, one must examine these patients very carefully and in several positions. With regard to traction reduction, on the operating table it is, I think, impossible to use the amount of traction which we have used in accomplishing this reduction. It has been demonstrated in these cases that traction of from 300 to 600 pounds (136 to 272 Kg.) in adduction in cases sufficiently recent will reduce the displacement. We have several cases in which the reduction was practically complete and confirmed by views in several directions. We have, however, had considerable difficulty in maintaining that reduction. At least a third and possibly half of the cases in which we have used traction have later showed some displacement, so that we are not yet ready to report on the final result, either anatomically or functionally.

THE NATURE AND ORIGIN OF THE PIGMENTED STREAKS CAUSED BY SEPARATION OF THE CHOROID*

F. H. VERHOEFF, M.D.
BOSTON

It is well known that on ophthalmoscopic examination pigmented streaks are sometimes seen in the fundus in cases in which there has been postoperative separation of the choroid. The streaks are black, have a granular appearance, and may show breaks in continuity. They may be straight or slightly wavy, of various lengths, and quite numerous. Not infrequently they branch. The largest may have about twice the width of a large retinal vein. They are most abundant at the periphery of the fundus, and many of them extend to the limit of the ophthalmoscopic field. Seldom do they reach as near as 2 or 3 mm. to the optic disk. Most of them are more or less meridional in direction and tend to be parallel to one another, but some run in a circular course. In the region of the streaks the fundus may show pale areas and scattered pigment dots. As far as is known, the streaks are permanent. They cause no demonstrable impairment of vision.

The streaks were first described in two clinical cases by Schur[1] in 1913; later Lindner[2] recorded two cases, and Plocher,[3] one case. Schur suggested that folds in the choroid played a rôle in causing them, Lindner that they were due to proliferation of the pigment epithelium such as sometimes occurs after separation of the retina, while Plocher offered no explanation. Fuchs[4] examined microscopically an eye in which separation of the choroid was still present after a perforating ulcer of the cornea. In the choroid he found creases in which the pigment epithelium on one side was in contact with that on the other and assumed that, in cases in which the choroid became replaced, such creases remained and thus explained the black streaks seen ophthalmoscopically. As will be seen later, this explanation was incorrect.

As Fuchs pointed out, these streaks, as seen ophthalmoscopically, differ in important respects from those known as angioid streaks. Especially do they differ in appearance and in the fact that they do not radiate from the optic disk. In spite of these facts, Guist[5] has advanced the view that angioid streaks are due to folds in the choroid, resulting from flat separation of the latter dependent on exudation.

Hitherto the microscopic appearance of the streaks has never been described. Recently I had an opportunity to examine microscopically two eyes in which such streaks were present and five eyes in which separation of the choroid still existed, and I was able to ascertain the exact nature and origin of the streaks. The important features of the cases in which the streaks were found are described herewith. Full details of the other cases are not essential for the purposes at hand and will be omitted.

REPORT OF CASES

Case 1.—A man, aged 68, was admitted to the Massachusetts Eye and Ear Infirmary, Feb. 23, 1928, with the diagnosis of chronic congestive glaucoma and bullous keratitis of the right eye. The tension of the eye was 50 mm. Schiötz and its vision was reduced to light perception with faulty projection. The left eye was normal and had normal vision without a glass.

February 24, an iridectomy was performed on the right eye. April 29, the lens was cataractous. July 6, the tension was 45 mm. (Schiötz). The anterior chamber was obliterated. Cataract operation was attempted, but vitreous was lost and the cataract was not removed. Feb. 23, 1929, light perception was still present. The right eye was enucleated.

Pathologic Examination of Right Eye.—The eye was fixed in a diluted "solution of formaldehyde-U. S. P." (1:10) for forty-eight hours, followed by 2.5 per cent hydrochloric acid in a 70 per cent alcohol for twenty-four hours.

The cornea showed pannus degenerativus and marked changes characteristic of old bullous keratitis. The iris below showed marked fibrosis and was adherent to the cornea from its root to the pupil. The capsule of the lens was ruptured and lens matter was bulging the operative wound, which was covered by conjunctiva and a slight amount of connective tissue. The clefts within the lens were invaded by pus cells, many of which were necrotic, and there was a fairly large mass of macrophages with some pus cells between the lens and the cornea—phacoanaphylactic reaction. The anterior part of the vitreous contained a considerable number of swollen cells, apparently chiefly macrophages. Otherwise the posterior part of the eye was free from evidences of inflammatory reaction, except for a few macrophages here and there on the surface of the retina.

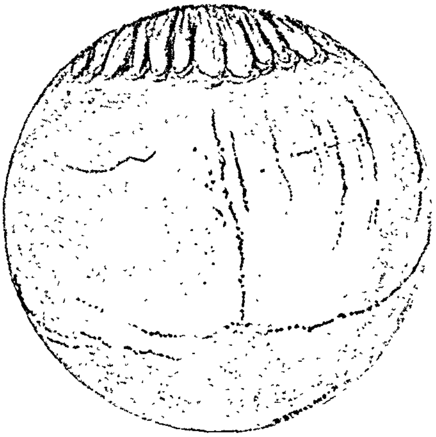

Fig. 1 (case 1).—Temporal quadrant of fundus, after fixation and immersion in glycerin, showing typical pigmented streaks. The retina is in situ.

The optic disk was deeply cupped. The retina and choroid were everywhere in situ. Ganglion cells were still present in considerable numbers in the macular region but were absent elsewhere. The choroid was everywhere smoothly applied to the sclera. Colloid excrescences were very few in number.

When the eye was opened after fixation, the vitreous was found separated from the fundus by fluid. The fundus showed on each side numerous pigmented streaks identical in appearance with those seen ophthalmoscopically after separation of the choroid (fig. 1). Ten of these were large; eight on one side, two on the other. All except two of these large streaks began near the ora serrata and ran in the direction of the disk, more or less parallel to one another. The largest of these was 9 mm. in length and about 0.2 mm. in greatest thickness. At the posterior end of this was a streak about 13 mm. long running equatorially. Two mm. behind the ora, there was another streak about 5 mm. long, which also ran circularly. The smaller streaks ran in various directions, but mostly either circularly or meridionally. The streaks appeared to consist of coarse pigment dots and showed small breaks in continuity. In the vicinity of the streaks the fundus often was paler than elsewhere and showed scattered dots.

Portions of the fundus showing streaks were excised, embedded in celloidin and sectioned as nearly as possible at right angles to the streaks. Before sectioning, some of the blocks were cleared in chloroform, others in glycerin. The streaks could be seen as such while being cut and were therefore definitely identified in the stained sections. One streak was cut for a short distance in serial sections, and another was cut longitudinally for a distance of 3 mm. Microscopically the streaks appeared as well defined thickenings of the pigment epithelium (figs. 2 and 3) and measured from about 0.028 mm. to 0.04 mm. in thickness and from about 0.056 mm. to 0.18 mm. in width. At their sites, the pigment epithelium consisted of from two to five layers of cells densely packed with pigment. The pigment granules retained the spindle form of those seen in normal pigment epithelium. The retina was closely applied to the streaks. In most instances it was slightly bulged up by the streak, but in some instances only its outer layers were compressed by the streak, the inner surface of the retina maintaining its normal level. Occasionally, the surface of the choroid beneath the streak was slightly depressed. In the vicinity of some of the streaks, the pigment epithelium contained somewhat less pigment than elsewhere. In the affected region there were areas, from three to seven cells in width, in which the cells were more densely pigmented than elsewhere and in which there were from one to three pigment cells on the inner surface of the pigment layer.

Case 2.—A woman, aged 73, with general arteriosclerosis and high blood pressure (240 systolic and 100 diastolic) was first seen at the Massachusetts Eye and Ear Infirmary, Jan. 8, 1930. The vision of each eye was reduced to counting fingers at 5 feet. There were numerous scattered retinal hemorrhages in each eye. The tension of each eye was normal.

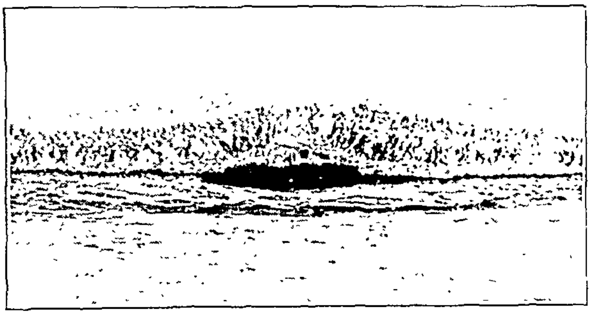

Fig. 2 (case 1).—Section stained in hematoxylin and eosin, showing a pigmented streak cut transversely. The slight depression of the surface of the choroid beneath the streak may be indicative of the preexistent crease; × 116.6.

January 27, the tension of the right eye was 75 mm., that of the left, 17 mm. (Schiötz). The vision of the right eye was reduced to perception of shadows.

January 30, a trephine operation and iridectomy were performed on the right eye, a very large trephine being used.

February 21, extensive separation of the choroid on both sides and below was noted.

November 17, the tension of the right eye was 49 mm., the fundus was not visible and the vision was nil. The right eye was enucleated.

Pathologic Examination of the Right Eye.—The eye was fixed as in the previous case. Sections showed marked sclerosis of the retinal vessels, scattered small retinal hemorrhages, glaucomatous cupping of the optic disk, and peripheral anterior synechia. The retina and choroid were everywhere in situ. There was slight if any edema of the retina. The retinal ganglion cells had entirely disappeared. The lens was not cataractous, but there was a delicate pupillary membrane over it. The trephine wound was covered over with fibrous tissue, which was bulged outward. Serial cross-sections of the central retinal vessels showed complete obstruction of the central vein due to endophlebitis.

When the eye was opened after fixation, the vitreous was found separated from the retina, and the small amount of it remaining was confined to the anterior part of the eye. The fundus showed many pigment streaks on each side, similar to those in case 1. Four of the largest were on the nasal side, each of which began about 4 mm. behind the ora serrata. One, about 10 mm. in length, had a meridional direction; one, about 11 mm. long, ran upward and outward; one, about 12 mm. long, ran downward and, about 1 mm. from its end, the other streak began and continued for about 11 mm. These streaks appeared to be made up of dots, and were about 0.25 mm. in greatest thickness. With the loupe many smaller streaks could be seen. These were irregular or curved, and some of them branched.

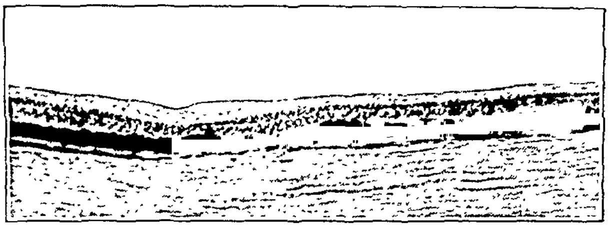

Fig. 3 (case 1).—Pigmented streak sectioned longitudinally; × 83.3.

Portions of the fundus containing streaks were excised and sectioned as in the previous case. For a short distance one of the finer streaks was successfully sectioned longitudinally. Microscopically, the streaks were essentially similar in appearance to those in case 1. In this case, however, occasionally a few of the cells in the central portion of a streak were partly or wholly free from pigment (fig. 4). In one instance a colloid excrescence was seen within a streak. This no doubt existed before the streak was formed. The retina was closely applied to the streaks as in case 1, and in all sections made of this eye the choroid was everywhere smoothly applied to the sclera and showed no indentations of the membrane of Bruch. In some areas within the regions of the streaks the pigment epithelium contained less pigment than elsewhere. Over the entire fundus the pigment epithelium showed numerous small colloid excrescences and also other changes which could not be certainly distinguished from those commonly seen in senile eyes.

COMMENT

In neither of these cases were the streaks seen ophthalmoscopically, but as seen with the naked eye and with the loupe, after the globes had been fixed in formaldehyde and opened,[6] the streaks were perfectly typical of those seen after separation of the choroid (fig. 1). The separation of the choroid had been observed ophthalmoscopically in case 2 but not in case 1. In case 1, however, two operations had been performed on the eye, the second one seven months prior to enucleation, so that there was an opportunity for the separation of the choroid to have occurred on two occa-

---

[6] As a fixative, solution of formaldehyde has certain disadvantages, but these cases illustrate one of its great advantages; namely, that it permits details in the fundus to be seen almost as well as they can be seen with the ophthalmoscope. After many other fixatives the streaks would have been invisible.

sions. Moreover, as Plocher has pointed out, the streaks are so characteristic that their occurrence is a certain indication that separation of the choroid has previously existed.

Microscopic examination of the streaks in these cases showed that they were situated between Bruch's membrane and the retina proper and were simply ridgelike thickenings of the pigment epithelium (figs. 2, 3 and 4). Occasionally the surface of the choroid beneath a streak was very slightly depressed. It is noteworthy that otherwise the choroid was perfectly smooth, and there was no obvious indication of its having been previously separated, other than the presence of the streaks.

Although apparently having no relation to the streaks, the fact may be worthy of mention here that the vitreous was found separated from the fundus in both of these cases. It is commonly believed that after the separation of the choroid has disappeared the vitreous returns to its normal volume, but these cases seem to show that this is not invariably true. It is possible, however, that the separation of the vitreous antedated the separation of the choroid in these cases.

The question now arises as to the mode of origin of the streaks. To obtain an answer to this, I have examined sections of the five eyes referred to in which separation of the choroid still existed. In one eye the separation was due to a recent perforating ulcer of the cornea; in the others the separation had occurred without an obvious cause.

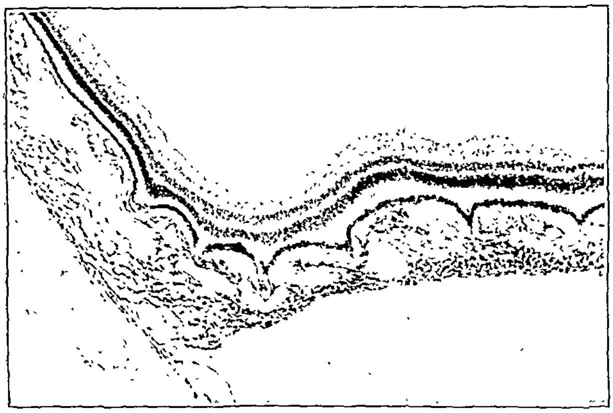

Fig. 5.—Section showing folds and creases involving surface of separated choroid in a case of perforating ulcer of the cornea; reduced from a photomicrograph with a magnification of 36 diameters.

In each of these eyes the choroid showed folds of various sizes, but they were more numerous in the eye with the perforating ulcer. The choroid and the retina together were involved in large wavelike folds, but only their inner surfaces showed small folds and creases. The small folds of the choroidal surface were rounded and inward, i. e., toward the retina, while the creases were between the folds and much sharper (fig. 5). As seen in the sections, the creases appeared as indentations, which involved chiefly the pigment epithelium, Bruch's membrane and the choriocapillaris. In some instances the pigment epithelium did not take part in the crease but bridged it over. In some of the larger creases the pigment epithelium was partly absent, partly depigmented or otherwise altered. In a few instances the epithelium on one side of a deep crease was in contact with that on the other side, as Fuchs described. In a few of the creases, the spaces within them were partly or completely filled with pigment cells evidently derived by proliferation of the original pigment epithelium (fig. 6). Probably in these the portions of the epithelium on each side of the creases had been for a time in contact and had fused together, and later the creases widened, thus causing the pigment cells to proliferate and fill the resulting spaces. From one of the eyes a segment of the separated choroid was excised and the retina peeled away from it. With a loupe, pigmented streaks could then be plainly seen on the choroidal surface (fig. 7). One streak branched into two at one end. The streaks were more numerous and much thinner than those seen in cases 1 and 2 (fig. 1), in which the choroid was in situ. The largest measured 0.02 mm. in width. A portion of the segment was then reembedded and the streaks were sectioned transversely. The sections showed definitely that the streaks were fine creases such as shown in figure 5.

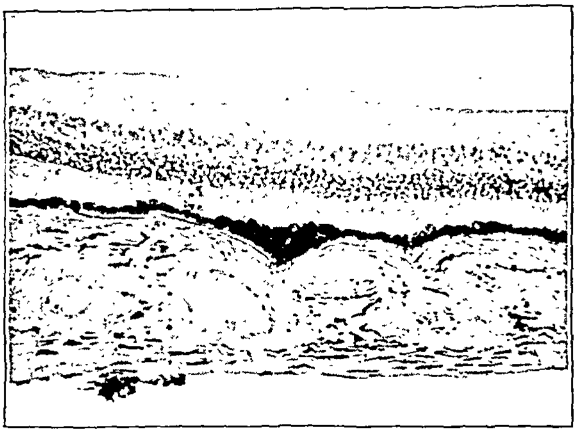

Fig. 6.—Section from same eye from which figure 5 was obtained, showing a crease filled with pigment cells. When the choroid becomes reapplied to the sclera, the pigment cells in such creases are lifted up so as to form pigmented streaks; × 111.

These fine pigmented streaks (creases) that exist while the choroid is still separated are not generally observed on ordinary ophthalmoscopic examination, no doubt because the separated choroid is poorly illuminated and appears dark. In a recent case, I was unable to see them when illuminated by the ophthalmoscope but could see them plainly, and also recognize folds in the choroid, when the latter was strongly transilluminated through the sclera.

Fig. 7.—Segment of the separated choroid, from which the retina has been peeled, in a case of spontaneous separation of the choroid. The pigmented streaks are more numerous and much finer than those seen after the choroidal separation has subsided (fig. 1) and correspond to creases such as are shown in figures 5 and 6.

The explanation of the formation of the folds and creases is probably as follows: Separation of the choroid is due to the fact that the pressure in the vitreous chamber has become less, for a time, than that in the perichoroidal space. As the choroid separates it is, with the retina, for obvious reasons, forced into folds. The two structures are also at the same time compressed into a smaller surface area than they originally occupied. The outer parts of the choroid and retina, being relatively soft, yield to the compression usually without folding further, but the membrane of Bruch with the choriocapillaris and the inner surface of the retina, owing to their greater rigidity, are forced into rounded inward folds associated with outward creases.

From the foregoing observations the manner in which permanent pigmented streaks are formed as a result of separation of the choroid is now apparent. When the choroid is reapplied to the sclera, it is stretched to its original dimensions, so that all the folds and creases entirely disappear, leaving its surface smooth. As a result, the pigment cells that had accumulated in some of the creases are lifted up in the form of ridges on the surface of the choroid, visible with the ophthalmoscope as pigmented streaks. At the same time, the retina is smoothed out and is closely applied to the streaks.

The granular appearance of the streaks is due to the fact that the accumulations of pigment cells were not uniform throughout the creases, and the irregularities and breaks in the streaks correspond to similar defects in the preexistent creases.

The paler areas sometimes seen in the affected portion of the fundus are due to diminution in the amount of pigment in the pigment epithelium, resulting, no doubt, from the abnormal conditions of nutrition existing while the choroid was separated. The discrete pigment dots, separate from the streaks, are due to increased pigmentation and proliferation of the pigment epithelium in small areas, possibly corresponding to small pits which existed in the surface of the separated choroid.

The reason that the streaks do not occur near the optic disk is that the choroid is so firmly united with the sclera in this region that it seldom if ever becomes separated here.

As to the frequency of their occurrence, it might be supposed, judging by the scarcity of the recorded cases, that these permanent streaks are extremely unusual. But it seems to me, nevertheless, that they may be of relatively frequent occurrence and are often overlooked. I have seen them in very few cases but am sure that I have not always examined the fundus, especially its periphery, with sufficient thoroughness to detect them. It is certain, however, that they do not occur in every case in which there has been separation of the choroid. Obviously, they would not be formed in cases in which the separation was of short duration, for the observations here recorded clearly indicate that the extent and duration of the separation are determining factors in their formation.

As to the time when the pigmented streaks are formed, the cases recorded in the literature afford no exact information. Lindner observed the streaks in his second case three days after the separation had subsided. But in this case a trephine operation had been performed three months previous to the final operation, so that the streaks may have occurred then and have been overlooked. Plocher discovered streaks in his case two months after the separation was first noticed, and before it had entirely subsided. The actual observation, by means of a loupe, of pigmented streaks on the surface of the separated choroid in one of the present cases (fig. 7), as previously described, shows that streaks actually exist before the separation has subsided. These streaks, however, are much finer and more numerous than those seen in cases in which the choroid has become replaced (fig. 1), and sections made of them show that they are really fine creases (fig. 5). They are not generally recognized on ordinary ophthalmoscopic examination, but, as previously noted, in a recent case I was able to see them by transilluminating the separated choroid through the sclera. No doubt, when the separation subsides and the creases have been smoothed out, all the streaks disappear except those in which pigment cells have accumulated. The permanent streaks, actual ridges of pigment epithelium, must certainly appear soon after the choroid has been reapplied to the sclera.

In a previous communication before this section, I[7] demonstrated the nature and origin of angioid streaks, showing that the latter are corrugations of the inner surface of the choroid, including the pigment epithelium, resulting from fibrosis of the outer layers of the choroid. From the observations that I have recorded, it can now be regarded as certain that the pigmented streaks resulting from separation of the choroid are entirely different in nature and origin from angioid streaks.

CONCLUSIONS

From macroscopic and microscopic studies of two eyes showing pigmented streaks in the fundus, and of five eyes in which separation of the choroid still existed, the following conclusions are drawn:

Pigmented streaks in the fundus resulting from separation of the choroid are entirely different in nature and origin from angioid streaks.

Very fine pigmented streaks exist while the choroid is still separated. These are furrow-like creases in the surface of the choroid. They are not usually visible on ordinary ophthalmoscopic examination but they may be seen, in some cases at least, by transilluminating the separated choroid through the sclera. All these creases disappear as such when the separation subsides.

The permanent pigmented streaks, seen after the separation has subsided, are ridgelike thickenings of the pigment epithelium.

The pigment cells composing the permanent streaks originally accumulate within some of the furrow-like creases that exist while the choroid is separated. When the choroid becomes reapplied to the sclera and these creases are smoothed out, the accumulations of pigment cells are elevated, thus giving the appearance of streaks.

82 Commonwealth Avenue.

ABSTRACT OF DISCUSSION

Dr. T. B. Holloway, Philadelphia: As Dr. Verhoeff has stated, the recorded case histories of pigmentation after detachment of the choroid are rare, and it is gratifying that these cases should have come under his observation and that his observations are available for this section. The only probable case of this character that I have seen was in an eye observed at the former Polyclinic Hospital, fourteen or fifteen years ago, and at the time the significance of the pigmentation was not understood. In character it corresponded to the type under discussion. It was not until I had occasion to review the literature concerning angioid streaks and saw references to this type of pigmentation developing after choroidal detachment that the case mentioned was recalled. Naturally, those who have described these cases have pointed out those characteristics that differentiate them from angioid streaks, or, as Verhoeff has suggested, fibrosis chorioideae corrugans. Nevertheless, it is interesting to note that each of these types of linear pigmentation has to do with the pigment epithelium, the one doubtless of vascular origin, with fibrosis, as the author has shown, as the contributing factor, while in the other case it is brought about as the result of what might be regarded as a mechanical sequence of a detached choroid. While it has been shown that these streaks may be visible with the ophthalmoscope within a few days after the choroid has become detached, Dr. Verhoeff has pointed out the more important fact that by the use of transillumination they may be observed during the period of detachment. This simply means that in a case of choroidal detachment the eye must be examined by transillumination as soon as it is permissible. If the author's belief in regard to the character of the cases with which he was dealing is accepted, there is little use to speculate as to theories when confronted by definite pathologic observations.

---

[7] Verhoeff, F. H.: The Nature and Pathogenesis of Angioid Streaks in the Ocular Fundus, Tr. Sect. Ophth. A. M. A., 1928, p. 243.

Dr. E. V. L. Brown, Chicago: One characteristic of the detachment streaks was not sufficiently stressed or discussed by Dr. Verhoeff, although definitely present and described in each of his cases; namely, their predominantly longitudinal and circular course. It seems to have been present in practically all other reported cases. There are two kinds of pigment streaks in the fundus, the angioid streaks and streaks due to detachment of the choroid, both due to changes in the choroid, the pathology of each of which Dr. Verhoeff has definitely established. There is a third kind which apparently is rare, or at least concerning which little has been written; namely, the kind due to arteriosclerosis of the choroidal vessels. This was first described clinically in two cases (and anatomically in one of the cases) by Siegrist in 1899. I would suggest a new explanation of these streaks; namely, that the streak or ridge formation is possibly due to inward pressure of certain larger choroidal vessels against the pigment epithelium. This pressure would bend the lamina basalis inward in a weakly convex curve just over the course of the vessel. Siegrist specifically notes that both ophthalmoscopically and anatomically there were no streaks over the completely sclerosed vessels; perhaps complete hardening took place in arteries only or in small veins and thus made no bending inward of the lamina basalis. His drawing shows only small vessels sclerosed, only larger ones with pigment. Possibly these larger vessel walls first become relaxed as described by Thoma decades ago, then distended, and press gently but constantly against the lamina and epithelium, like a tight shoe on a corn, and make the epithelium proliferate just along the line of pressure.

Dr. F. H. Verhoeff, Boston: I am aware, of course, that pigmented streaks sometimes result from separation of the retina, and I have seen them in cases of high myopia and other conditions; but such streaks occur so rarely and are so scanty when they do occur that they do not properly come within the scope of my paper. With the streaks described by Siegrist, however, I was unacquainted until his paper and that of Koeppl were called to my attention by Dr. Brown a few days ago. These streaks have no relation to postoperative separation of the choroid, but they are pertinent to my paper because they are histologically similar to the streaks investigated by me. Siegrist could offer no satisfactory explanation for their occurrence. Three possible explanations in addition to those offered by him suggest themselves to me: First, that they are due to antecedent, spontaneous separation of the choroid. Against this are the facts that they appear close to the optic disk, where separation of the choroid almost never takes place; that they follow the course of the choroidal vessels and have a definitely beaded appearance. Second, that they result from previous creases in the choroid. Against this is the difficulty of explaining how sclerosis of the choroidal vessels could cause such creases. Creases are shown in Siegrist's illustration, but they are probably artefacts dependent on postmortem changes. Third, that the streaks are caused by pulsation of certain choroidal vessels. When there is marked sclerosis of the choroidal vessels, it is reasonable to assume that for a time some of the latter may pulsate to an unusual degree and that the pulsation may locally stimulate the pigment epithelium to proliferate. Siegrist found, both ophthalmoscopically and microscopically, that the streaks occurred only in relation with thin-walled vessels. Against this explanation are the facts that such streaks are beaded and occur very rarely, but nevertheless at present it seems to me the most probable one. In regard to Dr. Holloway's comment about overlooking streaks, in the case in which I found creases I later had the patient come back and then found three large streaks in the lower inner quadrant, three in the upper outer quadrant, and a number of small ones. These streaks had not been seen on several other visits to the clinic, because a special effort had not been made to find them.

THE PREVENTION OF GOITER IN DETROIT AND CLEVELAND

O. P. KIMBALL, M.D.
CLEVELAND

The comparative study of the prevention of goiter in Detroit and in Cleveland demonstrates how quickly any community can completely eradicate endemic goiter when there is a unity of all the forces that direct its public health. Without this unity, public health cannot take care of itself. The safety of present methods of prevention of goiter also is considered.

Detroit and Cleveland are practically the same size, and as far as is known the natural conditions and the factors determining endemic goiter are the same. I have been intimately connected with the work in the two cities. In Detroit this preventive measure had the leadership and cooperation of the state department of Health, the city department of health, the school board, school physicians and the medical profession. In Cleveland there has been no unity of thought or action.

The Michigan State Department of Health, after surveys determining the incidence of goiter and the iodine content in the various water supplies throughout the state, early in 1924 outlined a definite program for goiter prevention. They decided on the use of iodized salt. A conference with the salt manufacturers and later with the wholesale grocery men was held, resulting in a definite cooperative plan that only iodized salt would be used as food in Michigan. Iodides have always been expensive, costing around $3 a pound even when bought in large quantities. To prevent an increase in the cost of salt, which might be used as an argument against the use of iodized salt, the manufacturers agreed to stand half of the increase in the cost of production, and the wholesale grocers the other half, thereby keeping the cost to the consumer the same as that of ordinary table salt. It was further agreed that the state department of health would do all the educative work, making advertising by the salt producers unnecessary. Under this plan iodized salt was put on the market throughout the state of Michigan in May, 1924.

A survey had been made in the Detroit schools in the winter of 1924, so that the incidence of goiter just preceding this prophylactic movement was fairly well established. This survey was outlined and directed by me with the assistance of two physicians who had worked with me, thus insuring uniform data. One of these physicians, Dr. Gudakunst, has been director of health education in the schools and has continuously emphasized the prevention of goiter. Further, the Detroit school board ordered the purchasing department to use only iodized salt in their cafeterias, which feed 50,000 children daily.

In Ohio the state department of health became interested and in 1925 appointed me as consultant on goiter to the state health department, for the purpose of carrying out a survey in various sections to determine the incidence of goiter and institute a definite program of prophylaxis. To this end in the fall of 1925 all the children in two counties in the southern section of the state, in two in the central section and two counties along the lake were carefully examined. Altogether, 60,000 school children were examined for thyroid enlargement. We planned to concentrate the efforts of the state department of health in these counties, expecting to be able to control the situation so that only iodized salt would be used. Then

a careful reexamination would be made at least every other year to determine the results.

In the spring of 1926, active opposition to the prophylactic measures began. An article by Hartsock[1] emphasized the great dangers of hyperthyroidism from the use of iodized salt. The state department of health almost immediately withdrew from its active campaign and only a partial resurvey was made in 1926. No further study was made by the state department of health.

In Cleveland the director of health service in the public schools has not had a concrete plan for the prevention of goiter; hence no unity of opinion on this point could prevail among the school physicians and nurses. Neither has there been a unanimity of opinion among the members of the medical profession of Cleveland. Some of the leading goiter surgeons have persistently and continuously opposed the use of iodized salt on the ground that it might cause hyperthyroidism. This theoretical possibility was stressed with such an effect that in this community it has been *generally accepted that the continued use of iodized salt* is actually dangerous. In my survey through the schools last year I found that most of the principals, teachers, nurses and school physicians were working under the impression that iodized salt was not a safe method of prophylaxis. This contrast in attitudes toward the general use of iodized salt for the prevention of goiter in Detroit and in Cleveland has created an ideal basis for this comparative study.

As previously stated, a survey was made in the Detroit schools early in 1924. This included both boys and girls from the first grade through high school. It was found that 36 per cent had a definite thyroid enlargement. No attempt was made to differentiate accurately the congenital adenomas from the active hyperplastic type, but I felt sure at the time that the incidence of congenital adenomas in this survey was approximately the same as in other sections of Michigan, where from 10 to 12 per cent was found. In the Cleveland schools no extensive goiter study was ever made.

In the fall of 1924, a goiter survey was made through several of the parochial schools. I myself made this survey for the city health department in order to start prophylaxis through these schools. All the children in one primary, one intermediate and one high school, approximately 1,200 children, were examined, a total incidence of goiter of 34 per cent being found.

Table 1.—*Comparison of Incidence of Goiter in Schoolchildren of Detroit and of Cleveland*

	Total Incidence of Goiter in Regular Schools, 1924	Total Incidence of Goiter in Special Schools, 1930-1931	Hyperplastic or Iodine Deficiency Goiter in Special Schools, 1930-1931	Number of Examinations
Detroit	36%	12%	0.3%	5,075
Cleveland	34%	30%	18.0%	3,175

During the school year 1930 and 1931 the Detroit school physicians examined more than 100,000 children from the first grade through high school. They reported that only 2.1 per cent showed a[illegible] enlargement of the thyroid, emphasizing that m[illegible]ce enlargements were small discrete a[illegible] genital goiter. That is what Dr. Marinus and I found in the examination of 5,075 children in the special schools of Detroit during the last two years. The total incidence of goiter was 12 per cent, but 97 per cent of these were only discrete adenomas or a persistent thyroglossal stalk (congenital goiter), with the remainder of the gland normal. We studied them for the presence of hyperplasia or a uniform colloid enlargement, which condition, we feel, means an iodine deficiency. Of this type (iodine deficiency goiter) we found only fifteen cases, or 0.3 per cent. We kept this differentiation constantly in mind: (*a*) congenital goiter with normal function and chemistry; (*b*) hyperplastic or iodine deficiency goiter. There was no thought of creating a new classification. These descriptive terms were used only to express our feeling as to the iodine deficiency, either at the time of the examination (hyperplasia) or a recent condition (colloid).

Table 2.—*Yearly Report of Incidence of Goiter in Detroit* *

	1924	1926	1927	1928	1929	1930	1931
Incidence of goiter	36%	9.7%	7.7%	7.2%	5.2%	3.1%	2.1%
Number of examinations	3,000†	69,805	78,085	115,535	107,853	141,366	114,969

* From Detroit City Health: School Health Service, Annual Reports, vol. 13-14.

† Approximately.

During this school year, a glandular survey has been made through the special schools of Cleveland. It is comparable in every way with that made in Detroit during the past three years, since the study in each city was directly under my supervision and every thyroid examination was made by me. The same classification of congenital goiter and iodine deficiency goiter has been maintained throughout, and because of this unity the comparison shown in table 1 seems significant.

The gradual decrease in the incidence of goiter in the Detroit schools is shown b[illegible] reports of the school physicians. The first ex[illegible] 1923 and 1924, showed an incidence of 36[illegible]y in the spring of 1926 after two[illegible] showed only 9.7 per cent. contained no iodine. This reduces the actual prophylaxis of goiter to about 15 per cent of the population. It is only right that I state here that all the nationally advertised brands of iodized salt contained exactly the amount stated on the label. I am pleased to report that the two salt companies which were responsible for the three brands of salt containing no iodine have agreed to make their products conform to the label, and recent examinations show that they are doing so.

It is very evident that the general use of iodized salt throughout Michigan has decreased endemic goiter to a minimum. I feel that sufficient time has elapsed since the origin of this prophylactic measure so that we can tell from the data whether or not the general and continuous use of iodized salt is likely to induce hyperthyroidism. The discussion of this work by two of Detroit's surgeons answers this question quite emphatically:

Dr. H. K. Shawan, surgeon at Grace Hospital and Receiving Hospital, states that there has been a marked and continuous drop in the number of toxic goiters seen in these two hospitals. His data from Grace Hospital were available:

> The following is a report of the number of patients with toxic goiter admitted to Grace Hospital. The steady gradual decrease in the number of toxic goiters, both toxic adenoma and exophthalmic goiter, is even more noticeable than I had previously believed:

1927	234
1928	175
1929	158
1930	129

Dr. R. D. McClure, surgeon-in-chief, Henry Ford Hospital, stated:

> There is no doubt in our minds that our goiter operations have fallen off since the use of iodine throughout Michigan, while the list of our other operations has increased in size. Our figures for goiter operations for a period so far as we have collected them show a marked decrease which at least is coincident with the use of iodized salt in Michigan:

1920	15
1921	38
1922	49
1923	95
1924	135
1925	213

[illegible] ly emphasized [illegible] prevention [illegible] igan is very

[illegible] tion of Goiter,

Since this comparison is only a part of a survey of feeblemindedness in the two cities, I again point out that, by the prevention of endemic goiter, Michigan has eliminated from her schools in the future thousands of cases of feeblemindedness (cretinoid type),[4] which have in the past and would in the future result from endemic goiter.

The rapid disappearance of endemic goiter among school children throughout Michigan is one of the outstanding achievements in preventive medicine.

A SIMPLER TECHNIC FOR PROMOTING EPITHELIZATION AND PROTECTING SKIN GRAFTS *

ADALBERT G. BETTMAN, M.D.
Clinical Associate in Surgery, University of Oregon Medical School
PORTLAND, ORE.

The literature is replete with articles on the healing of wounds, and I therefore hesitate to present a new one. However, after having given this method an extensive trial for a period of over eight years and having had it used during this period by colleagues who without exception returned enthusiastic reports of results, I have decided to present it to the profession.

When the acute stage of a burn is past, there follows a long and tedious convalescence with the resultant adhesions, contractions and heavy bands of scar tissue. A not unusual picture is a red, granulating, weeping, infected, painful area healing sluggishly with overabundant granulations and absence of epithelium. The treatment of this type of lesion taxes the ingenuity of the attending surgeon. Messy ointments are applied spread on gauze, or lotions are used. Changing dressings is extremely painful and not infrequently requires a general anesthetic. The method to be presented simplifies all these factors and is applicable to all lesions which present loss of epithelium, whether the result of burns, traumatisms, x-ray and radium burns, or ulcerations of various sorts.

All treatments applied to surface wounds are aimed to promote epithelization. The rate of growth of epithelium is increased relatively easily but, as the epithelium tends to advance, its progress is retarded or prevented by infection. The idea occurred to me to incorporate with the growth-stimulating factor some substance which would tend to limit or remove the infection. I appreciate the difficulty of chemical sterilization of infected areas but believe that, in certain conditions, antiseptics have a place.

It was at once recognized that to meet the indications the antiseptic must be of considerable potency, that it must be nonirritating, that it must not injure healing tissue, and that it must be effective in the strength used; also, that it must not be incompatible with the growth-stimulating element. Another important point was that the finished product must be susceptible of being applied in such a manner that the secretions may be carried away quickly.

A formula and a technic were worked out, prepared and tried. They gave results far superior to anything that had hitherto been used. However, not being

a careful reexamination would be made at least every other year to determine the results.

[4] Kimball, O. P., and Marinus, J. C.: Relation of Endemic Goiter to Mental Deficiency, Ann. Int. Med. 4: 569 (Dec.) 1930.

* Read before the Eighteenth Annual Meeting of the Alumni Association of the University of Oregon Medical School, Portland, March 11-12, 1931.

In the spring of 1926, active opposition to the prophylactic measures began. An article by Hartsock[1] emphasized the great dangers of hyperthyroidism from the use of iodized salt. The state department of health almost immediately withdrew from its active campaign and only a partial resurvey was made in 1926. No further study was made by the state department of health.

In Cleveland the director of health service in the public schools has not had a concrete plan for the prevention of goiter; hence no unity of opinion on this point could prevail among the school physicians and nurses. Neither has there been a unanimity of opinion among the members of the medical profession of Cleveland. Some of the leading goiter surgeons have persistently and continuously opposed the use of iodized salt on the ground that it might cause hyperthyroidism. This theoretical possibility was stressed with such an effect that in this community it has been generally accepted that the continued use of iodized salt is actually dangerous. In my survey through the schools last year I found that most of the principals, teachers, nurses and school physicians were working under the impression that iodized salt was not a safe method of prophylaxis. This contrast in attitudes toward the general use of iodized salt for the prevention of goiter in Detroit and in Cleveland has created an ideal basis for this comparative study.

As previously stated, a survey was made in the Detroit schools early in 1924. This included both boys and girls from the first grade through high school. It was found that 36 per cent had a definite thyroid enlargement. No attempt was made to differentiate accurately the congenital adenomas from the active hyperplastic type, but I felt sure at the time that the incidence of congenital adenomas in this survey was approximately the same as in other sections of Michigan, where from 10 to 12 per cent was found. In the Cleveland schools no extensive goiter study was ever made.

In the fall of 1924, a goiter survey was made through several of the parochial schools. I myself made this survey for the city health department in order to start prophylaxis through these schools. All the children in one primary, one intermediate and one high school, approximately 1,200 children, were examined, a total incidence of goiter of 34 per cent being found.

Table 1.—*Comparison of Incidence of Goiter in Schoolchildren of Detroit and of Cleveland*

	Total Incidence of Goiter in Regular Schools, 1924	Total Incidence of Goiter in Special Schools, 1930-1931	Hyperplastic or Iodine Deficiency Goiter in Special Schools, 1930-1931	Number of Examinations
Detroit	36%	12%	0.3%	5,075
Cleveland	34%	30%	18.0%	3,175

During the school year 1930 and 1931 the Detroit school physicians examined more than 100,000 children from the first grade through high school. They reported that only 2.1 per cent showed any enlargement of the thyroid, emphasizing that practically all these enlargements were small discrete adenomas; i. e., congenital goiter. That is what Dr. Marinus and I found in the examination of 5,075 children in the special schools of Detroit during the last two years. The total incidence of goiter was 12 per cent, but 97 per cent of these were only discrete adenomas or a persistent thyroglossal stalk (congenital goiter), with the remainder of the gland normal. We studied them for the presence of hyperplasia or a uniform colloid enlargement, which condition, we feel, means an iodine deficiency. Of this type (iodine deficiency goiter) we found only fifteen cases, or 0.3 per cent. Incidence of goiter	36%	9.7%	7.7%	7.2%	5.2%	3.1%	2.1%
Number of examinations	3,000†	69,805	78,085	115,535	107,853	141,366	114,969

* From Detroit City Health: School Health Service, Annual Reports, vol.13-14.

† Approximately.

During this school year, a glandular survey has been made through the special schools of Cleveland. It is comparable in every way with that made in Detroit during the past three years, since the study in each city was directly under my supervision and every thyroid examination was made by me. The same classification of congenital goiter and iodine deficiency goiter has been maintained throughout, and because of this unity the comparison shown in table 1 seems significant.

The gradual decrease in the incidence of goiter in the Detroit schools is shown by the reports of the school physicians. The first examination, 1923 and 1924, showed an incidence of 36 per cent. The survey in the spring of 1926 after two years of prophylaxis showed only 9.7 per cent. The decrease was so striking that I was asked to recheck this survey. It was found, however, that this incidence (9.7) was as accurate as could be obtained. This yearly report from Detroit is shown in table 2.

I have no comparable reports by the Cleveland school physicians. This year a partial survey was made: 1,600 girls, aged 13 and 14, were examined, and 33 per cent had definite thyroid enlargement. An examination of 500 girls, aged 17 and 18, showed 34 per cent with goiter.

In an effort to learn to what extent iodized salt is being used in Cleveland, the assistance of six schools in different sections of the city was enlisted. In 5,438 homes reporting, 1,587 stated that they used iodized salt, either continuously or at times, and 3,860 stated that they had never used iodized salt. From this study it was found that only 31 per cent of the homes in Cleveland have used iodized salt.

As a further check on this prophylactic measure, the department of chemistry of the Cleveland Health Department analyzed for iodine content all the leading brands of iodized salt being sold there. This study was carried out during March, April and May of this year. Of eight different brands of iodized salt, three did not contain any iodine. These were leading brands in this city, and it is plainly seen that approximately 50 per cent of the iodized salt being sold in Cleveland contained no iodine. This reduces the actual prophylaxis of goiter to about 15 per cent of the population. It is only right that I state here that all the nationally advertised brands of iodized salt contained exactly the amount stated on the label. I am pleased to report that the two salt companies which were responsible for the three brands of salt containing no iodine have agreed to make their products conform to the label, and recent examinations show that they are doing so.

[1] Hartsock, C. L.: Iodized Salt in the Prevention of Goiter: Is It a Safe Measure for General Use? J. A. M. A. 86: 1334 (May 1) 1926.

It is very evident that the general use of iodized salt throughout Michigan has decreased endemic goiter to a minimum. I feel that sufficient time has elapsed since the origin of this prophylactic measure so that we can tell from the data whether or not the general and continuous use of iodized salt is likely to induce hyperthyroidism. The discussion of this work by two of Detroit's surgeons answers this question quite emphatically:

Dr. H. K. Shawan, surgeon at Grace Hospital and Receiving Hospital, states that there has been a marked and continuous drop in the number of toxic goiters seen in these two hospitals. His data from Grace Hospital were available:

> The following is a report of the number of patients with toxic goiter admitted to Grace Hospital. The steady gradual decrease in the number of toxic goiters, both toxic adenoma and exophthalmic goiter, is even more noticeable than I had previously believed:

1927	234
1928	175
1929	158
1930	129

Dr. R. D. McClure, surgeon-in-chief, Henry Ford Hospital, stated:

> There is no doubt in our minds that our goiter operations have fallen off since the use of iodine throughout Michigan, while the list of our other operations has increased in size. Our figures for goiter operations for a period so far as we have collected them show a marked decrease which at least is coincident with the use of iodized salt in Michigan:

1920	15
1921	38
1922	49
1923	95
1924	135
1925	213
1926	210
1927	180
1928	130
1929	110
1930	97

Dr. Elliot Cutler of Cleveland gave me the data from Lakeside Hospital, which are shown in table 3. The number here includes all patients presenting toxic adenoma and exophthalmic goiter who were admitted to the hospital from 1925 to 1930, inclusive.

Table 3.—*Cases of Goiter at the Lakeside Hospital (1925-1930)*

	Toxic Goiters	Total Number of Surgical Operations
1925	98	1,093
1926	176	1,255
1927	174	1,322
1928	133	1,377
1929	123	1,433
1930	114	1,460

This assurance from the surgical data merely emphasizes my observations,[3] in 1928, that "The prevention of goiter as it has been carried out in Michigan is very efficient and entirely safe."

Since this comparison is only a part of a survey of feeblemindedness in the two cities, I again point out that, by the prevention of endemic goiter, Michigan has eliminated from her schools in the future thousands of cases of feeblemindedness (cretinoid type),[4] which have in the past and would in the future result from endemic goiter.

The rapid disappearance of endemic goiter among school children throughout Michigan is one of the outstanding achievements in preventive medicine.

[3] Kimball, O. P.: Efficiency and Safety of Prevention of Goiter, J. A. M. A. **91**: 454 (Aug. 18) 1928.

[4] Kimball, O. P., and Marinus, J. C: Relation of Endemic Goiter to Mental Deficiency, Ann. Int. Med. 4: 569 (Dec.) 1930

[*] Read before the Eighteenth Annual Meeting of the Alumni Association of the University of Oregon Medical School, Portland, March 11-12, 1931.

The technic of application here described is the means of securing the maximum result by the use of the formula.

The formula, which has been called oxyquinoline sulphate scarlet R ointment, is as follows:

		Gm. or Cc.		
℞	Oxyquinoline sulphate.............		6	gr. x
	Chlorbutanol (choretone)......... ..	2	4	gr. xl
	Liquid petrolatum..................	4	0	℥ i
	Scarlet R ointment, 5 per cent.....	120		℥ iv

When 10 per cent scarlet R ointment is used, take 2 ounces and petrolatum, 2 ounces.

The oxyquinoline sulphate and the chlorbutanol are ground separately into fine powders and then mixed separately with portions of the liquid petrolatum. All the ingredients are then made into a red ointment. The finished ointment is heated until fluid, and rolled gauze bandages, 32 by 44 mesh, or coarser, are immersed in the hot ointment until the entire bandage is thoroughly impregnated, until all bubbling has ceased. When cool, it is ready for use. The finished product has been called oxyquinoline sulphate scarlet R gauze.

The formula herewith presented will impregnate completely three 10-yard gauze bandages, 2 inches wide, or six, 1 inch wide, provided it is heated in a small vessel; for example, an aluminum measuring cup such as is ordinarily used in the kitchen.

When a bandage has been immersed in the ointment as described, the mesh of the outer layer or two is covered completely and these layers are discarded. The warp and woof of the rolled gauze are completely impregnated with the red ointment, but the interstices are open. A bandage so prepared will keep indefinitely if contamination is avoided.

The rationale of the ingredients is easily given.

Oxyquinoline sulphate is a definite chemical compound. It is a yellow crystalline powder, a powerful antiseptic, nontoxic, and it does not destroy growing cells. It does not coagulate albumin or injure mucous membranes. In this ointment its strength is as 1 to 200.

For over twenty years I have applied oxyquinoline sulphate powder to wounds by means of cotton tipped applicators wet with alcohol and have found it a most valuable application for preventing and overcoming early or potential infections.

Chlorbutanol, trichlortertiarybutyl alcohol, is a definite chemical compound having marked local anesthetic properties and is mildly antiseptic.

Scarlet R ointment containing 5 per cent Scarlet R Medicinal Biebrich is definitely stimulating to the epithelium and promotes its growth. This dye is a definite chemical substance, aminoazotolueneazobetanaphthol. This preparation has enjoyed wide use for many years, but its value is greatly increased by the formula here presented.

Dimazon, diacetylaminoazotoluene, has been used in place of the scarlet R, but the results seemed more satisfactory with the red ointment.

The application of oxyquinoline scarlet R gauze to the wound is very simple. Excess secretions are removed by gently but firmly pressing with dry gauze. When cotton is used on wounds, small bits adhere. Short pieces of oxyquinoline scarlet R gauze are cut and laid directly on the wound, completely covering the entire surface with but a single layer. Overlapping is reduced to a minimum. Dry gauze is then applied in sufficient thickness to carry away the secretions and to protect the wound. A bandage keeps the red gauze in close contact with every part of the wound surface.

The dressings are changed every second to fifth day, care being taken that the new epithelium is not disturbed. The dressings usually come away readily. When they do not, which is rare, they are left until the next dressing and are never pulled off. Frequently the red gauze is left in place until complete epithelization has occurred.

Infection slows up the normal rate of wound healing, and when infection is eliminated healing goes on with surprising rapidity. By the use of this method the healing time is greatly shortened, resulting in soft scars with less tendency to bind and, therefore, a minimum of deformity. Healing is rapid and the wound is clean throughout.

When ointment is applied to gauze as one spreads butter on bread, the mesh is closed in the center by a thick layer and the edges are devoid of ointment. The application of such a dressing holds the secretions in at the center and allows the dry gauze at the periphery to stick to the wound. When secretions are held in contact with a wound, the tissues beneath are broken down. When secretions are carried away, this breaking down does not occur.

Lest it be misunderstood, let it be distinctly stated that the formula and method here described are not a primary treatment for burns. The best results as first treatment of burns are obtained by using tannic acid and forced fluids. The treatment here described is for the healing of the resulting ulcerated surfaces.

An important use of this dressing is in preparing wound surfaces for skin grafting. The application of oxyquinoline scarlet R gauze will rapidly clean up infected granulations and make them ready for Thiersch or other skin grafts. The application of this gauze for three or four days is often sufficient. Following Thiersch or Reverdin grafting, the gauze is applied over the grafts, and the dressing is not changed for four or five days or longer. Rapid healing minimizes the formation of scar tissue between grafts. Chronic ulcers of the leg, x-ray and radium burns, and other sluggish processes respond readily.

When oxyquinoline scarlet R gauze is used, skin grafts will take very frequently where otherwise they would not. It is during the waiting period while the denuded area is being made ready for skin grafting that scar tissue with its resulting contractions is increasing. By the use of this method, skin grafting can be done early and disfiguring contractions and webbings prevented.

Dressings are changed less frequently when oxyquinoline scarlet R gauze is used. Every fourth, fifth or sixth day the entire dressing is removed, while every second to fourth day the outer dressings may be changed. By replacing the outer dressings as necessary, the mesh in the oxyquinoline scarlet R gauze is kept open, and the new dressings carry away the drainage.

The application of a very thin layer of the ointment is made occasionally directly to healing incisions and is an aid to the production of invisible scars.

A boy, aged 9 years, received an extensive burn extending from the umbilicus to the left ankle. The entire skin surface sloughed, leaving an ugly, weeping wound. The immediate treatment with tannic acid and forced fluids was satisfactory, but under several later treatments he was most uncomfortable and required frequent narcotic medication. Within thirty minutes after the application of the oxyquinoline scarlet R gauze, he went to sleep without a narcotic.

An elderly man had a chronic ulcer of the leg, which resisted healing, although many types of treatment had been used. Under the application of oxyquinoline scarlet R gauze, the lesion was healed in two weeks.

An elderly woman received an x-ray burn involving an area 7 by 4 inches. Before I saw the patient, various treatments, including skin grafting, were tried over a period of eight months, without lessening the size of the wound in the slightest degree. The application of this gauze to the area healed it completely. The healing was progressive from the very start, a slow advance being noticeable from day to day. The resulting scar is soft and pliable, and there are no heavy bands and no contraction.

This report is made with confidence that those who use oxyquinoline scarlet R gauze as herein described will reap the satisfaction which I and those of my colleagues who have been using it have had.

629 Medical Arts Building.

THE CAUSE AND PREVENTION OF RADIODERMATITIS [*]

H. H. HAZEN, M.D.
WASHINGTON, D. C.

This study of 111 cases of radiodermatitis following the application of either x-rays or radium is based on patients seen in private practice. The cases are consecutive but include only those in which the total dosage can be estimated either absolutely or with a very fair degree of accuracy. Cases occurring as the result of high voltage therapy for malignant diseases of the breast, thorax or abdomen are not included, nor are instances in which a few telangiectases have appeared in a limited area following the treatment of skin cancer; nor is reference made to fibrosis of the lungs, or intestinal injury as the result of intensive irradiation.

Of these 111 cases, 40 occurred in men and 71 in women. Three resulted from the taking of roentgenograms; thirteen from high voltage therapy; seven occurred in roentgenologists; thirteen were from treatments received in beauty shops, and the remainder, or seventy-five, from superficial therapy. Eight cases were the result of high voltage therapy by dermatologists and fifty-eight of low voltage therapy by dermatologists, while five were from high voltage therapy by roentgenologists and seventeen from low voltage therapy by roentgenologists. Table 1 shows the years when treatment responsible for the radiodermatitis was received.

Table 1.—*Years During Which Treatment Resulting in Radiodermatitis Was Received*

Years	Number of Cases
1910 to 1912	8
1913 to 1915	17
1916 to 1918	21
1919 to 1921	18
1922 to 1924	11
1925 to 1927	19
1928 to 1929	17

When it is remembered that thirteen patients were damaged in beauty shops between 1927 and 1929, it will be noted that the number of cases of radiodermatitis attributable to physicians is decreasing. This is probably a just estimate, as the majority of operators know better the limitations of radiotherapy. Of these 111 cases, 7 were from radium and the remainder from x-rays.

Table 2.—*Location of Radiodermatitis*

Part of Body Affected	Number of Instances
Face	38
Neck	15
Hands	20
Feet	8
Body	13
Arms or legs	12
Scalp	11
Scrotum	3
Perineum	4
Gums	7

There has been a prevailing impression that radiodermatitis is usually manifest by the end of the first year and that it invariably appears before the end of the second year. In this series of cases, ninety-seven patients showed signs of injury before the expiration of twelve months, and an additional eight before two years had elapsed. Four cases showed nothing for three years, and in two instances the first signs of trouble appeared after forty-eight months. There are a few cases on record in which the appearance of telangiectasis has been delayed even beyond this period.

Table 3.—*Character of Injuries*

Type of Injury	Number of Instances
Depilation	6
Permanently dry hair	5
Localized dryness	2
Atrophy and wrinkling	6
Telangiectases	78
Keratoses	14
Acute second degree burns	5
Third degree ulcers	14
Injury to gums	7
Sclerosis of muscles	1
Cancer	4

The location of the radiodermatitis is shown in table 2.

It should be noted that many patients showed a radiodermatitis in several areas, which fact is responsible for the divergence in figures.

The character of the injuries is shown in table 3.

Of the third degree lesions, nine were due to treatment received from roentgenologists and five from dermatologists.

Regarding the character of the lesions, there is space for only a few words. Five cases of permanently dry hair occurred in children from an institution where ringworm had been epidemic for years. These children were depilated either four or five times, and two years after the last depilation the hair was rather scanty, thin, dry and partially white. Three of the cases of depilation were the result of roentgenography and the other three resulted from therapy. The injury to gums has already been discussed by me[1] in an article, "Injuries Resulting from Irradiation in Beauty Shops."

---

[*] Read before the Section on Dermatology and Syphilology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 12, 1931.

The conditions for which x-rays were given are listed in table 4.

Table 4.—*Conditions for Which Treatment Was Given*

Condition Requiring Treatment	Number of Cases
Acne	16
Superfluous hair	14
Psoriasis	4
Pruritus ani	4
Dermatophytosis	9
Tinea tonsurans	7
Tinea cruris	3
Warts	8
Dermatitis venenata	4
Lichen planus	1
Cancer	4
Keloid	5
Nevi	3
Lupus vulgaris	3
Tuberculous glands	4
Thyroid hypersecretion	5
Superficial nodules	2
Sarcoma	2
Excessive menstruation	2

Table 5 shows the location of the third degree burns, and the condition for which treatment was given.

Table 5.—*Third Degree Burns*

Condition Requiring Treatment	Number of Cases
Lupus vulgaris of face	2
Pruritus ani	2
Dermatophytosis of foot	2
Wart on hand	1
Cancer of ear	1 (radium)
Sarcoma of jaw	1
Sarcoma of axilla	1
Excessive menstruation	2

The location and primary conditions of the cases which resulted in serious keratoses are listed in table 6.

Table 6.—*Cases Resulting in Serious Keratoses*

Primary Condition	Number of Cases
Superfluous hair of face	1
Superfluous hair of legs	1
Psoriasis of feet	1
Psoriasis of legs	1
Dermatophytosis of foot	1
Wart on hand	1
Linear nevus of hand	1
Lupus vulgaris of face	1
Dermatitis of face	1
Industrial exposure in roentgenologists	5

It is to be noted that many patients suffering from comparatively benign conditions were among those who were most seriously damaged.

The patients mentioned in the foregoing lists met with the fates shown in table 7.

Of the 111 patients, 37 had been treated with rays filtered through 1 to 3 mm. of aluminum, and the remainder with unfiltered rays. These figures are of little value, as they fail to show the total number of patients treated with either filtered or unfiltered rays in whom no permanent injury developed. The attempt was made to learn whether various voltages had the slightest effect. So far as could be deduced in this series of cases, there was no difference in results of patients treated with a peak voltage of 80 or of 130 kilovolts.

It has also been stated that the face, neck, flexor surface of the arms, and the skin covering the joints are unusually susceptible. In seven patients the same dosage was given to the skin of the face, and either to the shoulders, arms or legs; the resultant injuries are practically the same in all places, which would tend to show that there is comparatively little difference in susceptibility of the skin in various areas. However, it should be noted that telangiectases did not develop on the back of the hands unless the total amount of rays received was in excess of 6 units, so it is evident that this portion of the body is unusually resistant.

In twelve persons, telangiectases developed without any preexistent erythema. But a few years ago the teaching was that such an event could never take place without an erythema following treatment. However, if one will recall that many roentgenologists have had telangiectases which developed from the cumulative effect of many tiny doses, the falsity of this teaching should be apparent. All twelve of these patients had been under close observation by competent men, and an erythema could scarcely have escaped attention. Two of the patients had received a total dosage of only 3 units; two had received a dosage of 4 units; four a dosage of 5 units, and the remainder a dosage between 5 and 6 units. It is worthy of comment that the patients in whom dilated vessels developed after a total dosage of but 3 units were both women with excessively dry skin.

Table 7.—*End-Results of Roentgenography and Roentgenotherapy in Some Cases*

Result	Number of Cases
Death from cancer of face	1
Amputation of arm	1
Amputation of leg	1
Amputation of fingers	3
Extensive skin graft to hand	1
Extensive skin graft to feet	2
Extensive skin graft to body	2

While this series of cases is comparatively small, it would seem obvious that a total dosage of 2½ units is all that can be safely administered to a patient with a very dry skin, and a maximum of 4 units to a patient with a normal skin. This is an important observation, as it tends to establish the total dosage that can be administered to any one patient over a period of years.

As patients can stand only a definite total amount of irradiation, it is absolutely incumbent on the radiologist to learn just what dosage has previously been received. Likewise, in estimating the total dosage which has been applied to the face, the number of dental roentgenograms should also be taken into consideration. When a patient has had from fifteen to twenty roentgenograms of the teeth taken, the total amount of x-rays received is not small.

Excluding the patients who were damaged in beauty shops, it was found that twenty-eight patients received their injuries from one heavy dose of from 1 to 3 units; sequelae developed in fifty-one after repeated heavy doses of from one-half unit up, and eighteen showed radiodermatitis after fractional treatments in which no dose was over one-fourth unit.

Another important point is that only seven patients showed sequelae when the diameter of the area treated was less than 1 inch (2.5 cm.). It is a well known fact that an area not more than one-fourth inch (0.6 cm.) in diameter will stand a total amount of treatment that would utterly destroy tissue in an area of 2 or more inches. To determine how much irradiation small areas will stand, a survey has been made of 250 cases each of cancer and of warts, and the following are the facts for unfiltered therapy:

---

[1] Hazen, H. H.: Am. J. Roentgenol. 23: 409 (April) 1930.

Area, one-fourth inch diameter: A single dose of 3 units or a total dosage of 9 units, provided that no irritating substances are used or that subsequent dosage is not repeated in the presence of an erythema, will cause a little atrophy but no other sequelae.

Area, one-half inch in diameter: The results are the same as noted in the preceding paragraph, except that telangiectases will appear in 10 per cent of the cases.

Area, 1 inch in diameter: Single doses of 2 units, or a total of 6 or 7 units, will result in some atrophy and a few telangiectases in 15 per cent of all patients.

Area, 2 inches in diameter: Single doses of 2 units, or a total of 6 units, will show considerable atrophy and some telangiectases in nearly all cases.

In the light of our present knowledge, certain of the patients were unsuitable for irradiation. In this group should be placed thirteen patients with hypertrichosis who were injured in beauty shops; two patients with hypertrichosis of the nucha; three with tinea cruris involving the scrotum; one with primrose dermatitis; three with large pigmented nevi, and two with lupus vulgaris and extensive scar formation in which the pathologic changes already closely resembled those found in a chronic radiodermatitis. In addition, the patients with keloids should have been permitted a long interval between treatments to allow for late shrinkage of the lesions, and the patients presenting tinea tonsurans should not have been depilated more than three times.

Regarding the causes of radiodermatitis it is probable that the list shown in table 8 is as accurate as possible at the present time.

Table 8.—*Causes of Radiodermatitis*

Causative Factors	Number of Instances
Handling radium with fingers	1
Meter out of order	9
Meter maladjusted	1
Omission of filter	1
Patient went to sleep and did not remove radium	1
Too many epilations (tinea tonsurans)	5
Movement of patient with tinea tonsurans	1
Timer stopped	1
Deficient timer	1
Too large areas for heavy dosage	5
Irritant drugs used by patients	5
Patients taking treatments from several physicians	5
No filter on radium	4
Protection slipped	1
Too many or too heavy treatments	69

It is probable that strict observation of the following points would eliminate many cases of radiodermatitis:

1. Patients should be carefully selected. Pigmented nevi should be treated with x-rays or radium only after careful consideration, as destructive doses are necessary.[2] The mild type of acne should be treated with x-rays only as the last resort; patients troubled with constipation or young patients should not be treated. Pruritus ani should be treated with irradiation only when all other methods have failed. Lupus vulgaris with extensive scarring already has pathologic manifestations similar to radiodermatitis and hence should be treated with the utmost caution. Dermatophytosis in the majority of instances will yield very much better to other forms of therapy than it will to irradiation. Warts, except plantar warts, are better treated by desiccation than by irradiation. Psoriasis,[3] because of its certainty to relapse and its chronicity, should be irradiated with the utmost caution. Keloids[4] frequently continue to shrink for three or four months with a unit or a unit and a quarter dose; hence treatment of keloids should be given at long intervals.

2. The apparatus should be modern. There should be two miliammeters, or the milliammeter should be standardized at least once every two months. The timer should be accurate and properly controlled. The apparatus should be standardized as to dosage; the best method is epilation of scalp hair.

3. The use of irritating drugs must be avoided by the patient who is receiving roentgen treatment. MacKee[5] has called attention to the fact that such drugs as iodine, phenol (carbolic acid), salicylic acid, the mercurials and all stimulating preparations are very prone to set up a dermatitis when used in conjunction with x-rays. Therefore the patient should never use any drug over an irradiated area without the knowledge and consent of the radiologist.

4. The patient should not take roentgen treatments from a number of physicians at the same time. It is perfectly amazing, but I have known at least one patient who was irradiated by three different physicians at the same time without any of the radiologists being aware of this fact. The patient should be educated, or at least instructed, never to seek roentgen treatments without giving the names of the men who have previously treated him.

5. Radium should always be filtered through either rubber or aluminum.

6. As small fields as possible should be used if heavy doses must be employed.

7. Fractional doses are much safer than quantities approaching erythema doses.

8. Erythema doses should always be avoided except in malignant conditions or in warts.

9. In the treatment of ringworm on scalps of institutional children, not more than three epilations should be done.

10. Dry skins should never have a total of more than 2½ units even over a period of years.

11. Ordinary skins should not have a dose of over 4 units, and very greasy skins not over 4½ units.

1911 R Street.

ABSTRACT OF DISCUSSION

Dr. Anthony C. Cipollaro, New York: The cause of acute x-ray injuries and of x-ray sequelae is overdosage. Dr. Hazen discussed many of the causes of and reasons for excessive dosage. In general these causes may be divided into technical errors and errors of judgment. While modern technic is by no means scientifically accurate, it has stood the test of time in practical therapy and it is absolutely safe for therapeutic purposes when employed with skill, care and judgment. Dr. Hazen said that telangiectasia occurs without antecedent erythema. I admit that the statements may be true, but I doubt that it is so. Dr. MacKee, in twenty-five years, has not seen a single instance of telangiectasia in which he was absolutely certain that a previous erythema had not occurred. So far as the size of the exposed surface is concerned, the biologic effect increases with the size of the surface until the area is 4 inches square, after which the increase in the size of the exposed area does not matter. The difference in the effect on an area 1 inch square as compared with an area 4 inches square is approximately 25 per cent. This is due to scattering of the rays by the tissues and also to secondary rays. I gather that Dr. Hazen does not believe that variation in individual and in topographic toleration is important. It may not be a major cause, but I believe that it is important. I shall call attention simply to the fact that an epilating dose applied to the scalp will evoke defluvium but not erythema; the same dose applied to the face will often effect erythema without causing alopecia. I do not agree that it is unsafe to give more than a total of 2½ units to dry skin, but I do believe that dry skin is at times less tolerant than is oily skin. The same is true of an inflamed or a florid skin. I desire to emphasize the importance of making the technic as accurate as possible. The dermatologist must not rely solely on the advice of the manufacturer or even on that of the physicist. He should obtain the help of the physicist by all means, become proficient in the use of instruments of precision, such as the voltmeter, the milliamperemeter, the spark-gap, the selenium cell intensimeter, the dosimeters based on ionization, and so on, obtain instruction and advice from reliable practical sources, study reliable textbooks and, finally, depend on skin effects. The modern ionization dosimeter is an excellent instrument. It is less reliable for unfiltered than for filtered radiation. At present I am unwilling to place sole reliance on these instruments. I use such instruments daily, but I depend largely on carefully interpreted skin effects.

[5] MacKee, G. M.: X-Rays and Radium in the Treatment of Diseases of the Skin, p. 370.

Dr. William H. Guy, Pittsburgh: This paper is one in which the potentialities are more serious perhaps than is realized, because the lay public, particularly the legal end, is watching professional views on radiodermatitis, and the number of suits each year becomes greater. Further, it is difficult to obtain insurance covering x-ray burns. Those individuals who are operating are subjected to the closest scrutiny before insurance companies will take the risk. One point I think should be emphasized in regard to dosage, size of application and so on, which is of the utmost importance in estimating the proper dosage in a given case, and that is the varying susceptibility of individuals. This is a moot point, but I am convinced that such a susceptibility does exist among patients, irrespective of dry blond skins or oily skins, and that it is a fact that patients often react to a dose that is well under an erythema dose. I have compared a few such patients with a normal individual of known susceptibility. I accomplish this by taking the arm of a known type and laying it beside that of the unknown type, applying the same dose of rays and noting the reaction that occurs. I found in a small series of patients that a certain proportion do have a definite susceptibility to roentgen rays. An objection may be made to this, that the manner of living, the amount of cosmetics and soap patients use, and the varying conditions in daily life may well determine differences in reactive phenomena; but these differences apply in all therapeutics and certainly do not argue against the essential fact that patients vary in the degree of reaction to the application of radiant energy.

Dr. C. Guy Lane, Boston: During the past twelve years I have had an opportunity to see most of the dermatologic cases in which the patients have been referred for therapy in the x-ray room at the Massachusetts General Hospital. In this department the interns change every three or four months. They are trained in roentgen therapy but have not had previous superficial therapy. Occasionally an assistant roentgenologist has been there for a period of time and has become competent to go ahead with the dermatologic therapy. It may be interesting to outline the method of educating these men. Emphasis is placed on the choice of diseases to be treated and the stage; the type of patient who should be treated, in respect to age, coloration, and the like; the necessity for definite standardization of apparatus, particularly the amount of previous treatment, both roentgen therapy and other recent therapy; the question of size of the area that is to be treated; the effect of the summation of doses, in that any previous roentgen therapy should be considered in estimating the doses to be given, and the necessity of examining areas that are not then under treatment. In addition, on the record there is a special column devoted to the total amount of treatment in skin units, and that is added to, so that the physician always has before him the total amount of treatment the patient has received at the institution and that is combined, so far as ascertainable, with the amount the patient has received elsewhere. By continually stressing these facts, we have attempted to improve results and to impress on these men the need for the utmost care in the therapy of dermatologic conditions.

Dr. George M. MacKee, New York: Dr. Hazen mentioned the delayed appearance of telangiectasia. I do see remarkably delayed cases. I think that the vast majority appear within two years, but I had one patient in whom a mild telangiectasia developed fifteen years after a single mild erythema dose. Apparently, the condition may appear any time from six months to twelve or fifteen years. The later it appears, the less severe it is likely to be. Also, in many instances, telangiectasia tends to become less marked with the passage of time. This is especially true of the very severe cases. Dr. Hazen mentioned filtration as a safety factor. I agree that there is a little more safety with filtered radiation than with unfiltered radiation, but on the other hand the deep effects of filtered radiation may, at times, be injurious. I am still in doubt whether a thin filter (0.5 mm. of albuminum) should be used as a routine or whether to adhere to unfiltered radiation. Possibly, in the future it will be necessary to use filtration because of greater accuracy when dosage is estimated with instruments such as modern practical ionization dosimeters calibrated in the international x-ray unit known as the roentgen. I agree that the best treatment for a third degree ulcer is excision or plastic surgery. Treatment of sequelae must be selected for the individual case. So-called x-ray skin that frequently ulcerates or in which keratoses are constantly developing should be removed by plastic surgery. In the literature, stress is placed on the total dosage. One wants to know that, of course, but more information is required. One wants to know not only the amount but how it was given: the intervals between treatments—one-fourth unit, for instance, given once a week or one unit given every three or four weeks. Dr. Hazen mentioned the combined effect of irradiation and various topical applications. I agree that ointments containing fairly large amounts of irritating chemicals lessen the toleration of the skin for x-rays or radium, and I believe that such applications should be avoided when radium or x-rays are being used. Erythema or exfoliation evoked by topical applications may hide x-ray erythema, and this may be one reason why telangiectasia is thought by many to occur in the absence of antecedent x-ray or radium erythema.

Dr. Howard J. Parkhurst, Toledo, Ohio: The undesirable sequelae are most likely to ensue in conditions which tend to recur or persist, such as sycosis vulgaris, recurrent dermatophytosis, recurrent or generalized neurodermatitis, and especially the generalized type of psoriasis. In many instances it frequently becomes necessary to substitute other forms of treatment. One great danger of undesirable sequelae occurs in irradiation of acne by overlapping on the anterior portion of the neck, as one cheek is treated and then the other. Another condition in which danger lies is the stubborn nail disease, particularly psoriasis of the nails, which may be irradiated for some time without appreciable benefit.

Dr. Thomas W. Murrell, Richmond, Va.: I believe that many men think they are covered by insurance when they are not. I called up my insurance agent and asked, "Am I covered for radium and x-ray dermatitis in my group insurance," and he told me that I was. I asked him to look it up that I might be sure. He called back and said that he thought I was, so I asked him to write the main office of the company and find out definitely. He told me later that the company said I was not covered, but that I could be if I paid an additional fee. I paid that promptly. This is just an example of an insurance company that has been in business in Richmond for fifty years thinking I was covered by my group policy, when I was not. I think it is advisable in all instances to find out from one's company directly whether one is covered or not before a suit comes up.

Dr. Samuel Ayres, Jr., Los Angeles: Another point that might be mentioned is the occurrence of roentgen sequelae following the use of carbon dioxide snow on areas that have been previously irradiated. I am not sure that we dermatologists always inquire into the possibility of previous roentgen treatment when we contemplate using carbon dioxide snow. I recall one instance in which carbon dioxide snow was applied for about thirty seconds with firm pressure in a patient who had received irradiation several months previously without any harmful x-ray effects. Following the application of snow, an ulcer the exact size and shape of the snow pencil developed, which took about two months to heal.

Dr. H. H. Hazen, Washington, D. C.: I wish to mention the danger of patients having roentgenograms taken by dentists. I think that the taking of an unrestricted number of dental pictures in a patient who has had quite a good deal of treatment for acne, for instance, is very dangerous. A second point is that too many roentgenologists are inclined to treat patients without finding out definitely how much treatment they have already received. One should be extremely cautious about finding out all the details of previous therapy.

Clinical Notes, Suggestions and New Instruments

ALLERGIC MANIFESTATION TO INSULIN

William H. Grishaw, M.D., Los Angeles

A study of this case was undertaken because of the marked allergic manifestations to certain insulin products and because of the therapeutic problem which it presents.

C. G., a man, aged 38, gave a history of bilateral pleurisy at the age of 16, which was diagnosed as tuberculosis and treated with rest for a period of about two years. He had had influenza while in the army in 1918, with a recurrence of the old chest condition, and pneumonia in 1922. For many years he had experienced attacks manifested by a rash over the body, with swelling of the hands and lips, and itching of the skin, without known cause. The attacks lasted from one to four hours and disappeared spontaneously. His mother had had diabetes mellitus and died at the age of 72. His father died of emphysema. One brother died of asthma.

The start of the present illness was in October, 1929, with a bronchitis. The patient was first seen by me in April, 1930, at which time he complained of thirst, polyuria, and loss of weight of four months' duration. The blood sugar (fasting) at that time was 365 mg. per hundred cubic centimeters of blood, and a twenty-four hour urine specimen showed 3.3 per cent sugar. A diagnosis of bilateral pulmonary tuberculosis with cavitation on the right had been made, and right pneumothorax had been instituted.

The patient was placed on a restricted diet, and with insulin the diabetes soon came under control. With each injection of insulin there appeared a reaction of the skin, with redness, swelling and itching, localized to the site of injection. This local reaction recurred with each injection for the next twenty-five days. On the twenty-fifth day, the day following his sixth pneumothorax, about fifteen minutes after his morning dose of insulin a generalized urticarial eruption with itching developed which lasted about four hours. The evening dose was given from a different bottle of insulin manufactured by the same company, following which he had the same reaction, with additional swelling of the hands, lips and eyelids. The next morning a small test dose from still another sample made by the same company (company A) was given, with a reaction identical to that given the night previous.

Later in the day, after all symptoms and signs had disappeared, a similar dose of insulin made by another firm (company B) was given and was followed in ten minutes by urticaria, itching and edema. A trial dose from still another firm (company C) gave no reaction whatever, and the patient has continued using this firm's insulin for the past twelve months, with no local or general reaction.

Insulin specimens taken at random, manufactured by these firms and including the specimens to which he originally gave general reactions, were used for intradermal tests, with the result that all insulin specimens manufactured by company A and company B gave definitely positive reactions, while those of company C gave negative results. Company A supplied me with insulin from both pork and beef pancreas as a source and also a "Special" U-80 preparation. These specimens gave positive skin tests. From company B I obtained their end-product in powdered form and a "purified" insulin also in powdered form. These powdered specimens were made up to U-40 strength, *hundredth normal* hydrochloric acid being used as a solvent, and the reaction was then adjusted to p_H 2.5. The stock powdered product gave a positive skin reaction while the "purified" gave a negative test. Beef, pork and veal proteins all gave negative skin reactions. The specimens to which the patient reacted have been tried intradermally in other patients with diabetes mellitus and no reaction was observed.

In order to determine whether the substance to which he reacted could be precipitated, various concentrations of acetone were added to the insulin specimens, and after filtration the acetone was driven off. The acetone-free filtrates of the specimens to which he reacted, tested intradermally, all gave negative tests. Both the insulin specimens and the filtrates have been tested intradermally on various occasions during the past year and the patient gave identical reactions at all times.

Presumably a part or all of the insulin activity was removed by the precipitation, but in order to determine whether there was any insulin left in the filtrates I injected mice with insulin to establish a control, and then with the filtrates. The mice were divided into four groups of three males and two females to the group. The first group received 1/150 unit of insulin per gram of body weight; the second, 1/125 unit per gram; the third, 1/100 unit per gram, and the fourth, 1/75 unit per gram. The result was an increasing number of convulsions over a given period of time with the increase in dosage. This was repeated, the filtrate being used in the same dose for the various groups, and the dose of the filtrate then being increased to ten times the original. With the filtrate there was no demonstrable effect on the animals.

Results of Tests with Insulin from Various Manufacturers

Firm	Insulin	Source	Skin Reaction	Acetone-Free Filtrate Reaction
Co. A	U-20	Pork	Positive	Negative
	U-40	Pork	Positive	Negative
	U-40	Beef	Positive	Negative
	U-80	"Special"	Positive	Negative
Co. B	U-20	Beef	Positive	Negative
	U-40	Beef	Positive	Negative

Dr. R. W. Lamson offered to attempt passive transfer skin tests on a small group of patients in the allergy clinic. This was done by sensitizing the skin with a 1 to 1 dilution of the patient's blood serum and twenty-four hours later injecting the insulin and filtrate intradermally, physiologic solution of sodium chloride being used as a control. No positive skin tests were obtained by this method. In other words, Dr. Lamson was unable to transfer passively the patient's sensitivity.

SUMMARY

This patient reacts to insulin manufactured by two firms but not to that of a third firm, which indicates that he is not sensitive to insulin as was at first thought, but is sensitive to some substance contained in the product of companies A and not in that of company C. This substance is [illegible] gives reactions similar to those seen in individuals [illegible] [illegible]

[illegible] Boulevard.

Council on Pharmacy and Chemistry

INTRAVENOUS USE OF BARBITAL COMPOUNDS

The Council has authorized publication of this report on the intravenous administration of barbital compounds.

W. A. Puckner, Secretary.

More than seven years has elapsed since the introduction of the intravenous use of barbitals, sufficient time to justify an assay of the possible value of the method. The chief object of intravenous use has seemed to be the possible employment of barbitals used in this way to produce anesthesia. All the possible changes following intravenous injection, a comparison of the experimental and clinical results, and a determination as to whether the intravenous use has peculiar advantages over other methods of administration, with equal safety, are here considered. There is no doubt that the characteristic hypnotic action of the barbitals can be obtained by oral administration. Since the barbitals act essentially as hypnotics, and not as anesthetics, it is reasonable to entertain doubts about radical departures from the orthodox usage of these drugs. Nevertheless, new methods of using and new uses for well known drugs merit attention. Moreover, the intravenous use of barbitals has been widely exploited by some manufacturers and serious attention has been given to the subject experimentally and clinically. The following considerations are based on an examination of the literature on intravenous medication as it concerns the barbitals.

HISTORY

The clinical use of barbitals intravenously dates from Fredet and Perlis[1] in France, who tried diethylallyl barbituric acid (somnifene) in 1924. Three years later, in 1927, secondary butylbromopropenyl barbituric acid (pernocton) was used in a similar way by Bumm[2] in Germany. Following the experimental trial of sodium isoamylethyl barbiturate by Page and Coryllos[3] in 1926, in this country, there came a period of intensive exploitation of this barbital derivative intravenously beginning with a preliminary report by Zerfas, McCallum, Shonle, Swanson, Scott and Clowes[4] and a clinical report by Zerfas and McCallum,[5] both in 1929. During the next two years several reports on experimental studies in animals appeared. However, by the year 1931 the reports on amytal and other barbitals intravenously decreased appreciably in number. There was likewise a decline in enthusiasm over the method. In fact, by 1931 most clinical reports that showed evidences of effort to determine the value of these drugs for intravenous anesthesia concluded that all the actions and benefits from the barbitals were obtainable from oral administration, as well as, if not better than, from intravenous administration. This moderation in claims for intravenous use by physicians coincided with a cessation of intensive exploitation by manufacturers.

The barbitals will not be considered individually in this report; a collective summary will suffice. Probably the most extensive, and likewise most reliable, studies have been made with amytal. Incidentally, it may be questioned whether wholesale clinical experimentation with a drug whose actions could have been predicted from results on animals was necessary or desirable. It is now generally conceded that all the barbitals act alike qualitatively, differing only quantitatively, so that nothing is to be hoped for in the way of better and safer therapeutics from a barbital alleged to be effective in small dosage. The old law of pharmacology which teaches that efficiency varies directly with toxicity has not been invalidated among the various barbitals placed before the medical profession. Nor are the chemical and physical properties of the barbitals sufficiently different in material ways to influence the present consideration.

EFFECTS ON THE BLOOD

In considering the effects of intravenous use of barbitals, both the direct effects on the blood of the injected barbitals, and reflex or remote effects caused within the circulatory system—secondary effects not aimed at or necessarily desired in their use as hypnotics and anesthetics—must be kept in mind. The barbitals are insoluble organic acids which require large amounts of alkali for solution. Amytal, for instance, requires a degree of alkalinity the equivalent of a buffer solution with p_H 9.5 or 9.8, or the reaction of nearly a ten thousandth normal solution of sodium hydroxide, which is approximately 900 times as alkaline as the blood (p_H 7.2 to 7.4). Solutions of sodium amytal with p_H 9.2 to 9.3 give incomplete and imperfect anesthesia with disturbing effects. Amytal, and for that matter any other barbital, will not remain in solution with the chemical reaction of blood, but is precipitated. Therefore, after intravenous injection, the barbitals must be precipitated in the blood stream or exist in a finely divided physical state, possibly adherent to the formed elements and the proteins of the blood. The situation then is the presence of a foreign body in the colloidal state within a sensitive colloidal system, namely, the blood, whose physical-chemical properties and physiologic function are unintentionally and undesirably affected. There is certainly no evidence in favor of a beneficial action on the respiratory function of the blood under these conditions and no reason for believing that such an action occurs. On the contrary, the changes produced by such foreign bodies, with extensive surfaces, are generally undesirable and harmful. The actions just mentioned have been adequately demonstrated for a large variety of agents by many authorities.[6]

The changes resulting from the disturbed colloidal state of the blood are quite independent of the intrinsic pharmacologic actions of the barbitals. These changes occur with all barbitals, but the weaker the barbital happens to be, pharmacologically and toxicologically, the greater will be the mass of the precipitate in the blood. Since the extent of tissues and blood surfaces involved is probably proportional to the mass of precipitate, and the immediate or colloidal disturbances depend on some surface action mediated by the flocculated material, the physiologic changes, including reflex reactions, may be out of proportion to the intrinsic toxicity. An exact correlation of the physical changes and the functional reactions is not possible, reported. Excretion of barbitals is comparatively slow, lasting about a week, the drugs tending to accumulate without complete destruction, except possibly amytal. Coma is lasting but may be accompanied by restlessness and tremors until death. Recovery from anesthetic doses is variable but may require up to thirty-six hours.

[4] Zerfas, L. G.; McCallum, J. T. C.; Shonle, H. A.; Swanson, E. E.: Scott, J. P., and Clowes, G. H. A.: Proc. Soc. Exper. Biol. & Med. **26**: 399 (Feb.) 1929.

[5] Zerfas, L. G., and McCallum, J. T. C.: J. Indiana M. A. **22**: 47 (Feb.) 1929; Anesth. & Analg. **8**: 349 (Nov.-Dec.) 1929.

[6] Hanzlik, P. J.: The Basis of Allergic Phenomena, J. A. M. A. **82**: 2001 (June 21) 1924.

Most of these actions have also been demonstrated after gastric and hypodermic administrations, except that the actions are slower and the initial fall of blood pressure does not occur and the later fall is not precipitous. This means that the gastro-intestinal and tissue absorption of the barbitals is definite and reliable, from which it follows that all the desired actions can be obtained by giving these drugs by mouth, and that the sudden undesirable actions on the blood and the collapse can be avoided, and, in fact, the sedative and hypnotic actions more satisfactorily controlled.

The toxic and fatal doses of the different barbitals have been found to vary considerably with the chemical grouping in the barbituric molecule, but the activity has varied in the same direction. In no case has the margin of safety been increased by increasing the general activity. Moreover, and this is important in the use of barbitals intravenously for a high degree of depression or for anesthesia, most investigators agree that the margin between doses giving such severe actions and the fatal dosage is too narrow for safety. In dogs, the average oral, rectal and intravenous anesthetic doses of amytal are reported to be about 55 per cent of the minimum fatal dose, but considerable variability exists. Anesthesia may not occur with doses becoming fatal.

In the treatment of the toxic and collapse actions, caffeine, epinephrine and ephedrine, used individually or combined, intravenous dextrose solution, and picrotoxin have been tried with variable success, generally with temporary benefit in frank collapse and with better results during impending, suspected or partial collapse, or if used as prophylactics; but the treated animals under these conditions might have recovered without the use of these antidotes.

CLINICAL STUDIES OF BARBITALS GIVEN INTRAVENOUSLY

Clinically,[9] the following actions after intravenous injection of barbitals, chiefly sodium amytal, have been reported:

1. Full effectiveness of from 12 to 25 mg. per kilogram in from three to five minutes.
2. Difficulty in determining exact and desired dosage.
3. Immediate and sometimes precipitous fall of blood pressure, from about 15 to 30 mm. and up to from 40 to 60 mm. of mercury, according to the dose, rate of injection, physical character of the solution and original level of blood pressure.
4. Slowed, shallow and irregular respiration.
5. Increased pulse rate.
6. Unconsciousness.
7. Deep sleep.
8. Cyanosis.
9. Preservation of reflex activity.
10. Laryngospasm.
11. Severe coughing.
12. Muscular rigidity.
13. Incomplete and imperfect analgesia.
14. Depression out of proportion to toxicity.
15. Retention of mucus in respiratory passages.
16. Decreased urinary elimination, urine containing trace of acetone.
17. Increase in phenolsulphonphthalein excretion at first, decrease later.
18. Transient renal irritation.
19. Decrease in oxygen consumption and tactile discrimination.
20. Allergic reactions with amytal and phanodorn.

Man is more sensitive than are animals. Mild euphoria without sleep and narcosis occurs after 60 mg. of sodium amytal.

In obstetrics, the second stage of labor and uterine contractions are not usually changed, but the infants are frequently apneic and require respiratory stimulation. Excretion of phenobarbital in milk is reported.

Postoperative actions have been reported as follows:

1. Prolonged depression lasting from twelve to eighteen and up to thirty-six hours, according to the dose and the individual.
2. Lack of patient's cooperation and orientation, and considerable confusion.
3. Restlessness and delirium, swallowing of tongue and cyanosis.
4. Decrease in intake of fluid and voiding.
5. Pulmonary congestion and edema due to shallow respiration.
6. All actions profound in the aged and debilitated.
7. Sudden awakening during operation under local anesthesia.

intravenous route would be an occasional rapid action in an emergency, as in the control of convulsions of toxic or disease origin, or in occasional operations. Hence their intravenous use should be limited for the present to conditions in which oral administration is not feasible either because the patient is unconscious, as in cerebral hemorrhage, eclampsia, or status epilepticus, or because he resists, as in delirium, or because a very prompt action is imperative, as in convulsion from local anesthetics.

Committee on Foods

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public. They will be included in the Book of Accepted Foods to be published by the American Medical Association.

Raymond Hertwig, Secretary.

EVAPORATED MILK ASSOCIATION EDUCATIONAL ADVERTISING

Sponsors.—Evaporated Milk Association, Chicago.

The following listed educational publications have been found acceptable as conforming to the Rules and Regulations with the exception of a few minor statements contained therein, which are being corrected in new revised editions. The association agrees to maintain its future advertising and publications entirely correct and in compliance with the Committee's Rules and Regulations. The Evaporated Milk Association is therefore entitled to display the seal of this committee on its publications and advertisements.

TITLES OF PUBLICATIONS

Milk — A Quart a Day
Quantity Recipes for Serving Twenty-Five to Fifty People
A Safer World for Babies
Why Should I Use Evaporated Milk?
Milk for Drinking
Frozen Foods — The Automatic Way
Planning Lunches for School Children
Milk-Made Candies
The Story of Evaporated Milk
Nutritive Value of Evaporated Milk
The School Lunch
Eating for Efficiency (Revised)
Send a Good Fellow Basket to a Needy Family
Statistical Data
Safety and Simplicity in Infant Feeding
Some Foods for Children Between 6 Months and 6 Years
Infant Feeding with Unsweetened Evaporated Milk
Evaporated Milk for Health and Protection
More Milk — Smaller Bills
The Adventures of Eva, Pora and Ted

The principal claims used by the association in promotion of evaporated milk which are acceptable are as follows:

1. Evaporated milk is pure fresh cow's milk with approximately 60 per cent of the water removed by evaporation under reduced pressure. It is not a patented or proprietary food but a staple commodity.
2. Evaporated milk is equal to pasteurized milk in all important food values; it supplies those vitamins which milk can be depended on to supply and in practically equal quantity. (Vitamin C is not present in any dependable or appreciable quantity in evaporated, pasteurized or raw milk.)
3. Evaporated milk casein curd in the stomach has a finer granular and softer texture or structure than that produced from raw or pasteurized milk; it resembles in physical structure the curd of human milk.
4. The fat of evaporated milk because of the homogenization processing is more finely dispersed than the fat of ordinary milk and therefore it is more readily acted on by digestive enzymes.
5. Evaporated milk is more speedily digested than raw or pasteurized milk or milk boiled only a very short time.
6. Evaporated milk is considered by many pediatricians to be the best form of cow's milk for preparing the baby's formula.
7. Evaporated milk is sterile and therefore is the safest milk obtainable; it cannot introduce pathogenic micro-organisms to induce diarrhea in infants.
8. Evaporated milk is usually less allergic than raw or pasteurized milk.
9. Evaporated milk is one of the most convenient and economical forms of milk for preparing infant feeding formulas.
10. Evaporated milk enables introduction of more milk in the diet because it is concentrated.
11. Evaporated milk whips. Because of the homogenization it produces a "buttery" flavor and a characteristic texture and consistency in foods in which it is used.

UNITED FRUIT COMPANY ADVERTISING CAMPAIGN FOR BANANAS

Importers.—United Fruit Company, Boston.

Distributors.—Fruit Dispatch Company, Boston.

Description.—Fresh bananas imported from Jamaica, Honduras, Colombia, Canary Islands, Mexico, Panama, Cuba, British Honduras, Hawaiian Islands and Guatemala.

Harvesting, Shipment and Distribution.—Bananas are harvested green even for use in the tropics. Tree ripened fruit loses its flavor, the skin bursts open and the ripened pulp is the prey to insects. The fruit in the proper stage of development is cut from the tree and conveyed as speedily as possible to the ship's hold for shipment. A cargo may consist of 75,000 bunches, a bunch being composed of from six to nine clusters, each consisting of from ten to twenty bananas. The ship's bins are well ventilated and are usually refrigerated. The temperature of the bananas is reduced as quickly as possible to 13 C. and maintained there.

On unloading, the bananas are inspected; damaged or too fully matured fruit is selected out for local distribution. The sound more immature bananas are shipped to the interior. Fruit for distant points is shipped in refrigerated cars under definite temperature and ventilation conditions.

The green bananas are carefully handled and ripened in storage rooms of wholesale dealers before final distribution to the retailer, for which purpose they are hung in specially equipped rooms held at 16-17 C. The essential requirements of ripening are humidity, temperature and ventilation. Usually one week is required for ripening.

Chemical Composition (submitted by the company).—

(proximate analysis of properly ripened banana)

	per cent
Moisture	75.3
Ash	0.8
Fat (ether extract)	0.6
Protein (N × 6.25)	1.3
Crude fiber	0.6
Reducing sugars as invert	7.1
Sucrose (copper reduction method)	11.1
Starch (by difference)	3.2
Total carbohydrates other than crude fiber (by difference).	21.4
(Mineral analysis: Sherman, Chemistry of Food and Nutrition)	
Calcium (Ca)	0.009
Magnesium (Mg)	0.028
Potassium (K)	0.401
Sodium (Na)	0.034
Phosphorus (P)	0.031
Chloride (Cl)	0.125
Sulphur (S)	0.010
Iron (Fe)	0.0006

Calorics.—0.95 per gram; 27.0 per ounce.

Vitamins.—The banana is a good source of vitamins A and C. Five grams is the minimum scurvy protective unit (Sherman, Luther, Campbell method). 2.5 units (U. S. P. method) approximates the vitamin A content. Vitamins B, G and E are also present.

Claims of Distributor.—The following statements used as a basis of claims in promotion of bananas have been accepted:

The banana is available at all seasons. Ripe bananas, or if cooked when partially ripe, are readily digestible even by infants and are valuable for modifying infant milk formulas because of the unique combination of readily assimilable sugars and vitamin C and are an aid against constipation. The vitamin and high carbohydrate content makes the banana a valuable supplement to milk, the mixture being a well balanced food. The carbohydrate contributes materially to the food energy value of mixtures of leafy vegetables and fruits. The final products of metabolism of the banana in the body are alkaline.

CHEMISTRY'S NEXT SERVICE TO MEDICINE

More than a century ago Laënnec, writing in the first volume of the *Archives générales de médecine*,[1] remarked that the aim of medicine is the cure of disease. For the attainment of this end Laënnec singled out three pathways, described by Cohn[2] as (1) that of the empiricists, who considered it sufficient to distinguish diseases by their apparent signs, (2) that of those who believed it possible to disclose the causes of disease without giving themselves the trouble of learning their effects, and (3) that of those who believed it was necessary to understand the diseases. Cohn adds, by way of interpreting or perhaps of supplementing Laënnec's meaning, that we believe it necessary as the basis of therapeutics to understand the mechanisms, that is to say, the processes which underlie the manifestations of disease, for it is these which it is one of our functions to attempt to correct. That is our practical aim.

For a long time investigators in the domain of the medical sciences have been so deeply engrossed with the efforts to classify diseases and to discover their etiology that practical therapeutics has received somewhat niggardly attention in many quarters. Medical practice has passed through a stage of therapeutic nihilism of which some signs still remain. Obviously, rational therapy depends on the knowledge secured by the intensive study of disease as such; but the relief of suffering and the temporary or permanent correction of defects are inevitable functions of the devotees of medicine. It is not always enough today merely to attempt to reinforce the patient's natural means of defense. The armamentarium of the open minded physician includes for therapeutic purposes drugs, foods, water, serums, vaccines, electricity, heat and cold, mechanical agents, rest, exercise, massage, climate, mental influences and, in fact, whatever physical, chemical and psychic agencies seem to be helpful. To the extent that he may be indifferent to most of these helps he is liable to deprive his patients of some real advantage in the attack on disease.

Students of medicine are sometimes resentful of what they regard as the intrusion of other disciplines or workers in other fields into their domain. This view has been expressed by Cohn in the assertion that a dependence on the outside world for the solution of its problems is in part a reproach to medicine. Probably no injury has yet been suffered, he adds, by society as a result of this dependence. But those advances which depend on knowledge of disease in patients and on actual direct contact with diseased persons have been made by the practitioners of medicine themselves. In this way is to be explained the significance of Sydenham, Jenner and Laënnec; they have taught the use of the classification of diseases, the fact that fevers are preventable, an approach to the diagnosis of visceral disease by means not immediately obvious. These have, after all, constituted the primary advances in medicine. It is this experience which encourages the belief, Cohn concludes, that the development of medicine is in all probability the work of physicians properly trained and supplied with adequate equipment.

In view of the foregoing, it might come as an unpleasant surprise to one not thoroughly conversant with the facts of medical progress to read the title of an essay recently addressed to a group of chemical engineers. The caption was Chemistry's Next Service to Medicine. This contribution, by A. W. Rowe[3] of the Evans Memorial in Boston, deals with the indispensable rôle of the chemist in the preparation of hormones, those substances which are potent regulators of various important bodily functions, such as growth, development, nutrition and reproduction. From drugs to hormones is a relatively simple step. In its pride of accomplishment, medicine must bear in mind that the formal exact study of the action of drugs did not begin until within the lifetime of some living physicians. The first laboratory for the investigation of drugs was established at Dorpat in 1856. Yet chemists had extracted the alkaloid morphine from opium in 1817. Endocrinology, divested of much of its ignorance, misinformation and pretense, seems destined to be one of the major factors in medical progress in the days ahead. The contributions of the chemists in making replacement therapy possible when, as often happens, underproduction of certain hormones leads to the serious effects of endocrine disorder—to serious and even fatal changes in "function level"—deserve frank recognition. Rowe has recalled, for instance, that with their powerful influence on the basic functions of protoplasm any abnormal secretory activity of the individual gland leads to an abnormal expression of those functions over which it exercises a regulating power. End-results such as gigantism, dwarfism, extreme obesity and emaciation, infertility, marked changes in mentality and in the secondary characteristics of sex, and a wide variety of other striking manifestations are thus produced.

[2] Cohn, A. E.: Medicine, Science and Art, Chicago, University of Chicago Press, 1931.

[3] Rowe, A. W.: Chemistry's Next Service to Medicine, Indust. & Engin. Chem. **23:** 1176 (Oct.) 1931.

The preparation of therapeutically available products representing "active principles" of endocrine tissues has been the contribution of the chemical laboratory. The hormones themselves are only a small part of the individual glandular masses or secretions. Isolation of the potent from the extraneous constituents has often involved great difficulty. Success in the chemical identification of the active components paves the way for chemical synthesis whereby freedom is won from dependence on animal sources often difficult to control. This again is a chemist's job. Rowe has presented challenges to the chemist engaged in this field. The first major problem, he points out, is in the isolation of active extracts, and this has been by no means a simple one. Some of the compounds, at least, are highly labile products and may be destroyed during the processes of extraction by the chemical agents used or even by other materials produced in other portions of the same gland from which they are derived. That insulin, the active material from the islands of Langerhans, a part of the pancreas, is destroyed by the digestive enzymes produced by other cells of the same gland is an illustration of the latter condition. A second problem of moment lies in the standardization of these active principles so that the dose administered may be estimated with some degree of precision. Existing in the organism, as they do, in small quantities and in concentrations capable of producing profound physiologic response, it is essential that means be devised to assay their potency. Even today, many preparations are given on the basis of so many grains or milligrams of the fresh or dried substance without any index of the real content of active material.

A further challenge to the chemist lies in the need of reducing the costs of products now attained through expensive processes of manufacture from unabundant materials. This has an economic rather than a purely scientific import; it is none the less important in the day's work of the physician. Rowe points out that the recently prepared extract from the suprarenal cortex, which has been demonstrated to be effective in Addison's disease, costs about $3,000 a year for the amount necessary to treat a single case. Even in those glandular failures in which the replacement therapy is at a minimum cost level through reasonably large supply of raw material and efficient methods of preparation, it can easily reach $100 a year, a far from negligible sum for a large group of wage earners. Epinephrine and thyroxine can now be produced synthetically. Further progress of this sort will represent contributions the importance of which scarcely needs debate. Rowe further says that adequate amounts of pure standardized chemical entities of established quantitative physiologic activity at reasonable cost will enable physicians to produce an enormous alleviation of human suffering, prolong life, and maintain physical efficiency. Let us not discourage what seems to some as an "intrusion" of the chemist into the domain of medicine.

THE TONSILS IN YOUNG WOMEN

Numerous comments in THE JOURNAL on the need for comprehensive statistical studies on the results of tonsillectomy, particularly in relationship to the important investigations made by Kaiser,[1] have apparently stimulated others to similar studies. Now Cunningham, at the University of California, has studied the results of the physical examination of 14,000 women students during the last ten years. More than a third of the young women entering the university during that period had a tonsillectomy; another third were considered as having normal tonsils; the tonsils in the remaining third were considered pathologic. The study was confined to white women students under 35 years of age, as well as to those concerning whose medical history important information could be obtained. The physical examinations required of all entering students were made mostly by specialists, three of whom served during the entire ten years. While the accuracy of the original histories may have suffered as a result of the haste and excitement attending the entrance examinations, the physical examinations were probably fully as accurate as records of the examinations for the army.

In her study of this work, Cunningham [2] endeavors to bring out the relation of the condition of the tonsils to the infectious diseases of childhood. Especial attention was given to cardiac conditions, for the results of these examinations determine where the student is placed in physical education classes in the university. Evidence of damage to the mitral valve was less among those with normal tonsils than among those students whose tonsils were absent or pathologic; in this respect the latter two groups seemed to suffer equally. The group whose tonsils had been removed showed about half the percentage of damage of the aortic valve that was shown by the group whose tonsils were thought to be normal and about one third of the percentage of damage of those whose tonsils were considered pathologic. Of course, tonsillectomy will not guarantee a halt in the progress of existing cardiac disease, and if the operation is to be used as a therapeutic measure it will produce the best results when done before the cardiac infection occurs or early in its course. The two groups of students with normal and with pathologic tonsils had about an equal number of painful experiences, which in their history may or may not have indicated previous attacks of rheumatism. There was a significant difference, however, between the two groups with normal tonsils and those on whom a tonsillectomy had been done. A high proportion of persons whose tonsils had been removed had had rheumatism.

---

[1] Kaiser, A. D.: Effect of Tonsillectomy on General Health in Five Thousand Children, J. A. M. A. **78**: *1869* (June 17) 1922; Effect of Tonsillectomy on the General Health of Twelve Hundred Children as Compared with an Equal Number Not Operated on, ibid. **83**: 33 (July 5) 1924; Results of Tonsillectomy, ibid. **95**: 837 (Sept. 20) 1930; The Relations of Tonsils and Adenoids to Infections in Children, Am. J. Dis. Child. **41**: 568 (March) 1931.

[2] Cunningham, Ruby L.: Normal, Absent and Pathologic Tonsils in Young Women: A Comparison of Histories, Arch. Int. Med. **47**: 513 (April) 1931.

The medical histories of these students were studied also to learn what relation existed between the tonsils and diseases of the respiratory tract, otitis media and the infectious diseases of childhood. The group with absent tonsils gave a history of a higher incidence of all illness and operations than did either of the other two groups. A possible explanation for this is that children who are often ill were most frequently operated on. The group of women students with normal tonsils and the group with pathologic tonsils differed little in the percentage of the incidence of measles, mumps, scarlet fever, diphtheria, chickenpox, whooping cough, rheumatism, pneumonia, pleurisy, chorea, chronic colds and in operations for appendicitis, mastoiditis, cervical glands and operations on the nose. The age when the tonsils were removed had no influence on the total incidence of measles, mumps, chickenpox, whooping cough, pneumonia and influenza. However, early removal of the tonsils seemed to have a slightly favorable influence on the incidence of scarlet fever and diphtheria.

Considering the large number of tonsillectomies and adenoidectomies that have been performed, it is unfortunate that the literature reveals a great lack of accurate information on the effect of tonsillectomy. Opinions still differ on this old question. There seems to be a growing tendency to question the value of tonsillectomy as a prophylactic measure against infectious diseases and as a cure for rheumatism, chorea and carditis. The report of this study agrees, in general terms, with the report of Collins and Sydenstricker, reviewed[3] in The Journal in 1928, and also with the studies of Kaiser. It indicates that tonsillectomy is a useful procedure, but the benefits, when a large control group is compared, are not so striking as could be desired.

COOPERATION IN NECROPSY WORK

The percentage of necropsies performed in this country is still lamentably low. A properly performed necropsy is not only necessary in many cases to establish the exact cause of death but is one of the chief means of advancement of medical knowledge. The reasons for failure to obtain necropsies are obvious. The physician in charge of a case lacks the scientific urge, the relatives of the deceased are opposed, and the mortician is, to say the least, cool, because necropsies may disturb the routine of his work. A joint committee of the New York Academy of Medicine, the New York Pathological Society and the Metropolitan Funeral Directors' Association recently held a series of meetings to discuss the problem. A substantial agreement was reached. All agreed that a necropsy by a pathologist is desirable in order to advance knowledge concerning the nature of the disease and to provide reliable records. The performance of necropsies in a hospital is a constant influence to improve the service and to help physicians serve the next patient with greater confidence and skill.

The hospital and its staff have not completed their services to the family on the death of the patient, but they owe to the family an account of what has occurred. This requires that a representative member of the family come to the hospital for a personal interview and to give permission for examination of the body of the deceased. The funeral director must recognize this relationship and should not oppose the discharge of this obligation. Unreasonable delay by the hospital in its attempt to obtain permission for necropsy is objectionable to a funeral director, as it may require him to cancel contracts for transportation and other services and thus increase his expense. The conflict of interests requires mutual consideration and cooperation. Arrangements should be worked out in every hospital whereby the unnecessary loss of time on the part of the funeral director may be obviated. Hospital employees in general must not give information to funeral directors or to any other unauthorized person in regard to persons critically ill or dead in the hospital. The hospital authorities should be certain that the necessary data for a death certificate are on the chart at the time of admission of the patient, with exception of the facts relating to the nature, progress and termination of the disease. Any interference by a funeral director with the legitimate efforts of the hospital to obtain permission for necropsy shall be regarded as a reportable grievance. The necropsy may be performed in a way to facilitate the work of the embalmer. The main longitudinal incision, the committee believes, should end over the midsternum, and curved incisions with the concavity toward the head should be carried laterally to each shoulder. When the skull is opened, the frontal bone should be cut above the hairline and the base of the skull cemented with plaster before the skull cap is replaced. When the neck organs and tongue are removed, the head should be embalmed through the carotids unless there is a serious contraindication. Other recommendations made by the committee as to technic are that necropsies should be completed at the time promised, if there has been an advance agreement, and that a representative of the funeral director should be a welcome associate at the necropsy table. The spirit of cooperation shown in the report of the joint committee is commendable. Similar cooperation everywhere would no doubt result promptly in an increase in the percentage of necropsies.

Gradually, competent embalmers are tending toward the encouragement of postmortem examination. In the November issue of the *Casket and Sunnyside*, a publication for morticians, appears an editorial commenting on a previous statement on this subject by The Journal. The concluding statement of this editorial reads:

---

[3] Tonsillectomy in the United States, editorial, J. A. M. A. **91**: 1195 (Oct. 20) 1928.

> We might as well recognize, first as last, that the welfare of the living, the public health, is the chief concern of the public, and that to permit the medical profession to secure sufficient scientific data, autopsies must be performed. We might as well also decide that if we explain our difficulties to the medical practitioners, rather than antagonizing them, they will be willing to cooperate with us in avoiding unnecessary mutilation of bodies committed to them for autopsy. Finally, we might as well realize that if we say "an autopsied body can't be embalmed or so prepared that family and friends may view it," we're stultifying ourselves and our claims to professional standing, and admitting our own incompetence.

The editorial points out further that the mortician should be proud of his ability to make presentable a body that has been subjected to postmortem examination and that the cry against such examinations on the part of morticians must be taken as a confession of incompetence. Such support from one of the leading trade publications in the field is an encouraging sign to scientific medicine. It means that the pathologist will now need only to instruct the family and not to convince the mortician.

MATERNAL MORTALITY

The propaganda which has made most of the people in the United States and elsewhere believe that our maternal mortality is worse than that of any other country in the world is difficult to overcome regardless of its inaccuracy. In his International Studies on the Relation Between the Private and Official Practice of Medicine, Sir Arthur Newsholme [1] has pointed out that international comparisons are not dependable because of the great variation that exists in different countries. In developing such statistics it is possible to discover considerable differences in puerperal death rates which do not correspond with real differences. The practices in England and Scotland do not differ markedly, but those in the Netherlands and in the United States differ greatly from those in England and Scotland. Indeed, Sir Arthur Newsholme feels that the international position is somewhat chaotic and that it is doubtful whether the chaos could be removed by the adoption of a rigid and detailed international system of rules, so much depending on the personal bias of the statistician responsible for relegating a dubious certificate embodying more than one item to its right compartment.

Recently, Dr. Robert J. Lowrie [2] has indicated the serious character of the difficulty of properly evaluating death certificates involving puerperal mortality in this country. Not every death certificate on which there is mention of pregnancy or childbirth can count as a maternal death, because pregnancy and childbirth are frequently complicated by cardiac disease, hyperthyroidism, tuberculosis, syphilis and similar complications. Reports of cases are available in which a fever appearing post partum was associated with the appearance of congestion of the lungs in a patient with a long history of tuberculosis. The question as to whether the fever was due to puerperal sepsis, pneumonia or recurrent manifestations of tuberculosis involved a decision too delicate to be shown adequately on the death certificate. Dr. Lowrie feels that our present method of determining maternal mortality rates is quite inaccurate and he offers a new system which is of interest. The analysis of the technic involved is a matter for biometricians.

Every one should realize the impossibility of accurate comparisons between maternal mortality rates in various countries and, indeed, in individual communities in the same country, in hospitals and in general practice. Enough evidence has been developed to indicate that proper prenatal care and adequate obstetric care will lower greatly the mortality and morbidity rates in any group. Let our efforts, then, be devoted to securing the benefits that may be had by such service rather than to acrimonious debates concerning odious comparisons. Let us avoid, furthermore, exaggeration of our difficulties for purposes of propaganda leading to unnecessary expenditures and appropriations.

THE CREDIBILITY OF NARCOTIC ADDICTS

The issues in a case at law sometimes may turn on the ability of the judge and the jury to appraise correctly the weight to be given the testimony of a narcotic addict. Is every narcotic addict hopelessly given to fabricating fairy tales, a pathologic or inveterate liar who lies even when he has no personal end to gain by doing so? Do narcotic addicts habitually live in a world of fancy, so that no matter how much they may wish to do so they cannot observe accurately and report correctly what goes on about them? Persons to whom these problems are matters of concern, and particularly those engaged in the administration of justice, will find them lucidly, dispassionately and cogently discussed in an opinion filed by Judge Henry Clay McDowell, of the United States District Court for the Western District of Virginia, in *Kelly* v. *Maryland Casualty Company*,[1] and adopted by the United States Circuit Court of Appeals, Fourth Circuit.[2] An abstract appears in this issue of The Journal.[3]

Judge McDowell was confronted by a medical problem: Should he or should he not permit the introduction of evidence of the use of morphine by a witness in a case on trial, for the purpose of discrediting her testimony? He went boldly outside the sources of information to which judges ordinarily resort and personally consulted such medical books as were available. The value of his written opinion is enhanced by his citations to the medical books he consulted and by his quotations from them. To a lawyer it may seem dangerous for a judge to base a ruling on what he has read in medical books not admitted as evidence. The rules of evidence almost everywhere forbid the introduction of such books as proof of the facts and theories stated in them. An apparent exception to the general rule denying the admissibility in evidence of medical books is sometimes made where an expert witness testifies that he bases his opinion on the work of a particular author. In such a case, however, the particular work may be introduced in evidence solely for the purpose of contradicting and thereby discrediting the witness. In the present case, so far as the record shows, the books consulted were not offered in evidence by the parties to the cause and they had no opportunity of advising or objecting with respect to their use. Probably the greatest danger in the method adopted by Judge McDowell, however, lies in the paucity of medical books ordinarily available to a judge for consultation and in his limited ability to appraise unaided the weight of the statements of fact and of opinion in the books that he consults. It is one thing for a judge to consult a law book for guidance, and another and quite a different thing for him to consult a medical book. Any law book that is likely to be consulted is based on authority, and the sources of such authority are stated, so that the accuracy of the book can be determined by any competent lawyer. In medicine, however, there are no "authorities" comparable to the authorities in the legal world, and the value of a medical book depends on the knowledge, skill, experience and moral courage of the writer, with none of which the average judge is apt to be acquainted. From a legal point of view the very fact that the book of any given medical writer is consulted as a possible basis for a legal decision makes the author a witness—a secret witness unless the parties to the cause are fully advised concerning the matter—a witness not under oath and not subject to cross-examination, whose testimony is by those very circumstances inadmissible.

[3] Narcotic Addiction as Affecting Veracity, this issue, page 1917.

The course adopted by Judge McDowell, however, wisely pursued as he seems to have pursued it, is a course that should no doubt be encouraged. Probably the best plan for any judge to follow, if he desires to emulate Judge McDowell's example, would be to seek guidance through the nearest available organized medical library, or through the state or county medical association, or even through the American Medical Association. Possibly the day may come when judges will be provided with the aid of official medical advisers to help them over the difficulties that beset the nonmedical reader when he tries to find his way through the mazes of medical bibliography.

Current Comment

PREPARING A PEDIGREE

The importance of heredity in relation to disease is generally recognized. Unfortunately, however, few realize that the study of heredity is a scientific problem and that the language and technic of studies in heredity are specific to that science. A study of heredity charts in various periodicals will indicate to any observer the necessity for uniformity in the use of various symbols and the desirability of completeness. Since heredity charts are likely to be used fifty or a hundred years after they are first prepared as well as at the time of their first publication, and since they are likely to be studied by investigators in various parts of the world, the need for simplicity and accuracy becomes still more apparent. The Eugenics Society of Great Britain[1] has prepared for those especially interested a pamphlet entitled "How to Prepare a Family Pedigree" and a book of forms, charts and directions to be used by those who undertake such studies. The forms are concise; the directions take into account all the considerations that have been mentioned. The current tendency in medicine toward greater attention to problems of constitution and heredity indicates still further the desirability of this material.

SIR DAVID BRUCE

The cabled news of the daily press announced the death, November 27, of Major General Sir David Bruce in England at the age of 76 years. Sir Ronald Ross, himself one of the distinguished investigators of our day, is said to have described Bruce as one of the medical geniuses who served the British Empire. He will long be remembered for his contributions to our knowledge of trypanosomiasis, or African sleeping sickness. The malady has long been known; indeed, there are references more than two hundred years old mentioning a sleeping distemper among Negroes of the Guinea coast. Not until the present century was the etiology of this disease put on a sound basis. First, actively moving bodies were observed in the blood of patients. The motile agents were presently identified as trypanosomes. It was the merit of Bruce and his co-workers to have demonstrated that there are insect vectors for the causative micro-organisms, tsetse flies being the offenders. The so-called Gambian sleeping sickness is now widely distributed in the tropical zone of Africa. As first shown by Bruce, the Gambian parasite, Trypanosoma gambiense, is normally transmitted by the tsetse fly Glossina palpalis, and its distribution is now almost coincident with the range of this species. According to Hegner,[1] the indications at present are that Trypanosoma gambiense and Trypanosoma rhodesiense, the recognized organisms of African sleeping sickness, are usually transmitted by the tsetse flies belonging to the species Glossina palpalis and Glossina morsitans. Other species of the genus

[1] Hegner, R. W.: The Transmission of Human Protozoa, Science 64: 28 (July 9) 1926.

Glossina may perhaps serve as vectors under favorable circumstances. The etiologic factor of Malta fever was described by Bruce as Micrococcus melitensis in 1887. This, too, was an epoch-making discovery among what Garrison has termed "the chief glories of nineteenth century medicine." During the World War the studies of a British committee under Sir David Bruce working under field conditions in France contributed to the important demonstration that trench fever is a louse-borne disease.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts from *2:25* p. m. to *2:30* p. m. on Monday, Wednesday and Friday over Station WBBM (770 kilocycles, or 389.4 meters), of the Columbia Broadcasting System.

The program for the week is as follows:

December 21.	Infantile Paralysis.
December 23.	Sleep and Growth.
December 25.	No broadcast.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARKANSAS

License Revoked.—The license to practice medicine of Dr. Thomas B. Sylar, Lepanto, was revoked by the State Medical Board of the Arkansas Medical Society at its regular meeting, November 10-11. Dr. Sylar was convicted and sent to the U. S. Penitentiary at Leavenworth, Kan., for violating the Harrison Narcotic Act.

Society News. — The Craighead-Poinsett County Medical Society entertained the First Councilor District and Northeast Arkansas Medical Society at Jonesboro, recently; the program included papers by Drs. Darmon A. Rhinehart, Little Rock, president, state medical society, on "Trends in Medicine"; Lee V. Parmley, "Medical Legislation," and Dr. Robert J. Haley, Jr., Paragould, "Early Diagnosis and Surgical Treatment of Perforated Gastric Ulcers."——Among others, Dr. Robert L. Sanders, Memphis, addressed the Second Councilor District Medical Society, Batesville, recently, on "Troublesome Cervix Uteri as Seen by the General Practitioner."

CALIFORNIA

Health at San Diego.—Telegraphic reports to the U. S. Department of Commerce from eighty-two cities with a total population of 36 million, for the week ended December 5, indicate that the highest mortality rate (19) appears for San Diego, and the rate for the group of cities, 10.8. The mortality rate for San Diego for the corresponding period last year was 16.7, and for the group of cities, 11.8. The annual rate for eighty-two cities for the forty-nine weeks of 1931 was 11.8, as against a rate of 11.9 for the corresponding weeks of 1930. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits, or that they have a large Negro population, may tend to increase the death rate.

Society News.—The San Francisco Heart Committee held its second annual graduate symposium on heart disease, November 19, sponsored by the San Francisco county medical and tuberculosis associations and the Health Council of the San Francisco Community Chest; a clinical pathologic conference also featured the meeting. Officers elected at this session include Drs. Arthur L. Bloomfield, chairman, and William C. Munly, secretary.——The Santa Barbara County Medical Society was addressed, October 12, by Drs. Ira B. Bartle, San Luis Obispo, on "Actinomycosis," and Henry J. Profant, Santa Barbara, on "Management of Mastoiditis and Petrositis."——A recent meeting of the Stanislaus County Medical Society, Modesto, was addressed by Dr. Joseph Catton, San Francisco, on "Medical Aspects of Recent Murder Cases."——The October meeting of the Monterey County Medical Society at Monterey was addressed by Dr. Edwin Schultz, Stanford University, on "Recent Advances in Poliomyelitis."——Dr. Carl R. Howson, Los Angeles, addressed the San Bernardino County Medical Society, San Bernardino, October 6, on "The Future of Medicine."——Dr. Dean Lewis, Baltimore, will address the Los Angeles Surgical Society, December 30, on "The History and Development of the Surgical Clinic."——Among others, Dr. Eldon W. Tice addressed the Los Angeles Obstetrical and Gynecological Society, December 8, on "Effect of Hot and Cold Packs on Blood Pressure in Abdominal Surgery," and Dr. Philip A. Reynolds, "Friedman Test for Diagnosis of Pregnancy."——Dr. Carl R. Howson, Los Angeles, was elected president of the Southern California Medical Association at its recent annual meeting; Drs. Harry E. Henderson, Santa Barbara, and Robert E. Ramsay, Pasadena, vice presidents, and Robert William Langley, Los Angeles, secretary. The next session will be held in Santa Barbara in April.——The San Francisco Pathological Society was addressed, December 7, by Drs. William H. Probert, Poughkeepsie, N. Y., and William T. Cummins on "Carcinoma of the Thyroid with Metastases"; P. Smith, "Retropleural Neurocytoma"; Dorothy A. Wood and Frederick L. Reichert, "Congenital Hemihypertrophy of the Leg with Neurofibromatosis"; Adelbert M. Moody, "Normoblasts in the Chorionic Villi in Early Pregnancy," and James F. Rinehart, "Studies on the Hemoglobin of Erythrocytes."

CONNECTICUT

Society News.—The Waterbury Medical Association was addressed, November 12, by Dr. James J. Hennessy, Waterbury, on "Treatment of Tuberculosis by Artificial Pneumothorax." Dr. John D. Booth, Danbury, gave a demonstration of the treatment.

Campaign to Prevent Colds.—With the cooperation of the student body and the faculty, the college board of health of Connecticut College, New London, has begun a campaign to prevent colds. Katharine Blunt, Ph.D., president of the college, is head of the board in conjunction with Dr. Mary K. Benedict, resident physician. It is proposed to build up resistance so that there may be as little susceptibility to colds as possible; to treat colds at the very start, thereby preventing their development, and to prevent those who do get colds from spreading them among the others. Instructions are placed in the dormitories and the students have been asked to go to the infirmary at the first suggestion of a cold so that treatment may be given before the cold develops. Students with colds will be kept in the dormitory until the danger of infecting others has been removed.

DISTRICT OF COLUMBIA

Personal.—Dr. Arthur C. Christie, president of the Medical Society of the District of Columbia, was elected president of the board of trustees of American University, Washington, November 2.——Dr. Radford Brown of Sloane Hospital for Women, connected with Columbia University, New York, has been appointed professor of obstetrics and gynecology and executive officer of the department in the George Washington University Medical School; he will assume his new duties, January 1.

New Building at George Washington University. — Construction will soon begin on a four-story addition to George Washington University Medical School, Washington. The building, which will cost about $75,000, will contain a central laboratory for the hospital, teaching laboratories for clinical microscopy, bacteriology and hygiene and preventive medicine, research laboratories for bacteriology, and animal quarters for experimental work for the entire school in addition to other research laboratories. This building will serve as temporary quarters until the medical school can move into a new plant, as a part of the proposed George Washington University Medical Center.

Medical Inspection of School Children.—According to the report made by a survey group of the public health committee of the Washington Board of Trade, medical inspection of schools in Washington is adequate so far as public service reasonably can be expected to extend. However, further medical and dental care of children provided by private means was recommended by a subcommittee. A survey of public bathing pools showed that all necessary steps for assuring sanitation are being carried out. The results of a survey of ways and means of promoting greater safety for the public in the handling of motor traffic are to be announced later.

ILLINOIS

Personal.—With the creation of a new health office, that of county epidemiologist, the position of health officer of DuPage County has been discontinued. William V. Hopf, D.D.S., Lombard, who was the health officer, will assume the duties of the new office.

Society News.—The Fulton County Medical Society was addressed, December 1, in Canton, by Dr. Frank E. Simpson, Chicago, on the use of radium in malignant tumors, and Dr. Paul G. Dick, Chicago, treatment of malignant conditions with X-rays; Dr. Josiah J. Moore, also of Chicago, gave a demonstration of the Canti cancer film.——Drs. Bransford Lewis and Alphonse McMahon, both of St. Louis, addressed the Sangamon County Medical Society, Springfield, December 3, on "A Survey of Urology for the General Practitioner" and "Differential Diagnosis Between Early Tuberculosis and Hyperthyroidism," respectively.——Dr. Samuel M. Feinberg, Chicago, addressed the Rock Island County Medical Society, December 8, on "Allergy in General Practice."——Dr. Frederick A. Baumgart was elected president of the newly created Danville Medical Society, and Dr. George T. Cass, secretary.——The Jo Daviess County Medical Society was addressed at Warren recently, among others, by Dr. Karl B. Rieger, Freeport, on "Thrombo-Angiitis Obliterans."——The Clinton County Medical Society was addressed at Carlyle, November 17, by Drs. William S. Carter, Trenton, and J. P. Murphy on "Otitis Media, Middle Ear Infection" and "Relation of Eyestrain and Headaches," respectively.——At the meeting of the Perry County Medical Society, December 3, Dr. Frank F. Maple, Chicago, spoke on "Abortion and Its Treatment," and Dr. James H. Hutton, Chicago, "Recent Advances in Endocrinology."

Chicago

Society News.—Edwin O. Jordan, Ph.D., was elected president of the Institute of Medicine of Chicago at its annual meeting, December 1; Dr. Arthur R. Elliott, vice president; Dr. George H. Coleman, secretary, reelected; Dr. John Favill, treasurer, and Dr. Ludvig Hektoen, chairman of the board of governors. Dr. Otto L. Schmidt gave the presidential address on "The Rôle of Medical and Hygienic Museums in Education."——Dr. Morris Fishbein addressed the Historical Club of the University of Illinois College of Medicine, December 2, on "The Future of Medicine."——The Chicago Gynecological Society was addressed, December 18, by Drs. Milton J. Summerville and Frederick H. Falls on "A Critical Study of the Technic and Clinical Value of the Sedimentation Rate in Gynecology"; Jacob P. Greenhill, "Thymophysin and Weak Pituitary: Comparison in 40 Cases," and Richard A. Lifvendahl, "A Sign for the Detection of Small Amounts of Free Blood in the Abdomen."——The Chicago Pediatric Society was addressed, December 15, among others, by Dr. Henry E. Irish on "Effect of Cod Liver Oil-Skimmed Milk Feeding on Bones After One Year."——The Chicago Neurological Society was addressed, December 17, among others, by Dr. Isadore Pilot on "Putrid Brain Abscess—Its Pathogenesis."——At the meeting of the Chicago Society of Allergy, December 21, Dr. Harry L. Huber, among others, will speak on "Dermatitis Due to Burweed Marsh Elder."——Drs. Thomas D. Allen and Ramon Castroviejo will address the Chicago Ophthalmological Society, December 21, on "The Autonomic Nervous System and the Eye" and "A New Knife for Ophthalmic Surgery," respectively.

KANSAS

Photographic Service.—The photographic department of St. Francis Hospital, Wichita, recently announced that its service is available to all physicians who desire it. The work will be done on a cost basis, a charge of $1 having been decided on for one photograph. The service comprises the production of clinical photographs of patients and gross specimens, photomicrographs, the copying of charts, drawings and printed or typewritten data, and the making of lantern slides. The photographic department is supervised by the pathologist of the hospital, although it is operated as an independent unit.

Society News.—The Labette County Medical Society was addressed, November 18, by Drs. Earle G. Brown and William C. Menninger, Topeka, on infantile paralysis.——The Franklin County Medical Society was addressed, November 21, by Drs. Sherwin E. Mella and Robert Lee Hoffmann, both of Kansas City, on "Diagnosis and Treatment of Common Skin Diseases" and "Urology," respectively.——The Wyandotte County Medical Society was addressed, November 14, by Drs. Elam A. Reeves, Kansas City, on "Placenta Praevia"; Earle G. Brown, Topeka, "Epidemiology of Infantile Paralysis," and James R. Elliott, Kansas City, Mo., "Management of Poliomyelitis During the Stage of Recovery."——The Harvey and Sedgwick county medical societies, in joint session at Newton, were addressed, November 3, by Drs. Arthur Steindler, Iowa City, on hip and back sprains and their connection with compensation cases, and James A. Wheeler, Newton, vitamins. Dr. Henry N. Tihen, Wichita, addressed the Sedgwick County Medical Society, November 20, on "Medical Organization."

MICHIGAN

Personal.—Dr. Alden G. Sheets has been appointed health officer of Eaton Rapids.——Dr. Lloyd S. Dunkin has been appointed health officer of Greenville to succeed the late Dr. Will H. Lester.

Dr. Moll Honored.—The Genesee County Medical Society tendered a testimonial dinner, October 28, to Dr. Carl F. Moll, Flint, president of the Michigan State Medical Society. The toastmaster was Dr. Frank E. Reeder. The program included talks by Dr. Moll; Dr. Frederick C. Warnshuis, Grand Rapids, on the state medical society; Judge V. W. Dodge, the physician and the probate court; Dr. Clyde C. Slemons, Grand Rapids, the physician and the state board of health, and Dr. Leslie L. Willoughby, the Genesee medical society.

Society News.—Dr. James D. Bruce, Ann Arbor, addressed a joint meeting of the Berrien County Medical Society and the dentists of the county, November 23, on "Focal Infections and Their Relations to Systemic Disease."——A symposium on infantile paralysis featured the meeting of the University of Michigan Pediatric and Infectious Disease Society, Ann Arbor, November 19-20.——Dr. Ralph Pemberton, Philadelphia, addressed the medical section of the Wayne County Medical Society, December 8, on "The Newer Outlook on Chronic Arthritis."——Dr. Harry W. Plaggemeyer, Detroit, addressed the Hamtramck Medical Society, November 20, on the activities of the Wayne County Medical Society.——Judge Charles B. Collingwood, Lansing, addressed the Calhoun County Medical Society, December 1, on "The Doctor in Court."——The Washtenaw County Medical Society, Ypsilanti, conducted a symposium on cancer at its meeting, November 24; the speakers included Drs. Frank L. Rector, Evanston, Ill., Max Ballin, Detroit, and Conrad Georg, Sr., Eugene B. Potter and Mark Marshall, all of Ann Arbor; Dr. George F. Inch addressed the society, among others, December 11, on "Importance and Necessity for Early Diagnosis and Treatment of Mental Cases."——Dr. William H. Alexander, Iron Mountain, addressed the Dickinson-Iron County Medical Society, December 3, on "Some Surgical Problems in Pulmonary Tuberculosis."——Dr. Karl A. Menninger, Topeka, Kan., addressed a joint meeting of the Wayne County Medical Society and the Detroit Society of Neurology and Psychiatry, December 15, on "Focal Suicide: Psychogenic Aspects of Physical Disease."

MINNESOTA

Personal.—Dr. Jay Arthur Myers has recently been promoted from associate professor to professor of preventive medicine at the University of Minnesota School of Medicine, Minneapolis.——Dr. Lincoln A. Sukeforth, public health director of Duluth, has retired after eight years' service.——Dr. Joseph A. Roy, Red Lake Falls, was elected mayor of that city in November.

Licenses Revoked.—At a meeting of the Minnesota State Board of Medical Examiners in St. Paul, November 10, the license of Dr. John Gerardi Halland, Motley, was revoked because of his habitual indulgence in the use of drugs. The license of Dr. David Gordon, Minneapolis, was also revoked at this meeting as the result of his conviction on nine counts of violating the Harrison Narcotic Act. Dr. Gordon was sentenced to eighteen years' imprisonment at Leavenworth. This was his second offense.

Society News.—Dr. Emil S. Geist, Minneapolis, addressed a joint meeting of the West Central and Kandiyohi-Swift county medical societies recently on "Treatment of Fractures."——The Washington County Medical Society was recently addressed by Drs. John C. McKinley, Minneapolis, and Wallace H. Cole, St. Paul, on infantile paralysis.——Dr. Frederic E. B. Foley, St. Paul, addressed the Minnesota Academy of Medicine, December 9, on "Embryology and Surgical Correction of Certain Renal Malformations." Dr. Irvine McQuarrie, Minneapolis, gave a thesis on "Some Recent Observations Regarding the Nature and Treatment of Epilepsy in Children."

MISSOURI

Personal.—The Missouri Commission for the Blind recently announced that Dr. Meyer Wiener had resigned as director of the department for the prevention of blindness, which he established in 1929. Dr. Wiener is associate professor of clinical ophthalmology in Washington University School of Medicine, St. Louis.——The library of Dr. Thomas J. Downing, New London, has been given to the St. Louis Medical Society by Mrs. Downing in compliance with a request of the physician before his death, Dec. 7, 1930. The collection consists of 743 volumes.

Society News.—Dr. Horace W. Soper, St. Louis, entertained four of his classmates in Washington University School of Medicine at a dinner, November 17, given in honor of Dr. George B. Tuttle, Kalaupapa, Hawaii. The physicians were Drs. Tuttle, Albert E. Taussig, Adolph G. Schlossstein and Edward J. Goodwin, St. Louis. Dr. Tuttle addressed the St. Louis Medical Society, among others, November 10, on "Leprosy in Hawaii."——At the December 8 meeting of the St. Louis Medical Society, Dr. Russell A. Hennessey, Memphis, Tenn., spoke on "Traumatic Lesions of the Urinary Organs," and Drs. Howard L. Stitt and Charles E. Wooding, Cincinnati, discussed "Bronchial Lavage and Its Medical Aspects."——The Kansas City Southwest Clinical Society held its monthly clinic at the Kansas General Hospital, December 8, when Dr. Morris Fishbein, Chicago, spoke on "The Trend in Medical Practice." The evening session in conjunction with the Jackson County Medical Society was addressed by Dr. Quitman U. Newell, St. Louis, on "Five-Year End-Results in the Treatment of Carcinoma of the Uterine Cervix."——The Twenty-Sixth District Medical Society was addressed, November 17, among others, by Bruce E. Ratcliff, D.D.S., Springfield, on "Teeth as Foci of Infection—Diagnosis and Treatment," and Dr. Duff S. Allen, St. Louis, "Thyroid Toxicosis."

NEW JERSEY

Dr. Theobald Smith Honored.—The Rockefeller Institute for Medical Research gave a dinner, November 20, at the department of plant and animal pathology near Princeton in honor of Dr. Theobald Smith, for many years director of the department. The occasion marked the opening of the Theobald Smith House, which was for many years the residence of Dr. and Mrs. Smith and has now been remodeled as a staff house for scientific workers. Dr. Simon Flexner, New York, director of the institute, presided at the dinner and addresses were made by Dr. William H. Welch, Baltimore, John D. Rockefeller, Jr., and Dr. Smith. Ground has recently been broken for the erection of new buildings for the division of plant pathology (The Journal, June 20, p. 2131). There will be a laboratory building two and a half stories high, eight greenhouse units and potting sheds. The name of the Princeton branch has been changed to the Department of Plant and Animal Pathology of the Rockefeller Institute for Medical Research.

NEW YORK

New State Hospital.—Dr. William J. Tiffany, superintendent of Kings Park State Hospital since 1928, has been appointed superintendent of the new Pilgrim State Hospital, Brentwood, the first units of which have recently been opened for the reception of patients. Accommodations for 1,000 patients are now ready and 480 have already been received. It is expected that the project will be completed in the summer of 1932. There will then be eighteen buildings, erected at a cost of about $20,000,000, with a capacity for 6,600 patients. The hospital is named for Dr. Charles W. Pilgrim, Central Valley, for many years superintendent of the Hudson River State Hospital, Poughkeepsie, and at one time chairman of the former state hospital commission. Dr. Tiffany has been in the state hospital service since 1904, except for a short period at St. Joseph's Hospital, Paterson, N. J.

Clinics on Cancer.—The tumor clinic of the Memorial Hospital, Albany, is conducting a series of monthly clinical meetings on cancer for all physicians interested. Each meeting begins with a clinicopathologic conference, followed by discussion of the incidence, history and classification of cancers of the region under study for the day and later by a tumor clinic and round table discussion of cases. For evening sessions, addresses by visiting physicians have been arranged. The first two were given by Drs. Ernest M. Daland, Boston, November 4, on "Importance of the Tumor Clinic in the Cancer Problem," and Burton J. Lee, New York, December 2, "Early Diagnosis and Treatment of Cancer of the Breast." Future lectures will be by Drs. George M. MacKee, New York, Jan. 6, 1932, on cancer of the skin; William P. Healy, New York, February 3, cancer of the female generative organs; Benjamin S. Barringer, New York, March 2, cancer of the urinary tract; Louis C. Kress, Buffalo, April 6, bone tumors, and Lloyd F. Craver, New York, May 4, medical treatment of the cancer patient. Dr. Brayton E. Kinne, Albany, is executive director of the tumor clinic.

New York City

New Red Cross Building.—The New York Chapter of the American Red Cross celebrated the twenty-fifth anniversary of its founding, November 5, with the dedication of a new twelve-story chapter house at Lexington Avenue and Thirty-Eighth Street. The house was built with funds from the Conrad Hubert Fund, administered by former Gov. Alfred E. Smith, former President Calvin Coolidge and Julius Rosenwald, Chicago philanthropist. Among speakers at the ceremony were John Barton Payne, chairman of the central committee of the Red Cross, Washington, D. C.; Dr. Livingston Farrand, president of Cornell University; John H. Finley, associate editor of the New York *Times*, and former Governor Smith.

Society News.—Members of the laboratory staffs of the hospitals in the Bronx and representatives of the medical examiner's office recently organized the Bronx Pathological Society, with Drs. Joseph Felsen as president; Charles H. Hochman, vice president, and William Aronson, secretary. Dr. James Ewing addressed the first meeting, December 15, on "The Place of Pathological Anatomy in Modern Medicine," and Dr. Felsen, "Tumors of the Colon and Rectum."——Dr. Theodore H. Weisenburg, Philadelphia, addressed the New York Physical Therapy Society, December 9, on "Physical Therapy in Diseases of the Nervous System."——Dr. Walter B. Cannon, Boston, addressed the section on neurology and psychiatry of the New York Academy of Medicine, December 8, on "The Autonomic Nervous System and Its Chemical Mediators."——A meeting of the New York Electrical Society, December 16, was devoted to discussions of the uses of electricity in medicine. Dr. Howard A. Kelly, Baltimore, presided and the following speakers gave addresses: Gioacchino Failla, Sc.D., Memorial Hospital, on the use of high voltage roentgen rays in the treatment of cancer; Drs. Charles F. Tenney, Jr., Fifth Avenue Hospital, on the fever-producing machine; Grant E. Ward, Johns Hopkins University Medical School, Baltimore, the so-called radio knife, and Horatio B. Williams, professor of physiology, Columbia University College of Physicians and Surgeons, the electrocardiograph.

NORTH DAKOTA

Unlicensed Practitioner Sentenced.—Robert G. Errington, who has operated in Fargo as a naturopath and "cancer specialist," advertising his offices as a "nature clinic," was sentenced, October 30, to spend thirty days in jail and to pay a fine of $300. He was committed to the Cass county jail pending the filing of an appeal bond, which was set at $1,000. In passing sentence, Judge P. M. Paulsen is reported to have said that Errington had openly defied the law not only in North Dakota but in other states. The Journal in 1928 reported that Errington had been found guilty of violating the basic science law of Minnesota and was fined $500 and costs. He had previously been sentenced in the same state to five months in jail for violating the medical practice act. According to the secretary of the state medical association, several persons have recently complained that Errington not only guaranteed cures, for which large sums of money were paid in advance, but had sued them on notes given by them in addition to the cash advances.

OREGON

Personal.—Dr. Henry H. Dixon, formerly of Denver, has joined the faculty of the University of Oregon Medical School as professor of neuropsychiatry.——Dr. Edward A. Weir has been appointed supervisor of public health activities for the U. S. Public Health Service in the district of Portland to succeed Dr. Frank S. Fellows, who was recently appointed district medical director of Alaska.——Dr. Josiah Morris Slemons, Los Angeles, addressed the Polk-Yamhill-Marion Counties Medical Society, Salem, November 10, on "Induction of Labor at Term."

PENNSYLVANIA

Society News.—At the meeting of the Delaware County Medical Society, December 10, Drs. Owen J. Toland, Philadelphia, and Aaron Lovett Dewees, Ardmore, spoke on "Prophylactic Obstetrics" and "Technic of Contraception," respectively.——Dr. Arthur F. Coca, New York, lectured in Pittsburgh on "Classification of Allergic Diseases with Reference to Diagnosis and Treatment," November 24, under the auspices of Montefiore Hospital.——Drs. James K. Everhart and Henry T. Price, among others, addressed the Pittsburgh Academy of Medicine, December 8, on "Transfusion in Infancy," and "Leukemia in Children," respectively.——Dr. Jesse O. Arnold, Philadelphia, addressed the Lycoming County Medical Society, Williamsport, December 11, on "Cause and Control of Eclampsia."

Philadelphia

Changes at Temple University.—Dr. Hugo Roesler, formerly of the University of Vienna, Austria, was recently appointed assistant professor of radiology at Temple University School of Medicine. Recent promotions include those of Drs. George W. Deitz, to associate professor of cardiovascular diseases of children; Edward C. Davis, to assistant professor in proctology; Thomas Carroll Davis, to assistant professor in rhinolaryngology and Samuel Goldberg, to clinical professor of pediatrics.

Society News. — The Philadelphia Association of Retail Druggists entertained Philadelphia physicians at a smoker, December 4. Addresses on the cooperation of the two professions were delivered by Drs. George C. Yeager, W. Burrill Odenatt and John O. Bower, and Prof. Ernest Fullerton Cook, Pharm.M., among others.——A symposium on juvenile delinquency was conducted at the meeting of the Philadelphia Psychiatric Society, December 11. Speakers were Drs. Frederick H. Allen, Samuel Leopold and James S. Plant, Newark, N. J., and Judge Paul N. Schaeffer, Reading.——Dr. Abraham Flexner, New York, addressed the College of Physicians of Philadelphia, December 14, on "The Graduate School and Full Time Teaching."——Dr. Charles E. G. Shannon delivered the postgraduate seminar of the Philadelphia County Medical Society, December 11, on squint as encountered by the general practitioner.——Dr. Hubley R. Owen addressed the Philadelphia Academy of Surgery, December 7, on "The Problem of Delayed Union and Ununited Fractures."——Drs. Hugh W. Josephs, Baltimore, and David L. Drabkin addressed the Philadelphia Pediatric Society, December 8, on "Nutritional Anemia: Its Prevention and Treatment" and "Recent Progress in Experimental Anemia," respectively.——The annual banquet of the Medical Alumni Association of the Medico-Chirurgical Society of Philadelphia was held, November 19. Dr. John J. Dailey, McAdoo, was elected president.——Dr. John A. McGlinn, among others, addressed the Obstetrical Society of Philadelphia, December 3, on "Reconstruction of the Urethra."——Dr. Louis Edeiken, among others, addressed the Philadelphia Roentgen Ray Society, December 3, on "Stimulating Doses of X-Rays for Amenorrhea and Sterility."——Dr. George E. de Schweinitz addressed the American Philosophical Society, December 4, on "Toxic Amblyopias with Especial Reference to Methyl Alcohol."

SOUTH CAROLINA

Society News.—Among speakers before the Fifth District Medical Society, Chester, November 1, were Drs. Robert W. McKay, Charlotte, N. C., on "Urological Problems of the General Practitioner"; William J. Henry, Chester, "Glandular Fever," and Hugh P. Smith, Greenville, "Primary Hypochronic Anemia."

Grant for Research on Goiter.—Bernard M. Baruch, New York, has recently given $13,000 to the South Carolina Food Research Laboratory at the Medical College of the State of South Carolina, Charleston, for investigations into the relation of diet to simple goiter. Seasonal and other variations in the amount of iodine available normally in the environment of persons in goitrous and nongoitrous regions will be studied. Goiter is not endemic in South Carolina.

TENNESSEE

Society News.—Dr. George I. Baker addressed the Knox County Medical Society, Knoxville, November 17, on "Management of Diabetes in Children." Dr. Harvey J. Howard, St. Louis, addressed the society, November 23, on "Mechanism of Defense of the Mucous Membrane."——Dr. Richard A. Barr addressed the Nashville Academy of Medicine, November 17, on appendicitis, with a review of 500 cases subject to operation. Other recent speakers have been Drs. John S. Cayce, November 3, on "Treatment of Hyperemesis Gravidarum," and William R. Cate, November 10, "Relationship of Hypertension and Nephritis."——Dr. John E. Frazier, Newbern, was elected president of the Walnut Log Medical Society, comprised of physicians of western Kentucky and Tennessee, at its meeting, November 13-14, at Walnut Log, on Reelfoot Lake. Among speakers at the meeting were Drs. Willard Bartlett, St. Louis, on "Results of Experience with Barbituric Acid Compounds for Surgical Anesthesia"; Peter Whitman Rowland, Jr., Memphis, "Immediate and Ultimate Prognosis of Certain Types of Cardiovascular Disease"; William T. Black, Memphis, "Differential Points in Diagnosis of Pelvic Masses," and Ernest H. Baird, Dyersburg, "Diseases of the Gallbladder."——The Tennessee Hospital Association will hold its annual meeting jointly with the Kentucky Hospital Association at Memphis in April, 1932, it has been announced.——Drs. Perry Bromberg and Samuel S. Riven, Nashville, addressed the Blount County Medical Society, Maryville, November 14, on "Renal Calculi" and "Thyroid Heart," respectively. The Knox and Monroe county medical societies were guests at the meeting.——Dr. John S. Freeman, Springfield, was elected president of the Middle Tennessee Medical Society, at its seventy-fourth semiannual meeting, November 6, at Fayetteville. The next meeting will be held in Sparta in May, 1932.——Dr. Edward C. Mitchell, Memphis, among others, addressed the medical society of Hardin, Lawrence, Lewis, Perry and Wayne counties, Savannah, October 22, on pyelitis and other diseases of the kidney.——Dr. Howard P. Hewitt addressed the Chattanooga and Hamilton County Medical Society, November 12, on "Prenatal Care and Management During Labor and Puerperium."——Dr. James L. Morton, Shelbyville, addressed the Bedford County Medical Society, November 19, on apoplexy.

TEXAS

License Revoked.—The license of Dr. Pedro M. Hernandez, Corpus Christi, was revoked, November 20, by the judge of the one hundred and seventeenth district court of Nueces County in a suit brought by the state board of medical examiners. The suit was based on the allegation that the license was obtained by fraud in that Hernandez had represented himself as a graduate of the National University School of Medicine of Mexico, whereas he had not attended or graduated from that school.

WEST VIRGINIA

Personal. — Dr. Vinton A. Selby, Clarksburg, resigned, November 1, as health officer of Harrison County and was succeeded by Dr. Americus J. Kemper, Lost Creek.

Society News.—Dr. Haven Emerson, New York, conducted a two-day institute for health workers during the meeting of the West Virginia Public Health Association, held at Morgantown, November 19-21. His subjects were "Preventable Disease from the Standpoint of the Public Health Official and the Medical Profession" and "Public Health Practices and Standards." Other speakers were Drs. John L. Lavan, Toledo, Ohio, on immunology, and Estella Ford Warner of the U. S. Public Health Service on the status of West Virginia's health program. Dr. William J. MacDonald, Wellsburg, was elected president and Dr. David Littlejohn, Charleston, secretary.——Dr. John R. Caulk, St. Louis, addressed the Ohio County Medical Society, Wheeling, December 11, on "The Cautery-Punch Operation." Dr. David Silver, Pittsburgh, addressed the society, December 4, on "Future Progress in the Care of the Cripple."

GENERAL

Radiological Society Awards Medals.—Two gold medals for distinguished service in the field of radiology were awarded to physicians at the recent meeting of the Radiological Society of North America in St. Louis. Dr. Carlos Heuser, Buenos Aires, Argentina, who was the guest of the society for the meeting, received a medal in recognition of work in methods of making roentgenograms for the study of pregnancy. Dr. Maximilian J. Hubeny, Chicago, was awarded a medal in honor of his research on the determination of dental focal infection, the injection of the sphenoid sinuses with a suspension of barium sulphate and oblique projection in the examination of the lumbar spine. Dr. Francis Carter Wood, New York, was elected president and Dr. Byron H. Jackson, Scranton, Pa., was made president-elect of the society; Dr. Donald S. Childs, Syracuse, N. Y., was elected secretary. The officers will assume their stations January 1.

Operations for Removal of Cataracts in India. — A group of American surgeons plan to perform about 100 operations for the removal of cataracts each day in India during the winter months, according to a recent report. The work is under the direction of Dr. Henry T. Holland, Shikarpur, who holds an annual eye clinic at the Seth Heranand Charitable Eye Hospital. The American physicians include, it is reported, Drs. Walter I. Lillie, Rochester, Minn.; Oscar B. Nugent, Agnes Beulah Cushman and Louis Bothman, Chicago; Watson W. Gailey, Jr., Bloomington, Ill., and Joseph J. Hompes, Lincoln, Neb. Certain sections of northern India are said to be characterized by a greater prevalence of cataracts than any other section of the world; some of the causes for this condition are intense sunlight and lack of proper nourishment which creates premature senility. The British government pays the surgeons, and the operations cost the patient nothing. A group of specialists performs the operations; a second group fits the patients with glasses after the operations have been performed. It is planned to treat more than 5,000 natives, the report stated.

Society News.—The American Urological Association will hold its next annual meeting in Toronto, Canada, May 30-June 2.——At the annual meeting of the Association of American Medical Colleges in New Orleans, November 30-December 2, Dr. Louis B. Wilson, director of the Mayo Foundation of the Graduate School of the University of Minnesota, was elected president; Dr. Herman G. Weiskotten, dean, Syracuse University School of Medicine, vice president, and Dr. Fred C. Zapffe, Chicago, secretary, reelected. The next annual meeting will be held in Philadelphia.——The twelfth annual meeting of the American Student Health Association will be held in New York, December 29-30. Among speakers listed on the program are Drs. Shailer U. Lawton, New York, on "Infectious Conditions in Relation to Physical Activity"; Thomas K. Richards, Boston, "Prevention and Treatment of Knee and Ankle Injuries"; Jay Arthur Myers, Minneapolis, "Eleven Years' Observation on Tuberculosis among University Students," and Milford E. Barnes, Iowa City, Iowa, "Health Examination of Food Handlers by University and College Health Services." Dr. Warren E. Forsythe, University of Michigan, Ann Arbor, is president of the association.——At the recent annual meeting of the Central Neuropsychiatric Association, Dr. Karl A. Menninger, Topeka, Kan., was elected president; Dr. Hans H. F. Reese, Madison, Wis., vice president, and Dr. Henry W. F. Woltman, Rochester, Minn., secretary. The next meeting will be held in September, the location to be decided later.

Follow-Up Committee of White House Conference.—Two conferences of the Follow-Up Committee of Section I of the White House Conference on Child Health have already been held to consider the scope of its work and methods of carrying it out. The objects of the White House Conference were (1) to study the present status of the health and well being of the children of the United States; (2) to report what is being done for child health and protection, and (3) to recommend what ought to be done and how to do it. It was to carry out this third objective that the organization of the Follow-Up Committee was authorized at the last session of the White House Conference (The Journal, June 6, p. 1962). The survey made by Section I revealed that the gaps in child health service were of two kinds: failure to apply much that is known, and the necessity for further investigation in the clinic and laboratory that the needs in the promotion of child health may be more adequately met. The committee's first function is to try to stimulate a more adequate application of the known by advising constructively on and initiating principles of health betterment in the working programs of existing organizations active in the promotion of child health. The committee's purpose will be to invite the formulation and acceptance by all the agencies involved in promotion and protection of the health of the child of a central program embodying the basic principles on which are founded the physical and mental stamina of the people. It is hoped to continue this committee for ten years, which would bring it up to the probable next national child health conference. Members of the committee include Dr. Ray Lyman Wilbur, Washington, D. C., honorary chairman; Dr. Samuel McC. Hamill, Philadelphia, chairman; Dr. Fred L. Adair, Chicago; Dr. Kenneth D. Blackfan, Boston; Ida M. Cannon, R.N., Boston; Dr. Anton J. Carlson, Chicago; Dr. Samuel J. Crumbine, New York; Dr. Clifford G. Grulee, Chicago; Dr. Henry F. Helmholz, Rochester, Minn.; F. J. Kelly, Ph.D., Chicago; Guy S. Millberry, D.D.S., San Francisco; Dr. Fred Moore, Des Moines, Iowa; Sophie C. Nelson, R.N., Boston; Dr. Everett D. Plass, Iowa City; Richard E. Scammon, Ph.D., Rochester, Minn.; Dr. Wingate Todd, Cleveland; Dr. Philip Van Ingen, New York; Henry F. Vaughan, Dr.P.H., Detroit, and Dr. Borden S. Veeder, St. Louis.

LATIN AMERICA

Research on Leprosy.—An international center for research on leprosy is to be established in Rio de Janeiro by the Brazilian government in cooperation with the Council of the League of Nations, according to plans made at the session of the council in Geneva, September 1. The object is to undertake work that may contribute, by means of epidemiologic, clinical and biologic research, toward prevention and treatment. A specialized course of instruction open to scientists, members of the medical profession and hygienists of all countries is planned. The cost of the installation and upkeep of the institution is to be met by the Brazilian government, but gifts, legacies and grants will be welcomed. The plans are for five years, at the end of which time an extension may be proposed. The governing body for the center as contemplated will consist of the members of the health committee of the League of Nations with one representative of the donating government.

FOREIGN

New Journal of Diseases of Digestive System.—A bimonthly journal, *Archivio Italiano delle Malattie dell'Apparato Digerente*, appeared for the first time in October, in Bologna, Italy. The first issue contains ninety-six pages of original articles on topics related to conditions or diseases of the digestive system. Dr. C. Frugoni, Padua, is the editor and Drs. G. M. Fasiani, Padua, and A. Busi, Rome, associate editors.

Hughlings Jackson Fund.—In answer to an appeal from admirers of the late Hughlings Jackson, a fund of £1,110 has been subscribed to endow the triennial lecture of the neurological section of the Royal Society of Medicine. A die is now being executed by James Metcalfe for the medal, which will bear on the obverse side a portrait of Jackson. The first medal will be presented to this year's lecturer, Sir Charles Sherrington.

Bubonic Plague in China.—An unusually extensive spread of bubonic and pneumonic plague is being reported in the north China provinces of Shansi and Shensi. The first report of Dr. Percy T. Watson, director of the hospital at Fenchow, Shansi, showed that 100 villages were infected. Late in October Dr. Watson with fifteen members of his staff left for the plague-infected area, the nearest point of which is four days' journey west of Fenchow. It was stated that every year at this time bubonic plague breaks out in this region. The plague recedes in December, as cold weather diminishes rat-flea population. The mortality from bubonic plague in northern China is about 95 per cent. The Chinese government gives attention to plague prevention throughout the entire year. The Fenchow staff takes on the work at the request not only of the Shansi provincial legislature and governor but also of the Chinese national health administration; both these organizations provide funds for expenses. The Chinese national quarantine service sent three physicians in addition to the head of the department, Dr. Wu Lien Teh.

Government Services

Dr. Stiles Retires from Public Health Service

Dr. Charles Wardell Stiles, zoologist of the U. S. Public Health Service since 1902, retired from active duty, October 1. Dr. Stiles, a native of New York, received his early education at Connecticut Wesleyan University and studied later at various foreign universities, taking the degree of doctor of philosophy at Leipzig in 1890, and doctor of medicine from the University of Paris Faculty of Medicine in 1896. Many honorary degrees have since been conferred on him. Dr. Stiles began his service with the government in 1902 as consulting zoologist to the bureau of animal industry of the department of agriculture, and professor of zoology in the public health service. He has held teaching positions in medical zoology at Georgetown University, the Army Medical School, the Naval Medical School and Johns Hopkins University. From 1909 to 1914, he was scientific secretary of the Rockefeller commission for the eradication of hookworm. He is the author of many books relating to his specialty and recently finished a key catalogue of the parasites of men and animals, indexed in all the most important languages (The Journal, September 19, p. 860). Representatives of the public health service, the bureau of animal industry, the bureau of plant industry, the bureau of biological survey, U. S. National Museum, medical departments of the army and navy, Johns Hopkins University and other groups gave a dinner in honor of Dr. Stiles, October 7, at the Cosmos Club, Washington. Among the speakers were Drs. William H. Welch, Baltimore; William Sydney Thayer, Baltimore, and Arthur M. Stimson.

Appointments in Drug Control Unit

Drs. Northen O. Tribble, Atlanta, Ga., and Virgil S. McDaniel were recently appointed to fill vacancies in the drug control unit of the food and drug administration, U. S. Department of Agriculture. These vacancies were caused by the resignation of Dr. James J. Durrett, chief of drug control, and Dr. George E. Clarke, medical officer in drug control unit. Dr. Frederick J. Cullen was advanced to succeed Dr. Durrett. Dr. McDaniel was transferred from the U. S. Public Health Service.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Nov. 21, 1931.

Research on the Cause of Cancer

It may be remembered that in 1925 Dr. W. E. Gye, with the help of the microscopist Mr. J. E. Barnard, F.R.S., brought forward the theory that cancer is due to the cooperation of a virus (consisting of minute spheroids rendered visible by dark-ground illumination and photographed by ultraviolet rays) and a "specific factor." His researches attracted world-wide attention, but his theory was not considered established. Dr. Gye, however, was so convinced of its truth that he retired to the laboratories of the National Institute for Medical Research and now, after six years' patient work, has produced, in conjunction with Dr. W. S. Purdy, a book on the cause of cancer which embodies his later researches. The authors are satisfied, contrary to the prevalent view, that cancer is a parasitic disease. They attribute the difficulty of accepting their view to the complexity of the mechanism involved: two components of a widely different nature, neither of which can act alone. Dr. Gye has shown that malignant tumors can be produced in chickens by injecting extracts of tumors rendered free from cancer cells. He did this with the Rous sarcoma, verifying the results obtained by Rous. It has been argued, however, that Rous sarcoma is not a true cancer and that therefore the results are not applicable to the latter disease. Dr. Gye is now able to report that he has been able to extract from cancer a "something" which, when added to an extract of the Rous sarcoma treated in such a way as to destroy all virus or living organism, caused a growth when injected into a chicken. The deduction seems to be that the cancer also contains the living organism. This is the crucial experiment of the series, but it cannot yet be repeated with reasonable regularity. Hence it is concluded that "the question of the direct demonstration of viruses in new growths of mammals remains in a disappointingly inconclusive state. The subject has more than theoretical importance. There is an immediate practical aspect. If methods of handling mammalian viruses and of classifying them by immunity experiments could be discovered, then, since we have shown that large animals produce antiviral antibodies readily, the way to prophylactic immunization of man against cancer would be available." This is the immediate and urgent problem of cancer research. So far, the opinions of experts is guarded. Dr. J. A. Murray, director of the Imperial Cancer Research Fund Laboratory, says that Dr. Gye evidently recognizes the difficulties of the investigation and the extent to which the demonstration is not conclusive. Without a more careful consideration of Dr. Gye's new presentation of his views, Dr. Murray would not commit himself to any fuller statement. Professor McIntosh, director of the Cancer Research Laboratories, Middlesex Hospital, says: "The book is an important contribution to our knowledge of cancer."

Fewer Fatal Accidents

The continued attempts to reduce the fatal accidents from automobile traffic are at last bearing fruit. In the first nine months of this year there was a reduction of 10 per cent in accidents resulting in death, but a small increase was shown in other accidents. Last year an average of twenty persons a day were killed in the streets. In each of the last ten years the number has exceeded that of the previous year, but this year there were 293 fewer deaths than in the corresponding period of 1930. There was a slight increase in the total number of accidents, from 95,995 to 102,187, but this rise is held probably to be due to the fact that under the new road traffic act accidents must now be reported to the police, who thereby get to hear of more nonfatal accidents than in the past. Lieut. Col. J. A. A. Pickard, general secretary of the National Safety First Association, commenting on these facts, said that they were a source of great satisfaction to the association. They proved that the pessimists were wrong who prophesied that the passing of the road traffic act and the abolition of the speed limit would result in twice as many people being killed on the roads. The figures confirmed the association's observations that not only were automobile drivers generally showing more consideration to other road users but pedestrians were doing their share by being more alert and careful. Much of the credit was due to the local safety first councils, of which there were now nearly fifty.

Another Gigantic Nursing Home

Arrangements are made for the erection of a nursing home in the Marylebone Road, the consulting quarter of London, with 600 beds for patients, and hotel accommodations for relatives and friends, at a cost of $5,000,000. It is proposed to erect a building of nine stories, containing full facilities for all varieties of spa, electrical and other medical treatments, which will be available both for residents and for outpatients. It is anticipated that it will be possible to limit the charges of the nursing home to $5 a night and to reduce considerably the charges for many varieties of medical treatment. At present it is only in the hospitals that such facilities exist for medical treatment, and as a rule these are not used by the well-to-do. The latter are nursed in their own homes or in the small nursing homes, of which the facilities are very limited. The plan includes lounges of the hotel type, a roof garden laid out to give the greatest possible amount of sun and shelter, a pump room where every variety of medicinal water will be available, and a gymnasium for therapeutic purposes. It is intended to extend the scheme to Liverpool, Manchester and other large cities.

Award to Dr. W. B. Cannon

The Baly medal of the Royal College of Physicians is awarded every alternate year to the person who is deemed to have most distinguished himself in the science of physiology, especially during the two years immediately preceding. It has been awarded to Dr. W. B. Cannon, professor of physiology at Harvard. In presenting it, the president, Lord Dawson, described Dr. Cannon's contributions to knowledge as a monument of industry and achievement. Since Dr. Cannon took his M.A. degree in 1897, scarcely a year has passed that has not shown a harvest from his labors. Lord Dawson therefore could refer only to such pieces of his work as appeared to be landmarks. His first period, 1898-1910, was concerned with the experimental study of the movements and digestive activities of the alimentary tract, by means of the roentgen rays after opaque substances had been swallowed or injected. This work had recast our knowledge of digestion. In his second period, Cannon passed to the study of the effect of emotional states on gastro-intestinal function and thence to the physiology of the suprarenals—the association between epinephrine and fear, anger and hunger. Then came the war, and he worked in a casualty clearing station on the British front and later with General Finney of the U. S. Army at Dijon. Since the war he had been engaged in research into the function of the sympathetic, including the part played by it in the internal secretions.

In reply Dr. Cannon said that, over and over again, researches carried out in one direction proved by accident to be fruitful in another, and this had happened to him. The director of a scientific institution should always remember that the stimulus to work and the active cooperation received from students and collaborators must be taken into account when an individual is selected for personal award.

ITALY

Sept. 30, 1931.

The National Congress of Pediatrics

The Società italiana di pediatria held recently its fourteenth national congress at Florence, under the chairmanship of Prof. G. B. Allaria, director of the Clinica pediatrica of the University of Turin, aided by numerous foreign pediatricians. The session was opened in the Great Hall of the University with an address by Professor Allaria, who described the work of the Società di pediatria, which was founded in Turin in 1898 and which recently established also regional chapters. The speaker emphasized that the activity of the pediatric clinics is always directed toward ends that make for an improved national life. He explained also the proposal that the training of practicing physicians in pediatrics be made more comprehensive; furthermore, that health officers be required to take suitable courses in pediatrics, with the financial aid of the communes. The courses should be given at regular intervals and should take into account the fact that the professional activity of the health officer is devoted in large part to the prevention and treatment of diseases of children. Professor Allaria recalled the wonderful service rendered, in the field of pediatrics, by such great national organizations as the Opera nazionale per la protezione della maternità e dell'infanzia, the Red Cross, the Consiglio delle ricerche, and the Società di ortopedia, radiologia, eugenica e talassoterapia.

Addresses were delivered also by Professor Lereboullet, of the Academy of Paris, and Professor Mouriquand, of the Academy of Lyons.

Prof. Francesco Valagussa, subcommissioner of the Opera pro maternità e infanzia, reported that the society during the past three years expended 106,000,000 lire, or more than $5,000,000, in aid of mothers; 178,000,000 lire, or more than $9,000,000, in aid of children, and 24,000,000 lire, or $1,200,000, for the education in hygiene of the people of the rural districts. The results secured were as follows: In the ambulatoriums of the society, 88,442 mothers and prospective mothers, and 304,448 infants and children, were treated; fifty-nine ambulant chairs were created for maternal aid and puericulture, with 2,138 consultants, in which 88,095 mothers and gravidas and 1,800,000 children received aid. Aid was given during the nursing period to 77,000 legitimate mothers and to 27,000 unmarried mothers who recognized their obligations to their child. Prophylactic treatment in threatened tuberculosis was given to 23,000 children, and 6,000 were admitted to institutions as curable patients and as educable though abnormal. The hygienic conditions of 2,800 institutes were improved as a result of 3,141 sanitary inspections. By means of special legislative provisions, the society has brought it about that nearly all illegitimate children are at present recognized and fed at the breast. The number of such children recognized increased from 4,800 in 1927 to 27,580 in 1930. The society appointed a commission, with Prof. Filippo Bottazzi of Naples as chairman, for the study of alimentation in the institutes that receive children. The commission, to which works on pediatric subjects were contributed by physiologists, pediatricians and obstetricians, compiled dietetic tables that will be used in all the institutes. Just recently, the society established in Rome an aid center for mothers and children, which comprises ambulatoriums for nurslings, quarters for the admission and treatment of infants, quarters for the temporary admission of weakly children of an abnormal constitutional type, laboratories, rooms for roentgenologic and light treatment, and an experimental kitchen. The department for children is now complete, and the department for mothers is nearing completion and will begin to function in a few days. The work of the ambulant chairs for maternal aid and for puericulture is in full swing. They assist the mothers by training them in their duties, and apply to the nurslings the acquirements of puericulture and pediatrics. As a result, the morbidity and mortality in the rural districts have been greatly reduced. After Professor Valagussa's speech, the official topics on the program were taken up.

PURULENT PLEURITIS IN CHILDREN

The first topic, "Purulent Pleuritis in Children," was entrusted to four essayists. Professor Nasso, of the University of Messina, mentioned the various diseases, and most important of all, bronchopulmonitis, that give rise to purulent pleuritis. He considered the general and the local symptoms, which vary with the age and the condition of the patients, and explained the various clinical forms that pleuritis may assume in children. He discussed the various methods of clinical and etiologic classification, and described the course, the outcome and the possible complications of the disease. The speaker spoke finally of the differential diagnosis and of the prognosis, emphasizing that it is necessary to bear in mind, among various other data, the age of the patient and the primary disease.

Professor Castronuovo of Messina discussed methods of radiologic research applicable for the diagnosis of empyema and showed their value in determining the various clinical forms of purulent pleuritis.

Professor Laurisch, of the University of Naples, discussed the pathogenesis and the pathologic anatomy of purulent pleuritis. On the basis of 840 personal cases observed in the Clinica pediatrica of Naples, he connected purulent pleuritis with inflammatory conditions of the lung. He referred to certain bacteriologic data pertaining to pus in the pleura, and to the physicochemical conceptions that, according to most recent theories, regulate the formation of pus.

Professor Cocchi of Florence discussed the various methods of treatment for empyema. He demonstrated that better results are secured with medical treatment. He explained the method he used in about fifty cases, by means of which he succeeded in lowering the mortality to about 6 per cent.

In the discussion, Professor Lereboullet of Paris pointed out that in nurslings pleuritis is often associated with bronchopulmonary lesions, and that it is not exceptional to find it accompanied by pulmonary abscess. Professor Mouriquand of Lyons called attention to the importance of the symptom of dulness in the axillary region for the diagnosis of purulent pleuritis.

Professor Comba, director of the Clinica pediatrica in Florence, closed the discussion. Of the various methods discussed during the congress, the medical method appeared plainly the most advantageous, and only in a few special cases is surgical intervention justified. The physician should keep in mind all the methods proposed and apply in an individual case whichever promises to further the best interests of the patient.

ENCEPHALITIS IN CHILDREN

The second topic on the program, "The Syndromes of Encephalitis in Children," was introduced by Professor De Toni of Bologna, who explained the types of lesions encountered in various forms of encephalitis. The anatomic lesions are rarely characteristic, and hence an exact classification of the types of encephalitis, taking account of etiologic, anatomic and clinical criteria, has been impossible. With respect to the origin of the disease, a virus has been invoked concerning the existence and nature of which opinions are widely divergent.

Professor Taccone discussed the acute forms of encephalitis, observing that the diversity of the symptoms and the diverse mode of their development constitute clinical pictures so varied and inconstant that it is difficult to group them and describe them under separate and distinct headings. Nevertheless, Taccone sought to give a clear picture of the acute forms of encephalitis, not only of the primary disease but also of the types occurring secondary to infectious diseases and of the epidemic forms. The prognosis depends on various factors, such as the age of the patient and the time of the development of complications involving the nervous system. The author spoke also of the treatment of encephalitis by means of injections of serum of convalescents.

Professor Bergamini of Parma considered the chronic forms of encephalitis and the sequels that occur in children. Also in these cases the subject is complicated by the difficulty of classifying forms of diverse symptomatology. The speaker explained both the psychic and the neurologic forms and emphasized that the prognosis of the chronic types of encephalitis must be very reserved, owing to the possible appearance of late and new symptoms.

Professor Midulla, delegate of the Opera Nazionale Balilla, explained the activities of the society that he represented, in addition to its educational work. He spoke of the service organized in the ambulatoriums and in the consultation centers, and of the adoption of the biotypologic record card, with which two million youths are now provided. He took up then the prophylactic work against social diseases and insurance against accidents, which have decreased in number in spite of the increase in the number of persons insured. The congress passed a resolution commending the activities of the Opera Balilla in the promotion of health and robustness of children and the human race.

Professor Galeazzi emphasized the need of collaboration on the part of pediatricians to organize a system of aid for lame, paralytic and mutilated children.

After the general discussion on encephalitis, the congress passed a resolution, presented by Professor Frontali of Padova, pertaining to the possible relations between vaccination against smallpox and the appearance of encephalitis. Since in recent years there has been developing, in medical circles and among the public, an exaggerated fear of smallpox vaccination, owing to the observation of cases of encephalitis following vaccination, the congress thought it advisable to announce that the vaccinal etiology is far from being demonstrated, and to urge that no changes be made in the laws and the practice of compulsory vaccination, which is the sole protection as yet known against epidemics of smallpox.

Professor Spolverini, director of the Clinica pediatrica in Rome, announced a new technic in artificial feeding. In spite of the fact that the best adapted food is used (cow's milk), and the most precise rules are followed, artificial feeding often gives results that are anything but satisfactory and commonly constitutes an ever present menace, especially in the institutes to which large numbers of nurslings are admitted. Studying the problem of cow's milk from the point of view of colloidal equilibrium, Spolverini and his co-workers succeeded, by means of the addition of a so-called colloid protector, in modifying the intimate structure of some constituents of cow's milk (particularly the casein), so as to bring about that certain phenomena of digestion (precipitation, coagulation and other processes) may be completed in almost the same manner as in the case of human milk. The colloid protector best adapted for the purpose has been found to be acacia. In applying this method for four years in his clinic, Spolverini has obtained very favorable results, aided by researches and laboratory examinations, and he expressed the hope that his colleagues might try the method and that they would confirm his observations.

DIETARY REGULATIONS FOR GROUPS OF CHILDREN

The last day of the congress was devoted to the elaboration of the topic "Dietary Regulations for Collective Groups of Children." The first speaker, Professor Macciotta of Cagliari, discussed the food requirements and the methods of determining them, emphasizing the importance of the surrounding conditions and of the constitutional status of the individual. He considered the alimentary value of the principal foods, pointing out that the most important source of vegetable proteins and carbohydrates lies in cereals. Professor Brusa of Milan spoke on alimentation in the first year of life and took up the diet of wetnurses. Professor Lucca of Turin explained the criteria to be followed in choosing the diet of older children up to the time of adolescence—criteria which vary according as it is a question of complete alimentation (continued stay in an institution) or partial alimentation (admission for part of the day), and dependent also on the age and the constitution of the person. The discussion was taken up by Professor Mouriquand of Lyons, Professor Bergamini of Parma, Dr. Capecchi, and others.

After a general discussion, the conventionists took a trip to Siena and then proceeded to Perugia, where the congress closed. Professor Allaria was chosen president of the society and Professor Valagussa was elected vice president. Rome was selected as the meeting place for the next congress.

International Congress of Surgery

At the ninth International Congress of Surgery, to be held at Madrid in 1932, the delegates from Italy will be Prof. Leonardo Dominici of Perugia, who will discuss "Diagnosis and Treatment of Intraspinal Tumors;" Professor Lusena of Genoa, who will consider "Surgery of the Esophagus," and Professor Uffreduzzi of Turin and Dr. Lorenzetti of Milan, who will describe "The Recent Advances in Surgical Anesthesia."

BERLIN

(From Our Regular Correspondent)

Nov. 2, 1931.

Modifications in Hospital Construction

The economic crisis has brought about marked retrenchments wherever it has been possible. In Berlin three hospitals have been closed entirely; in others, certain departments have been abolished. Nevertheless, in the opinion of many persons, there is need of a private hospital for the middle class, with moderate prices. Hence, in spite of the stress of the times, born of a certain courageous, optimistic spirit, a 100-bed hospital (landhausklinik) has been erected in Wilmersdorf (near Berlin) by the Vaterländischer Frauenverein, affiliated with the Red Cross Society. The new institution combines in a practical arrangement and with pleasing architectural features three functions in three partially separated buildings: the clinic, the aerztehaus and the nurses' pavilion. The aerztehaus, for the accommodation of the fifteen physicians on the staff, forms a right angle with the clinic building. At the apex of the angle are the entrances, the staircases, the elevators and the administration offices, so that, aside from the soundproofing, which was carried out with great care, all the essential noise-makers of the whole building are concentrated in one corner. The clinic comprises sixty rooms of uniform character, all provided with balconies toward the south and roll-back windows, in three parts, extending to the floor (for fresh-air treatment and the like). Perfect technic in the service of health is combined with comfort, which is accomplished through the shape of the rooms, the color scheme and the furnishings. The culinary department is managed by a well known restaurant chain, under medical supervision (an excellent innovation). For all the prescribed diets special menus are presented for the patient's choice, without the normal charges fixed by contract being exceeded. The clinic is managed from a caritative point of view on a nonprofit-sharing basis and is thus not a private sanatorium in the ordinary sense; nor is it a hospital but is in a class by itself. In a period of social readjustment, which in its destructive phase is not yet completed, this institution is a good idea brought promptly to realization, which will bring aid and hence encouragement to the middle class, which is at present most endangered. At the same time the cost per bed, including the building costs for the clinic, nurses' pavilion and the aerztehaus with all its furnishings, was under $2,000.

Giessen, together with its university, has likewise accomplished wonders. In spite of the enormous difficulty in procuring funds, an orthopedic university clinic, which was urgently needed, has been supplied and has been recently opened. The clinic, which is under the directorship of Professor Pitzen, was built by the Hessischer Fürsorgeverein für Krüppel, which collected the money for the institution, one may say, a penny at a time, and placed it at the disposal of the university to be used for purposes of instruction and research. It has a sickroom section and a therapeutic section. The sickroom section is one-storied and is designed for seventy sickbeds, although there is enough space for a hundred beds, in case of need. The southern front of the sickrooms consists almost entirely of windows, all of which can be opened wide. The sickrooms are connected with the therapeutic section by a structure 21 meters long (likewise enclosed) which houses the medical baths and the gymnasium and serves at the same time as an auditorium. The gymnasium is connected by wide glass doors with a large campus, which is used for various athletic purposes. On the same plane as the sickrooms and the gymnasium is the first story of the therapeutic section, in which are the rooms of the administration, the policlinic, the x-ray room, the operating rooms, the workshops and the laboratory. The location of a portion of the workshops between the consultation room and the operating rooms is based on the desire to assure the absolutely necessary close connection between the physician and the orthopedic mechanics. All the rooms designed for patients lie on the same plane. The patients are not harassed by staircases, inclined planes or elevators. On the second floor of the therapeutic section are the rooms for the personnel, and in the basement are the culinary department, the heating equipment and further workshops. The total cost of the building was 350,000 marks ($83,300), or nearly $1,200 per sickroom.

Otto Warburg, Nobel Laureate

For his discoveries in regard to the nature and the mode of action of the respiration ferment, the Nobel prize in physiology and medicine, for this year, has been awarded to Otto Warburg, who is director of the Kaiser-Wilhelm-Institut for cell research in Dahlem (near Berlin), which was recently established for him by the Rockefeller Foundation. He is one of the most original investigators in the field of the chemical processes in the living cell. He was the first to demonstrate the decisive influence of the great surface development on the cell processes and studied out the biologic aspects of the notion of surface catalysis. He invented an exact precision method for the determination of the metabolism of the cells under various conditions—more particularly, of the oxygen intake of the cells, cell respiration and sugar decomposition in the cell without oxygen. Warburg opened up thereby a new outlook for the theory of cell metabolism and particularly of cell respiration.

Warburg's most important researches are in the field of the physiology of tumors and the mechanism of biologic oxidations. As for tumors, and especially the so-called cancer cells, he has demonstrated that these, in contradistinction to the normal body cells, are relatively independent of the available supply of oxygen; that is to say, that they have a metabolism without oxygen. Whereas normal animal cells die quickly in the absence of oxygen, the cancer cell can without oxygen continue to exist, to grow and to proliferate. Even when oxygen is available, it continues its oxygenless metabolism, the sugar decomposition, the same as yeast. Warburg developed from these observations a theory of the origin of tumors, in which there is certainly an element of truth. His contributions on the mechanism of cellular respiration are exceedingly important. He demonstrated that in every breathing cell there is a special oxidizing system—a respiration ferment, which activates the available oxygen material; that is to say, converts it into active oxygen. This respiration ferment he defined more precisely as an iron-containing organic dye, which closely resembles the hemin of the hemoglobin but is not identical with it. He was therefore the first to recognize with certainty the long suspected connection between iron in the cell and oxidative metabolism. The action of the respiration ferment is checked by hydrocyanic acid, so that the cell dies, which explains the exceedingly high toxicity of cyanogen compounds. He showed furthermore that iron also plays a part in the fermentation. More recently, he has announced the results of experiments that prepare the way for the harmonization of his respiration theory with the apparently entirely opposed theory of Heinrich Wieland of Munich, who was awarded, a few years ago, the Nobel prize in chemistry. Warburg is a theoretician and is a master of the chemical and the physicochemical method of research. He is an experimenter of the first rank and makes use of his mastery of method for his researches on the most difficult life processes.

VIENNA

(From Our Regular Correspondent)

Oct. 31, 1931.

Sudden Deaths of Eminent Physicians

During the past week, several eminent members of the medical profession in Vienna have died suddenly. First, Dr. Foramitti succumbed to a cerebral hemorrhage in a taxicab. He was the director of the Austrian ministry of health, also the Austrian delegate to the international health commission of the League of Nations, and the head of the hospital administration of our republic. His death, at the age of 58, is a great loss for the public health administration in our country.

The second death was that of Prof. Dr. Constantin Economo, the widely known investigator in neurology and brain research. This versatile scientist died in the midst of active service. He was the founder of the recently established laboratory for brain research in Vienna. In 1917 he became known throughout the world through his first published comprehensive description of epidemic encephalitis, which he observed in soldiers in the Vienna hospitals. His second important publication was an atlas of the cellular structure of the brain, in the form of 112 magnificent plates—a monumental work that required thirteen years (1912-1925) to complete. A second part, an atlas of the fibrous structure of the brain, had not been completed at the time of Economo's death. The deceased, an assistant of the Nobel laureate Professor v. Wagner-Jauregg, was asked to assume the directorship of the Klinik für Psychiatrie und Nervenkrankheiten, as the successor of his teacher; but he preferred to complete his researches on the brain, without being hampered by the duties of a clinical teacher. In connection with the organization of the first International Neurologic Congress of the postwar period, which was held in September of this year, Professor Economo, although in poor health, overexerted himself, which was possibly one reason for his unexpected death.

The third death was that of Dr. Arthur Schnitzler, the poet-physician. By his dramas and psychologic novelettes, significant through the intuitive feelings of the characters, and in which he anticipated the psychoanalytic researches of Freud, he was at an early age diverted from his medical practice; but in all his literary productions he gave abundant evidence of his medical training, especially as a psychoanalyst.

While this letter was being written, news came that the eminent roentgenologist Prof. Guido Holzknecht had died as a martyr and victim of his profession. He had suffered for years from carcinoma, which, some time ago, necessitated the amputation of several fingers of each hand. Six months ago, his right arm had to be amputated. There developed, however, soon afterward a carcinosis of the skin of the thorax, with metastases in the abdomen, which hastened the end. Holzknecht was one of the first to recognize the significance of Roentgen's discovery for the progress of medicine. With his keen insight, he was able to separate the essential from the insignificant and to utilize it for research and diagnosis. Roentgen's discovery dates back to 1895. Six years later, Holzknecht published his "Atlas der Erkrankungen des Thorax," which gives evidence of his genius and his almost prophetic insight. Soon afterward he published his articles on "The Roentgenologic Diagnosis of Disorders of the Digestive Apparatus." Of great importance was his construction of the dosimeter for the measurement of the dosage of roentgen rays, which made possible the general use of the rays for therapeutic purposes and is known everywhere as the H instrument. This great medical achievement goes back to 1902. The Holzknecht unit is still employed. Holzknecht's importance as a creative guide was soon recognized, and, in spite of bureaucratic obstructionists, he succeeded in organizing the Central-Röntgen-Institut in the Vienna General Hospital and to make it one of the greatest institutes of the kind. Here a Holzknecht "school" developed, from which countless promising pupils have gone forth to occupy prominent positions in all parts of the world. From here have gone out the methods for the location of foreign bodies (projectiles), and the diagnosis of gastric cancer, kidney stones and cranial disorders. Holzknecht's fame was greater abroad than at home. He was generally regarded as the leading figure in roentgenology, and his work on roentgen injuries is a classic. The tragedy of his life was that he was doomed to die from such injuries. Thirty years ago, before he had invented his dosimeter, he observed in himself the first signs of roentgen "burns." His long-drawn-out illness did not, however, prevent him from continuing his research.

Inaugural Lecture of Prof. Dr. Denk on Cancer

Dr. Denk, the newly appointed professor for the first chair of surgery at the University of Vienna and the successor of Professor Hochenegg, began his lectures with a comprehensive inaugural address, delivered before a large audience composed of professors and students, on "The Modern Methods of Combating Cancer." After paying respect to his predecessor, he emphasized that his predecessor's chief care was the study of neoplasms. Continuing this tradition of the Vienna "school," he stated that he would likewise regard the combating of cancer as a most important need, in order that the continuity of the work of Professor Hochenegg might not be interrupted. The chief needs looking toward the cure of cancer are early diagnosis and early operation, the combating of recurrences, and the detection of persons who are threatened with cancer. To this category belong patients with precancerous disorders, subjects with hereditary tendencies to cancer, twins one of whom has already developed cancer, and the like. Periodic examinations with a view to prophylaxis are quite in order, which imposes an important rôle on the family physician, especially if it should prove possible to perfect the tests for cancer that are now available. In Graz (Styria), where Professor Denk has served as director of the clinic, he made use of the existing welfare services and applied control tests to persons operated on, thereby building up an organization that achieved favorable results. Periodic health examinations may become valuable as a means of promoting early diagnosis and treatment. On the other hand, postoperative supervision by welfare workers is an important measure to combat recurrences in season. Dr. Denk elaborated in Graz many new operative methods, which have made the operation on cancer much easier and more effective. Likewise radium treatment will contribute in great measure to an improvement in the operative results. With reference to the bloodless methods, the clinic must carry out just as careful researches, which (for the time being, at least) should be based chiefly on animal experimentation and on observations and use as postoperative treatment. In any event, Professor Denk expects from these researches, especially from the prophylactic side, great progress. A center for the detection of all cancer patients in Vienna is, in his opinion, an absolute necessity, in order to detect early recurrences, which should be treated, for the most part, by bloodless methods; but without the cooperation of the general practitioners such supervision would be impossible.

TURKEY

(From Our Regular Correspondent)

Ankara, Oct. 21, 1931.

Fourth National Medical Congress

The fourth biennial national medical congress recently convened in Ankara and was attended by more than 400 physicians from all over the country. Following the opening address, in which Ismet Pasha, prime minister, referred to the reports on nutrition as important subjects for discussion, Prof. Dr. Refik, minister of health and social assistance, who presided, addressed the congress. Prof. Dr. Server Kamil of the medical faculty of the department of hygiene reported on nutrition in cities, and Dr. Zeki Nassir on investigations into the question of nutrition in urban and rural communities. Prof. Dr. Kadri Rashit Pasha of the department of pediatrics discussed infant feeding, and Dr. Hamit Osman spoke on nutrition of the preschool child and of children of school age. Dr. Ali Shukri read a paper on the pathogeny, prevention, treatment and incidence of rickets in Turkey and Dr. Murat Ibrahim on the orthopedic and surgical treatment of rickets.

NUTRITION AND DIET IN TURKEY

In the report on nutrition and diet in cities in Turkey, Dr. Server Kamil suggests the establishment of cooperative agencies by means of which a good food supply may be insured at low cost. He recommends also that organizations concerned with the establishment of soup kitchens for the poor broaden their activities, that food inspection in cities be more severe, that food prices be standardized, and the public be educated in matters of food and nutrition and that, in particular, the bread, meat, milk and water supply of cities receive more attention. Owing to the scarcity of fresh milk, the import of all brands of evaporated, powdered and condensed milk is growing from year to year. He stated that pasteurized milk is not even in Istanbul available to the public and that the per capita consumption of milk in that city is 42 Gm. a day.

The report on the investigation into the question of nutrition in urban and rural communities revealed that from 70 to 90 per cent of the diet of the rural population in Turkey is of vegetable origin, and that the chief nourishment of the peasant is "bulgur," whole wheat which has been soaked previous to boiling and is then dried in the sun and coarsely pounded on a hollow stone. This serves for the preparation of soups and pilav. Country bread is made of wheat, rye, millet, barley and corn mixtures, from which, owing to the use of primitive implements, the bran has not been removed. An important fact is that the intake of animal protein of the rural population is most inadequate and that only mutton is used and no pork whatever; the latter is on sale only in large cities, such as Istanbul and Izmir. The peasant as a rule partakes of meat on rare occasions, only such as the Bairam days, the sacrifice offered being a lamb; or on the occasion of the celebration of a wedding party, or in case of an accident that makes it necessary to kill an animal. The demand for eggs in cities causes eggs to be more and more a luxury among the rural population; eggs in villages are as a rule now served only to guests. Butter, so important an article of diet though solely a country product, is also, for economic reasons, rarely consumed by the producer. A considerable part of the rural population, especially in eastern and central Anatolia, does not know how to grow green leafy vegetables but includes in the diet raw onions, tomatoes, garlic, wild grasses and herbs, the knowledge of which has been handed down to them by their forefathers. Of fruits the peasant eats only those which grow in his particular village: the largest proportion is sold raw or dried. The antiscorbutic lemon is something never used in the peasant household.

What the peasant brings home in his bag from the city is sugar, salt, tea and coffee, which he values highly. Almost every peasant family owns a cow, a goat or a sheep. The rural population, however, does not drink milk, as it is turned into butter for sale, but of sour milk, or yoghurt, ample use is made in the diet. Sugar, a precious article, is seldom used for sweetening foods; as an addition to bread, honey or "pekmez," a nonfermented preparation of grapes, is used. While rice occupies an important place in the preparation of the city diet, its use is rare in rural communities. The peasant engaged in farm work takes a heavy breakfast before sunrise, a light lunch in the field, and a heavy supper in his home after sunset. A great number of city people do not take any breakfast at all or only a light one, but they take a heavy lunch and supper.

According to the geographic and climatic conditions and those of transportation and prosperity, five distinct zones in relation to diet in rural communities become obvious: the Black Sea coast, western Anatolia, the Mediterranean and southern provinces, and those of eastern and of central Anatolia. As the geographic condition of the Black Sea coast does not permit of the growing of wheat, corn bread is used there almost exclusively, and the oil of hazelnuts is utilized for the preparation of foods. Olive oil is not used by the inhabitants of eastern, central and southern Anatolia, but in western Anatolia and especially in the Mediterranean provinces ample use is made of it as well as of cottonseed oil, and, in the region where opium is cultivated, poppy oil is given preference over any other fat. In central Anatolia, sesame oil is used. Arabian influence in dietary habits, such as the use of highly spiced food and of raw meat, is noticeable in the southern provinces, while in the eastern provinces Russian, Caucasian and Persian influence is noticeable.

Of the deficiency diseases, ophthalmia and beriberi seldom occur, though some cases of pellagra are known to have come under observation. Because of the absence of iodine in water and food, endemic goiter prevails in some regions; scurvy is rare, and, owing to plenty of sunshine almost the year round, the incidence of rickets in rural communities is small. In the light of the newer knowledge of nutrition, the dietary habits of the rural population, which constitutes three fourths of the whole population, are deplorable; the existing conditions are largely due to established habits, ignorance and poverty. Absence of cheap transportation plays a large factor in the great difference between the dietary habits of urban and of rural communities. The most important aspect in regard to the problem of nutrition in rural communities is that the state of affairs so affects the constitution of the rural population that each generation has a lowered resistance to disease and is particularly susceptible to tuberculosis.

Prof. Tevfik Salim Pasha suggested that, among growing children unable to get the required amount of food, the sport activities in schools should be restricted; that the institute of hygiene now nearing completion take a lead in the education of the public in matters of food and nutrition, and that diet kitchens in connection with hospitals be established. Dr. Fahreddin Kerim stated that, much to the detriment of the population, alcohol had lately found its way into rural communities. Dr. Abdulkadir Lutfi recalled the deficiency diseases in the army during the World War and stated that today the conditions in relation to proper food were satisfactory. Dr. Ali Shukri reports that the difference in the incidence of rickets in urban communities (from 20 to 30 per cent) and in rural communities (from 5 to 10 per cent) is probably due to the fact that, winter and summer, the country children are out in the open almost all day.

Communications were read on such subjects as calcium metabolism, rickets and roentgen treatment, foreign bodies in the stomach, treatment of tuberculosis by artificial pneumothorax, lymphogranuloma, kidney stones, surgical treatment of stomach ulcers, the malaria campaign in Turkey, encephalitis following vaccination for scarlet fever, combined scarlet fever and diphtheria vaccine, simultaneous bilateral artificial pneumothorax, blood groups, new surgical treatment for old dislocations of the hip joint, hookworm eradication, ringworm in Turkey, food poisoning through Gärtner's bacillus, thymus tumors, suicides in Turkey, treatment of tetanus by suboccipital injection, treatment of diphtheria, thoracic and abdominal measurements in relation to the general development of infants, hemorrhage of the brain due to blackwater fever and to malaria, the method of early diagnosis in tuberculosis of the lung, and the Friedman vaccine.

A tea given at the model farm of the Turkish president marked the close of the three days of the congress. Prof. Dr. Refik, minister of health, was again asked to preside over the congress, at which intestinal parasites, amebic dysentery and mineral waters in Turkey will be discussed.

A Sign of Supermaturity of the Fetus

At a recent meeting of Hungarian gynecologists, Dr. Francis Szello read a paper entitled "A Sign of Supermaturity of the Fetus." He said that in his investigations he started with the physiologic fact that of the carpal bones the first to appear are the capitate and hamate; this is proved by the lime nucleus which is found at necropsies and by roentgenograms. These nuclei are never found in so-called mature infants born at the end of a regularly carried out gestation. They appear at the earliest in the second half of the first month of extra-uterine life, and at the latest in the sixth month. From this, he concludes that if, at the time of birth, both or one of these nuclei is present, the fetus is supermature. This is at present, he says, the only sure sign of supermaturity that can be easily shown on roentgenograms. If present, it is absolute proof, while its lack is not contradictory to supermaturity.

Harmful Effects of Iodine Injections Given as Abortifacients

According to Prof. J. Frigyessi, the rapid increase in the number of criminal abortions and the inflammatory diseases which they cause plays an important part in the great number of cases of sterility and extra-uterine pregnancy observed in late years. In one group of cases he blamed the action of intra-uterine iodine injections, used for provoking abortion. At the meeting of the medical society he reported two cases, in both of which violent cramps followed iodine injections; subsequently sterility, lasting for years, and finally extra-uterine gravidity resulted. In both cases he found knots, the size of a bean, in the uterine end of the tubes; the histologic preparations which he demonstrated showed in both cases a circumscript adhesion of the mucous membrane folds of the tubes, caused by the caustic action of tincture of iodine. The treatment consists in the excision of the knots and the restitution of the continuity of the tube by its implanation. But more important is the prophylaxis by the avoidance of intra-uterine iodine injections.

Marriages

Robert Hardin Hackler, Jr., Asheville, N. C., to Miss Harriet Gresham Bates of Richmond, Va., November 20.

Mac M. Dickman, New York, to Miss Dorothy Kaufman of Westmount, Montreal, Que., Canada, October 11.

Albert Welker Collins, Anderson, Ind., to Mrs. Janet McKenzie Dovey of Ottawa, Ill., November 14.

Walter Orthner, Huntingdon, Pa., to Miss Lee Katherine Strohacker of Philadelphia, October 31.

Rufus Preston Sykes, Asheboro, N. C., to Miss Blanche Lentz of Winston-Salem, November 7.

Elam A. Drum to Miss Mattie Elizabeth Walker, both of Richmond, Va., October 24.

Herbert C. Schlosser to Miss Lucille Short, both of Elkhart, Ind., November 14.

Frank Victor Theis to Miss Hazel Ericsson, both of Chicago, December 9.

Joseph Coates, Galax, Va., to Miss Ada Lee Cannaday of Pulaski, October 30.

Deaths

Charles Edward Dowman ⊕ Atlanta, Ga.; Johns Hopkins University School of Medicine, Baltimore, 1905; member of the Southern Surgical Association, Associated Anesthetists of the United States and Canada, American College of Surgeons, Society of Neurological Surgeons, American Neurological Association and the Association for Research in Nervous and Mental Diseases; professor of pathology, Birmingham Medical College, 1911-1913; associate in surgery, University of Alabama, 1913-1915; instructor, associate and assistant professor of surgery, Emory University School of Medicine, Atlanta, 1915-1924; served during the World War; neurologic surgeon to the Scottish Rite Hospital for Crippled Children, Grad Memorial Hospital, Georgia Baptist Hospital, Piedmont Hospital and the Henrietta Egleston Hospital for Children; aged 49; died, November 14.

Walter Aikman Sherwood ⊕ Brooklyn; Columbia University College of Physicians and Surgeons, New York, 1896; member of the American Surgical Association and the American College of Surgeons; served during the World War; aged 55; consulting surgeon to the Methodist Episcopal Hospital, Brooklyn, and the Eastern Long Island Hospital, Greenport; director of the department of surgery, Brooklyn Hospital, where he died, November 21, following an operation for appendicitis.

William Columbus Cox, Everett, Wash.; Jefferson Medical College of Philadelphia, 1885; member and past president of the Washington State Medical Association; member of the American College of Surgeons; member of the state board of medical examiners, 1900-1903; formerly mayor of Everett; honorary president of the staff of the General Hospital of Everett; aged 73; died, September 25.

Albert Ellis Douglas ⊕ Nashville, Tenn.; University of Tennessee Medical Department, Nashville, 1892; member of the American Psychiatric Association; proprietor of a sanatorium bearing his name; formerly superintendent of the Central State Hospital; aged 65; died, November 15, in Oklahoma City, of pneumonia following an operation.

Ulysses Grant Souder ⊕ Auburn, Ind.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1902; aged 65; medical superintendent of the Dr. Bonnell M. Souder Hospital, where he died, November 24, of Vincent's angina, pneumonia and acute lymphatic leukemia.

Summerfield J. Miller ⊕ Madera, Pa.; Medical Department of the University of the City of New York, 1886; state senator, 1914-1922; formerly bank president; aged 72; died, November 10, in the Mercy Hospital, Altoona following an operation for hypertrophy of the prostate and myocarditis.

Herbert Thomas Penny, Cliftondale, Mass.; Central College of Physicians and Surgeons, Indianapolis, 1889; Columbian University Medical Department, Washington, D. C., 1896; member of the Massachusetts Medical Society; aged 68; died, November 19, of coronary occlusion and arteriosclerosis.

William Judson Lamson ⊕ Summit, N. J.; Columbia University College of Physicians and Surgeons, New York, 1896; medical superintendent of the schools in Summit; aged 60; on the staff of the Overlook Hospital, where he died, November 28, of perforated ulcer of the duodenum.

Max Beegel, New York; Columbia University College of Physicians and Surgeons, New York, 1908; member of the Medical Society of the State of New York; on the staffs of the Jewish Memorial Hospital and the Gouverneur Hospital; aged 45; died, November 24.

William Lee Samuels ⊕ Reno, Nev.; University of Louisville (Ky.) School of Medicine, 1897; past president and secretary of the Nevada State Medical Association; on the staff of St. Mary's Hospital; aged 57; died, November 1, of acute yellow atrophy of the liver.

Benjamin Richard White, Rochester, N. Y.; New York Homeopathic Medical College and Hospital, 1899; member of the Medical Society of the State of New York; on the staff of the Genesee Hospital; aged 55; died, November 13, of pneumonia.

Samuel P. Sesmer, Louisville, Ky.; Imperial Jurjev University, Russia, 1894; member of the Kentucky State Medical Association; aged 62; died, November 9, in the City Hospital, of chronic nephritis, uremia, bronchopneumonia and arteriosclerosis.

Ulysses Grant Poland ⊕ Muncie, Ind.; Medical College of Indiana, Indianapolis, 1895; formerly city health officer and county coroner; on the staff of the Ball Memorial Hospital; aged 66; was found dead in bed, November 11, of heart disease.

Claude Addison Tallman, Maumee, Ohio; Northwestern University Medical School, Chicago, 1900; served during the World War; aged 53; died, November 21, in the Flower Hospital, Toledo, of injuries received in an automobile accident.

Geoffrey Joseph Fleming ⊕ Ontario, Calif.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1898; member of the American College of Surgeons; aged 58; died, October 9, of pneumonia.

Eddie De Baun Thixtun, Gosport, Ind.; Central College of Physicians and Surgeons, Indianapolis, 1898; member of the Indiana State Medical Association; aged 63; died, November 21, in the Methodist Episcopal Hospital, Indianapolis.

John F. Shoemaker, St. Louis; Medico-Chirurgical College of Philadelphia, 1893; member of the Missouri State Medical Association, and the American Ophthalmological Society; aged 63; died, November 21, of cerebral hemorrhage.

Robert Woodworth Bell, Jr., Walla Walla, Wash.; Albany (N. Y.) Medical College, 1892; member of the Washington State Medical Association; connected with the U. S. Veterans' Bureau; aged 61; died, November 13.

James Ellis Brayshaw, Wilmington, Del.; Jefferson Medical College of Philadelphia, 1920; member and formerly secretary of the Medical Society of Delaware; aged 34; died, November 18, in the Homeopathic Hospital.

Claude Bertrand Cole ⊕ Toledo, Ohio; Long Island College Hospital, Brooklyn, 1889; University of Pennsylvania School of Medicine, Philadelphia, 1893; aged 65; was found dead, November 22, of cerebral hemorrhage.

Samuel W. Latham, Eldorado, Ill.; St. Louis College of Physicians and Surgeons, 1901; formerly mayor of Eldorado and state senator; aged 53; died, November 1, of pneumonia, as the result of an injury received in a fall.

Charles W. Felix, Martwick, Ky.; University of Louisville School of Medicine, 1890; member of the Kentucky State Medical Association; died, November 18, in the Methodist Episcopal Deaconess Hospital, Louisville.

George Blythe Morris ⊕ Goldsboro, N. C.; University of Maryland School of Medicine, Baltimore, 1910; aged 47; on the staff of the State Hospital at Goldsboro, where he died, November 15, of pulmonary tuberculosis.

Edwin Joseph Reeves, Princeton, N. J.; Tulane University of Louisiana Medical Department, New Orleans, 1893; member of the American College of Surgeons; aged 62; died, November 22, of endocarditis and arthritis.

Carlos M. White ⊕ Visalia, Calif.; Rush Medical College, Chicago, 1901; past president of the Tulare County Medical Society; on the staff of the Kaweah Hospital; aged 59; died, in November, of arteriosclerosis.

John Richard Williams, Carrollton, Ohio; Bellevue Hospital Medical College, New York, 1881; formerly county coroner and member of the board of education; aged 73; died, November 23, of heart disease.

Frederick Barrett, Gilbert, Minn.; Rush Medical College, Chicago, 1897; served during the World War; for seventeen years mayor of Gilbert; aged 56; was found dead in bed, November 4, of heart disease.

Atlee Mairs, Charleston, W. Va.; Jefferson Medical College of Philadelphia, 1910; member of the West Virginia State Medical Association; aged 48; died, November 14, of a self-inflicted gunshot wound.

John T. Harris ⊕ Tonawanda, N. Y.; University of Buffalo School of Medicine, 1883; for many years health officer and medical school inspector; aged 75; died, November 21, of coronary thrombosis.

Omar H. Tudor, Kenton, Ohio; Miami Medical College, Cincinnati, 1875; member of the Associated Anesthetists of the United States and Canada; aged 82; died, November 11, in the McKitrick Hospital.

Joseph Omer Guimond, Chicopee, Mass.; School of Medicine and Surgery of Montreal, Que., Canada, 1889; also a druggist; aged 71; died, November 8, in the New Haven (Conn.) Hospital.

Joseph B. Gallagher, Montreal, Que., Canada; McGill University Faculty of Medicine, Montreal, 1910; on the staff of the Montreal General Hospital; aged 47; died, November 25, of septicemia.

Wilbur Marchand Lilley ⊕ Brownsville, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1899; aged 56; was found dead in bed, November 10, in California, of heart disease.

Albert Edward Mucklow, Brooklyn; Bellevue Hospital Medical College, New York, 1897; member of the Medical Society of the State of New York; aged 56; was found dead in November.

William Andrew Wilson, New York; St. Louis University School of Medicine, 1904; member of the American Urological Association; aged 52; died suddenly, November 28, of heart disease.

Carl Hattermann, Chicago; Rush Medical College, Chicago, 1886; member of the Illinois State Medical Society; aged 73; died, November 28, of lymphatic leukemia and gastric hemorrhage.

William Mason Green, Hastings, Neb.; Creighton University School of Medicine, Omaha, 1901; aged 56; died, November 8, in the Masonic Sanitarium, Bettendorf, Iowa, of carcinoma.

Willis Perry Woodard, Oak Park, Ill.; College of Physicians and Surgeons, Chicago, 1894; aged 72; died, November 22, of bronchopneumonia, cerebral hemorrhage and arteriosclerosis.

Edward C. Barstow, Washington, D. C.; Howard University School of Medicine, Washington, 1895; Spanish-American War veteran; aged 62; died, November 10, of heart disease.

Frank Arthur Zeller, Union City, Ind.; Ohio Medical University, Columbus, 1898; member of the Indiana State Medical Association; aged 61; died, November 14, in Visalia, Calif.

Edward W. Hawthorne, Gypsum, Kan.; University Medical College of Kansas City, Mo., 1894; member of the Kansas Medical Society; aged 77; died, November 17, of myocarditis.

Eugene H. Mohr, Alburtis, Pa.; Jefferson Medical College of Philadelphia, 1881; member of the Medical Society of the State of Pennsylvania; aged 74; died, November 12, of uremia.

William Loranzo Nuckolls, San Francisco; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1904; aged 65; died, September 25.

Charles Warren Weaver, Healdsburg, Calif.; Medical College of Ohio, Cincinnati, 1879; aged 77; died, September 10, in the Dante Sanatorium, San Francisco, of coronary thrombosis.

John C. McCandless, Chicago; Chicago Physio-Medical College, 1893; member of the Illinois State Medical Society; aged 66; died, November 30, of carcinoma of the bladder.

Daniel Brooks Stidworthy, Homer, Neb.; Sioux City (Iowa) College of Medicine, 1894; served during the World War; aged 65; died, November 14, of pernicious anemia.

John Thomas Wilson, Chicago; Meharry Medical College, Nashville, Tenn., 1895; aged 67; died, November 19, in the Dailey Hospital, of myocarditis and coronary sclerosis.

Edward Christian Rohrbach, Flat River, Mo.; American Medical College, St. Louis, 1908; aged 56; died, November 3, in St. Mary's Hospital, St. Louis, of sarcoma of the liver.

John George Moore Sloane, Holford, England; University of Toronto Faculty of Medicine, Toronto, Ont., Canada, 1895; aged 58; died, August 24, of cerebral embolism.

Roy Ezra Sleppy ⊕ Pittsburgh; Western Pennsylvania Medical College, Pittsburgh, 1899; served during the World War; aged 56; died, November 10, of cardiac asthma.

Fred E. McKeeby, Olney Springs, Colo.; Medical Department of Omaha University, 1894; member of the Colorado State Medical Society; aged 61; died, November 12.

William Albert Lang, Long Beach, Calif.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1881; aged 67; died, September 9, of chronic myocarditis.

Joseph P. Dobbin, Quebec, Que., Canada: Laval University Faculty of Medicine, Quebec, 1902; on the staff of the Jeffrey Hale Hospital; aged 53; died, October 17.

Emil Gustave Reinert ⊕ Hartford, Conn.; Baltimore Medical College, 1895; aged 65; died, November 21, in West Hartford, of carcinoma of the lip with metastasis.

Leonard E. Stocking, Agnew, Calif.; St. Louis Medical College, 1876; superintendent of the State Hospital; aged 81; died, October 29, of chronic myocarditis.

Thomas K. Wissinger, Columbus, Ohio; Starling Medical College, Columbus, 1879; aged 71; died, November 19, of arteriosclerosis and cerebral hemorrhage.

James Weir Heddens, Pasadena, Calif.; Jefferson Medical College of Philadelphia, 1879; aged 74; died, November 8, of arteriosclerosis and chronic myocarditis.

Arthur Montgomery Pelton, Los Angeles; University of Michigan Medical School, Ann Arbor, 1866; aged 87; died, September 7, following a prostatectomy.

Victor T. Roth ⊕ Pottsville, Pa.; Medico-Chirurgical College of Philadelphia, 1891; aged 61; died, October 14, of cerebral hemorrhage and chronic nephritis.

William Laughlin Dunning, Newburgh, N. Y.; Bellevue Hospital Medical College, New York, 1892; aged 67; died, November 17, of cerebral hemorrhage.

William Boyd Secrest, Los Angeles; Ohio Medical University, Columbus, 1898; aged 62; died, November 2, of chronic myocarditis and coronary sclerosis.

John Willias Swetnam, Soldier, Ky.; Physio-Eclectic Medical College, Cincinnati, 1877; aged 80; died, October 5, of chronic interstitial nephritis.

Carl Henry Guess, Buffalo; University of Buffalo School of Medicine, 1880; aged 77; died, November 20, of diabetes mellitus and myocarditis.

Elbert D. Beckner, Hoxie, Kan.; University of Nashville (Tenn.) Medical Department, 1906; aged 53; died, October 20, of cerebral hemorrhage.

Robert Gideon Baxter, Caneyspring, Tenn.; University of Nashville Medical Department, 1885; aged 71; died in November of paralysis.

Henry Merrill Thompson, San Francisco; Jefferson Medical College of Philadelphia, 1906; aged 53; was found dead, October 20.

Leopold Gross ⊕ New York; University and Bellevue Hospital Medical College, New York, 1910; aged 48; died, November 10.

Henry M. Beatty ⊕ Trenton, N. J.; Jefferson Medical College of Philadelphia, 1885; aged 73; died, November 13, of heart disease.

George B. Roberts, Vanderbilt, Pa.; College of Physicians and Surgeons, Baltimore, 1886; aged 74; died, November 11, of nephritis.

James F. Brewer, Asheville, N. C.; Memphis (Tenn.) Hospital Medical College, 1899; aged 56; died, October 24, of myocarditis.

Payn Bigelow Parsons, New York; Albany Medical College, 1897; aged 59; was found dead, September 19, of heart disease.

Frank Charles Hood, Gold Run, Calif.; Hahnemann Medical College, San Francisco, 1884; aged 76; died, September 3.

Charles John Peirce, Los Angeles; Dartmouth Medical School, Hanover, N. H., 1885; aged 73; died, September 21.

Mary Jane Bearby, San Jose, Calif.; Homeopathic Hospital College, Cleveland, 1872; aged 87; died, September 3.

Ira H. Rea, Harbert, Mich.; Harvey Medical College, Chicago, 1898; aged 74; died, November 28, of pneumonia.

Alexander W. Shaver, West Hamilton, Ont., Canada (licensed, Ontario, 1877); died, October 2.

George Cryer Parker, Fort Smith, Ark. (licensed, Arkansas, 1903); aged 72; died, September 19.

M. M. Tubb, McMinnville, Tenn. (licensed, Tennessee, 1889); aged 75; died, November 24.

Joseph C. Hooten, Ellerslie, Ga.; Atlanta Medical College, 1893; aged 60; died, September 25.

Bureau of Investigation

THE CONVERSE TREATMENT

A Columbus, Ohio, Concern That Sells an Alleged Epilepsy Cure

The Converse Company, which on its letterheads is described as "The Converse Treatment Company," operates from 30 Smith Place Avenue, Columbus, Ohio. The head of the concern is said to be one Herbert E. Sanderson who, if reports are to be believed, has been in the "patent medicine" business for about fifty years. Connected with Sanderson (according to the company's stationery) are Frank J. Dawson and Donald W. Dawson, with L. P. Jackson, M.D., as "Medical Referee."

Dr. Louis P. Jackson of Columbus, who has practiced at Delphoss and Van Wert, Ohio, was, according to the records, born in 1867 and holds a diploma from the Starling Medical College of Columbus for 1898. Dr. Jackson is not a member of his local medical society nor of the American Medical Association.

The Converse Treatment has been discussed in The Journal at different times, but the large number of inquiries received by the Bureau of Investigation from both laymen and physicians makes it desirable to bring again to the attention of the profession and the public the facts regarding this mail-order exploitation of epileptics.

THIS WILL BE TREATED CONFIDENTIALLY.

Very truly yours,

H. E. SANDERSON.

30 South Place Avenue COLUMBUS, OHIO

Photographic reproduction (greatly reduced) of a two-page leaflet sent out by Sanderson of the Converse concern to officials of villages and small towns in an effort to obtain "sucker lists" of epileptics. The "mayor," "president of the city council," or "justice of the peace" to whom the leaflet is sent, is offered trivial bribes for the names of sufferers from epilepsy.

In the days before the passage of the Food and Drugs Act, the Converse Treatment was known as the "Converse Cure," and was described as "The only positive cure known, adopted and recommended by the leading physicians of the country." This statement, being one hundred per cent false, is no longer made by the company, although the implications in the 1931 advertising are almost as false and misleading. In the early days, the Converse nostrum was put out from Mount Vernon, Ohio, by a Mrs. Converse, who was said to have "discovered" the "cure." Although the company has for years claimed—and still claims—that its nostrum has been used by hospitals, sanitariums and physicians, no names or addresses are given to make a check-up on such claims possible.

Since the concern has been under the control of Sanderson, "sucker lists" of epileptics have for many years been obtained by sending broadcast to officials in rural communities a printed circular offering a small dictionary, a fountain pen, a cook book or a song book, free to those who will send a given number of names of epilepsy victims.

Of course, no information is given by the Converse concern regarding the composition of its product. In a booklet sent out at the present time, the public is told:

> "The Converse Treatment is prepared of the purest and most carefully selected herbs and medicines in its component parts, and with scrupulous exactness. Its distinguishing characteristic is the employment of a certain herb. This herb is gathered at a distance for the Converse Company at a particular season of the year and prepared for use in its laboratory. The Converse Treatment avoids entirely the powerful drugs known as Opiates, so often given for this trouble and is free from Alcohol, Morphine, Opium, Cocaine, Chloral, Heroin, Eucaine, Chloroform, Cannabis Indica, Acetanilid, or any of their derivatives."

The implication plainly is that the Converse nostrum is essentially herbs. Listing drugs that a "patent medicine" does *not* contain is an old trick in the business.

In the same booklet from which the quotation given above is taken, it is stated that the Converse Treatment has never been advertised in newspapers or magazines, but that the demand has "come entirely from results attained." The facts are, of course, the demand has actually come from those victims of epilepsy who have received the plausible and misleading "literature" of the Converse Company and whose names have been given the concern by those who are willing to furnish the contact at the price of a fountain pen or cook book.

As long ago as 1912, the Converse Treatment was analyzed by the late Senator E. F. Ladd, when he was the aggressive Pure Food Commissioner of North Dakota. Professor Ladd's report showed that the essential drugs in the Converse Treatment were the bromides. In 1915, the A. M. A. Chemical Laboratory, at the request of the Bureau of Investigation, made a thorough analysis of the Converse Treatment and the findings confirmed the earlier analysis of the North Dakota chemists. The A. M. A. Chemical Laboratory reported that from its analysis, it was evident that those who took the Converse Treatment in the dosage recommended obtained bromides corresponding to 58 grains of potassium bromide daily.

The Converse Treatment, quite obviously, has all the limitations and dangers of a bromide mixture.

TRIPLE L MEDICINE COMPANY

The Postal Authorities Declare Thomas N. Walker's "Syphilis Cure" a Fraud

In this department of The Journal for September 19, this year, there was published a brief story on the issuance of a fraud order against the West Medicine Company and Western Medical Clinic, exploited in Colorado. It was brought out in this item that the West Medicine Company was established in 1893 by one Charles West, the father of Amos C. West, who, at the time of the issuance of the fraud order, was the owner. A Dr. George D. Hoschouer had also operated the business prior to the acquisition of the concern by Amos C. West. Hoschouer conducted the concern under the name of the Western Medical Clinic, but when Amos West took it over, the name was changed back to the West Medicine Comany. The concern was selling through the mails two preparations, known, respectively, as *"909"* and *"Brigham Young Tablets,"* the former an alleged cure for syphilis and the latter an equally alleged cure for "lost manhood." Amos C. West, it was brought out by the federal authorities, had no medical training, but was, in fact, a chiropractor and a real-estate operator. On August 24, this year, the Postmaster General debarred the West Medicine Company and the Western Medical Clinic from the United States mails.

Now, the postal authorities have issued another fraud order directed against the Triple L Medicine Company and one Thomas N. Walker of San Francisco, Calif. Walker, it seems, is a linotype operator and has conducted, as a side-line, a piece of mail-order quackery known as the Triple L Medicine Company, operating the business from his residence. The man has no medical or pharmaceutical training. "Triple L," as Walker calls his nostrum, is the same product that was known as 909, sold by the West Medicine Company of Denver. When the Post Office authorities began investigating the Triple L Medicine Company, Walker admitted that his Triple L was the old 909 "cure" for syphilis. Chemical analysis by the federal authorities of this alleged cure showed it to contain 3½ grains of gold and sodium chloride to the ounce. This combination, of course, has no value whatever in the treatment of syphilis, and in fact, if taken over a long period, may produce very serious effects on the user. As a result of the investigation, the Hon. Horace J. Donnelly, Solicitor for the Post Office Department, recommended to the Postmaster General that a fraud order be issued against the Triple L Medicine Company and Thomas N. Walker, debarring these from the United States mails. Such an order was issued Dec. 3, 1931.

In this connection, it may be said that in May, 1929, the Bureau of Investigation of the American Medical Association received information from Dr. C. B. Pinkham, Secretary-Treasurer of the Board of Medical Examiners of the State of California, relative to the Triple L Medicine Company, which was, at that time, under investigation by the state authorities. It was brought out that associated with the Triple L Medicine Company, at that time, was one R. L. Stine, M.D., who, it was alleged, had formerly been connected with the Dean Pile Institute of San Francisco. When Stine was interviewed by the state authorities, he is said to have admitted that he did not know what were the ingredients of the Triple L Liquid, which he was advising patients to take.

Correspondence

DISTRIBUTION OF BROMIDES IN THE BODY

To the Editor:—Because of your interesting editorial on the distribution of bromides in the body (THE JOURNAL, October 17, p. 1152), I should like to call attention to an illustrative but apparently little known piece of work on this question. The work was published by Erik Wilén in the *Uppsala läkareförenings förhandlingar* **31**:*373, 1926*, and contains carefully performed bromide (Br^-) and chloride (Cl^-) analyses on different tissues from a man who died after having taken during three days a quantity of about 100 Gm. of sodium bromide. The death ensued about a week after the beginning of administration of the sodium bromide. Wilén calculates that about 50 per cent of the sodium bromide ingested remained in the body at the death. Like Toxopéus, he found the concentration of bromide (Br^-) in the brain as a whole less than in several other tissues; e. g., blood, lungs, heart, spleen. However, when different parts of the brain were examined separately, it turned out that the bromide concentration in the cortex cerebri was about twice as great as that in the basal nuclei, of the cerebellum and of the white substance. The bromide concentration in the cortex was indeed exceeded only by that in the blood. Wilén correlates these observations with the selective action of bromides on the cortex but points at the same time at the relatively great water content of the cortex as a conceivable, simple chemical explanation of its relative richness in bromide.

GUNNAR BLIX, Uppsala, Sweden.

TUBERCULOSIS AND FLORIDA

To the Editor:—This communication, while dealing more specifically with Florida, is applicable to other resort states and winter playgrounds.

It has come to the notice of physicians in Florida that a considerable number of persons with pulmonary tuberculosis of varying grades of involvement and activity are sent to this state during the winter months for the purpose of availing themselves of Florida's climate and sunshine. The reason for this is apparent. These patients want to get away from the cold and confining northern winters and want to enjoy an outdoor existence.

People have been educated to the value of sunshine; hence one of the alluring enticements is that they can take the "sun cure" on the beaches and enjoy the salubrious climate. The unfavorable feature of the expedition is that they are left to shift for themselves. If the home physician knows the value of controlled exercise and the danger of a break in the routine of living, the patient is asked to report to him by letter at certain intervals. In many cases no definite instructions are given, and the patient is told to "lie in the sun" and take plenty of milk and eggs.

The result is that the patient arrives and equips himself to enjoy the bathing beaches. He puts on a bathing suit and goes out to lie for a half hour or two hours on a sunny beach. This brings on a bad attack of sunburn with its attending fever and misery and perhaps a lighting up of a quiescent lesion. The patient may decide to take a car or bus trip to another part of the state—he wants to see Florida. He goes to an occasional night club or is a fairly regular attendant of the race tracks. His rest hours are forgotten. His regular retiring hours are a memory. In the spring he returns to his family physician with an extension of his lesion or perhaps a history of pulmonary hemorrhage, and the physician blames the Florida climate as being unsuitable for pulmonary tuberculosis.

If this patient had followed his routine of living as closely as when under the observation of his home physician, he would be more definitely benefited than if he had remained at home. Florida has a suitable climate for the treatment of tuberculosis, but no climate can overcome a regimen that would wear down a healthy man. Tuberculosis here as elsewhere must be treated rationally, and a person who has been under the guiding care of a physician at home should be supervised wherever he goes, whether it is Florida, California or Arizona. If physicians recommending Florida to their patients would insist that these patients put themselves under the care of a physician when they arrive, much benefit would be derived from such a sojourn away from home.

This communication is written primarily to the end that tuberculous patients be put under the supervision of physicians when they go to a winter resort and that the resort physician keep in professional communication with the medical adviser who recommended the trip.

W. A. CLAXTON, M.D., Jacksonville, Fla.
Tuberculosis Clinician, State Board of Health.

PURE AIR AND CLEAN STREETS EXHIBIT

To the Editor:—Lack of proper methods of street cleansing and of the removal of waste detracts from the appearance of the city and invites negligence on the part of the public. It carries in its trend more important consequences than unsightliness and the pollution of bay waters. The open garbage can is a feeding place for insects and rodents and thereby contributes indirectly to the transmission of many diseases of which flies, vermin and rats are carriers. Improper sweeping results in filling the air with dust, as does the practice of dumping ash cans into open carts. Other deleterious elements in the air one breathes in the city are the carbon monoxide from the exhaust of automobiles, the smoke and soot which come from the chimneys of buildings and from stacks of boats plying in the city waters, the mineral dust that comes from building operations and from the tearing up of streets, the cleaning of buildings by sand blasting, and other similar sources.

The New York Meteorological Bureau in New York City measures daily the amount of dust suspended in the air, and it was found that over the Central Park area, which is probably one of the most favored areas in the city, the amount of dust and soot suspended averaged 3.97 tons daily to the cubic mile of air, during 1930. On moist days this suspension creates a pall which deprives the city of much sunlight and, particularly, of ultraviolet rays. Aside from the injury to the eyes and to the air passages, which the impurities of the air create, the amount of economic loss caused, directly or indirectly, is considerable. According to the estimates made a great deal of coal and oil is being wasted by improper combustion, and the destruction of fabrics and household effects runs into hundreds of millions annually. As has been well said, excessive smoke is not a necessity but a luxury of laziness and indifference.

It is not only for the purpose of impressing on the public mind the menace to health of impure air and dirty streets that an exhibit will be held at the New York Academy of Medicine, 2 East One Hundred and Third Street, New York, under the joint auspices of the Academy Committee on Public Health Relations and the Committee of Twenty on Outdoor Cleanliness. It is being arranged primarily as an educational measure to stress the possibility of preventing this nuisance and health hazard. The exhibit, which will be open to the public, will begin Jan. 12, 1932, and continue for eight days. It will consist not only of graphs, charts, photographs, and various scientific instruments of precision used in measuring contamination, but principally of models of modern street cleaning apparatus, stoking devices, ventilating machines, and moving pictures depicting modern methods. In this endeavor the cooperation of the city, state and federal authorities is being enlisted, as well as that of scientific organizations and of the manufacturers of proper equipment.

Inquiries may be addressed to the undersigned as executive secretary of the Public Health Relations Committee, 2 East One Hundred and Third Street, New York.

E. H. L. Corwin, New York.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

USE OF POTENT LIVER MATERIAL IN PERNICIOUS ANEMIA

To the Editor:—I have a patient who has pernicious anemia and has been on the liver diet for four years, part of the time taking the extract. At present his red blood cell count is falling, despite the fact that he takes three vials of the extract a day. Cord changes are also developing rapidly. At present there is an extreme degree of irritability of the bladder and frequency of urination. At times the patient has tonic spasms of the legs. Please advise me as to whether anything can be done for the bladder or for the contractions in the legs. Please omit name.

M.D., Kansas.

Answer.—The treatment of pernicious anemia is not merely with liver or a potent substitute but with enough liver or potent substitute for the given individual case. A falling red blood cell count is a clear-cut indication for the patient to take much more potent material. It is naturally important to know that the patient is receiving a potent product. Progressive cord changes are also a clear-cut indication for the patient to receive much more potent material, no matter whether the red blood cells are present in normal or in decreased numbers.

Exactly how much potent material should be considered optimal for this case cannot be foretold. It would be wise to give the patient, by mouth, potent liver extract derived from not less than 1,000 Gm. of liver a day. The patient may have difficulty in absorbing or utilizing the product when given by the intestinal route, and if so an extract given parenterally may be of great advantage. Economically, it would be of advantage to administer a potent liver extract intramuscularly. Likewise, so that there would be no delay in having ample potent material enter the patient's body, it would be wise to give him daily intramuscular injections of at least 2 cc. (each cubic centimeter representing extract derived from 5 Gm. of liver) of a potent liver extract properly prepared for use in this manner.

It is important to remember that infections, such as pyelitis, can inhibit the action of the active principle effective in pernicious anemia, and it should be ascertained whether the patient has any infectious condition of the genito-urinary tract, and if so it should be treated appropriately. Symptoms referable to the bladder are prone to improve under treatment with an adequate amount of potent material.

Physical therapy frequently aids to decrease such symptoms as the patient has had referable to his legs. The most important thing to do, however, is to treat the patient with enough potent terial.

The following liver extracts for oral administration have been accepted for New and Nonofficial Remedies: Liver Extract No. 343 (Lilly), Concentrated Liver Extract-Armour, Liver Extract-Fairchild, Liver Extract-Lederle, Marine Liver Extract-White. Solution Liver Extract Parenteral-Lederle, proposed for intramuscular or intravenous injection, has also been accepted by the Council on Pharmacy and Chemistry.

TREATMENT OF THROMBOPHLEBITIS

To the Editor:—In view of repeated reports that ambulatory treatment of phlebitis complicating injection of the varicose veins is the method of choice, is there reason to believe that the time-honored treatment of infectious phlebitis by rest should be changed? Or, worded differently, do absolute rest and immobilization form the proper method of treatment for the average case of thrombophlebitis (not associated with varicose veins)? Please omit name.

M.D., Virginia.

Answer.—Thrombophlebitis in nonvaricose veins must be grouped into a deep and a superficial variety. Superficial thrombophlebitis, if it occurs in small patches and without elevation of temperature, is best treated with adequate elastic support and no immobilization. If it is of the ascending type, accompanied by a rise in temperature and a high white blood cell count, a high ligation of the saphenous vein results in an efficient barrier to the thrombosis. The patients are kept in bed only for a few days, until the pulse rate becomes normal, and may then get up, with adequate support.

The treatment of deep thrombophlebitis is one of the most neglected questions of the day. The object of rational treatment should be (1) to minimize the danger of embolism and (2) to combat from the start the persistence of edema, which will lead to irreversible changes in the tissues. There is a paradoxical relationship between the extent of the clot in the deep vein and the danger of embolism. The more extensive the deep clot is and the more pronounced the "milk leg," the smaller the percentage of lung infarcts and fatal pulmonary emboli seems to be, whereas the small, silent clots break loose more often and end fatally in patients who have no, or barely any, sign of venous obstruction. The rule of keeping these patients in bed for from four to six weeks is entirely arbitrary. A better, more rational plan is to watch the pulse and the white blood cell count and to permit some muscular action about ten days after the pulse has become normal. Any elevation of the pulse would necessitate further immobilization. The leg should be strapped from the toes to the thigh with an elastic bandage, which not only influences the edema but diminishes sudden rises of venous pressure during movements. Other methods of diminishing the acute edema are in the experimental stage.

An absolute immobilization of the patient is not necessary and, in fact, is not even possible. The patient, with leg splinted and lying flat on the back, does more straining with every bowel movement than a slight turning on the side or sitting up would produce. When one reads the interesting statistics of Kappis (*Deutsche Ztschr. f. Chir.* **223**:317, 1930), who reports 100 cases of deep thrombophlebitis treated merely by strapping, but in an ambulatory manner, with a resulting percentage of infarcts and fatal emboli which does not exceed the ratio in an immobilized group of patients, one must seriously wonder whether immobilization of deep phlebitis really prevents embolism at all. Until the question is settled on the basis of adequately controlled statistics, it seems safer to keep patients in bed without bathroom privileges, but not under strict immobilization. The loosening of the thrombus must be regarded more in the light of a chemical process, in which the present crude mechanical measures are yet utterly helpless.

POSSIBLE POISONING FROM LACQUER

To the Editor:—A college student, who came to my office complaining of weakness, nervousness and loss of weight, stated that he worked with lacquer for about six weeks this summer. The question arises whether this may have some influence on his condition.

Ara D. Sharp, M.D., Albion, Mich.

Answer.—Unfortunately, the term "lacquer" provides little information on which any opinion may be formed, in reply to this query. No less than thirty volatile substances may enter into lacquers, many of which are toxic. The number includes methanol, butanol, amyl alcohol, glycols, acetone, butyl acetate, amyl acetate, ethyl acetate, benzene, toluene, xylene, naphtha and lactates.

Lacquers may contain plasticizers of harmful nature, such as tricresyl phosphate, which is believed to be the agent responsible for "jake paralyses." Some lacquers are pigmented and thus open up the possibilities of harm from such agents as arsenic compounds and *para*-nitraniline. Without the intent of making a diagnosis, it is at once agreed that the manifestations mentioned may readily arise from the toxic action of some of the ingredients listed. Examination of the blood is a likely source of information as to the harmful action of benzene or its homologues, toluene or xylene. The best approach to exact facts lies in determining the precise content of the lacquer to which exposure was provided. With this information, special examination may then be made in keeping with the toxic action of the ingredients established. If the condition originated during or shortly after exposure, the lacquer is of far greater etiologic import than would be true if the condition developed with many weeks intervening between exposure and disability.

ULCERATIVE COLITIS — ENDAMOEBA HISTOLYTICA

To the Editor:—A white man, aged 43, well developed and fairly well nourished, had diarrhea and upper abdominal distress of intermittent character and of about eight months' duration. The past history is essentially negative. The patient is a welder and railroad mechanic. About one year ago he went to the oil fields of Kansas to help lay a pipe line. While there he was in good health, but the conditions in the camp and the water supply did not meet with his approval and he left. He was in good health for a short time following that trip, and then a diarrhea developed, which lasted about ten days. He did not have any fever or any malaise that he recalls. Since then the attacks of diarrhea have recurred with greater frequency, and in between he has had normal periods of good health. There has been a steady loss of weight, amounting to about 35 pounds (16 Kg.) in a year. For the past two and one-half months the diarrhea has been persistent, and he first noted the occurrence of the upper abdominal pain, which at first was spasmodic and transient in character, but occurred in the left upper quadrant and gradually has been going lower along the course of the descending colon. For about six weeks this has been more or less constant. The stools are watery with gross bright and dark blood present. At no time has he noted any fever. There has been loss of strength, and a noticeable increase in nervousness. On his initial visit, about three weeks ago, the physical examination was essentially negative except for the evidence of the loss of weight and the extreme nervousness. Blood examination was well within the normal limits and no leukocytosis or leukopenia was noted. The blood Wassermann test and urinalysis gave negative results. The lower end of the colon was markedly ulcerated and this seemed to extend up as far as could be seen on ordinary examination. The mucosa was congested and several small bleeding points were noted. Stool examination of the freshly passed specimen revealed a large quantity of blood, mucus and numerous ameboid organisms reported by the pathologist to be Amoeba coli. Nothing else of interest was noted. Roentgen examination revealed, at one time, marked retention of the barium in the stomach and a somewhat spastic condition of the lower bowel. On another occasion there was rapid emptying of the stomach and relatively the same condition of the lower bowel. No evidence of new growths was noted. The patient has been on high gelatin retention enemas and bismuth subcarbonate. There has been some amelioration of the symptoms and a slight improvement in the general condition. Would I be justified in making a diagnosis of colitis due to Endamoeba histolytica and in treating the case as such? Is there any substance less toxic than emetine to be used, and what mode of administration would prove most efficacious? A low residue diet of the accepted type is strictly adhered to, but no change has been noted in the stools. How large a factor is the nervous element in the progress of this case? Please omit name.

M.D., South Dakota.

ANSWER.—It would appear from the observations presented that the patient is affected with an ulcerative colitis. In addition to amebic colitis a bowel disease due to pernicious anemia, tuberculosis, metal poisoning, toxic thyroid infection (chronic ulcerative colitis as described by Bargen) or toxic colitis caused by working with or handling volatile oil distillates must be considered. Malignancy, sprue and pellagra appear to be unlikely etiologic agents but must not be discounted altogether. It is uncommon for a pure neurosis to cause a colitis accompanied by free bleeding.

The blood count is not stated; an eosinophilia would appear at some stage of the illness, were the cause Endamoeba histolytica. In view of the contradictory roentgen observations on the stomach, tests for acidity and mobility on the exhibition of a full, mixed meal are indicated.

If the colon lesions are due to Endamoeba histolytica, the proctoscopic study should reveal typical umbilicated ulcers, discrete or coalescing, and smears from the lesions, examined either on a warm slide or after staining by iodine or hematoxylin, should reveal characteristic protozoa.

The management consists in (1) absolute rest in bed; (2) warm compresses to the abdomen; (3) a warm, liquid and later semisolid, bland diet; (4) irrigations of the colon, from two to four times daily, with an abundance of physiologic solution of sodium chloride at 45 C., a temperature above the thermal death point of the ameba (Rivas); or, if ulceration and bleeding are of advanced degree, bowel irrigations with warm mercurochrome-220 soluble, 1:2,000; (5) the control of spasm and frequent painful movements, during the early days of management by the administration of 4 Gm. of bismuth subgallate in 60 cc. of hot water, after each bowel movement and four times daily, and of 65 mg. of powdered opium with 16 mg. of extract of belladonna; (6) amebacidal therapy: 32 mg. of emetine hydrochloride injected intramuscularly, three times a day and the dose being gradually increased by a half every second day, until, provided no depressing signs or symptoms are exhibited, 0.1 or 0.13 Gm. is being employed. Very few patients take the maximum dose without discomfort or signs of circulatory depression. If emetine is poorly borne, 0.15 Gm. of neoarsphenamine may be given intravenously daily or every other day, provided it is well tolerated.

Ipecac is considered an excellent amebacide. From 4 to 16 Gm. may be given in doses, progressively increasing, if the powdered drug is given in 0.32 Gm. keratin capsules or in pills well coated with phenyl salicylate (pinhole-free). On an empty stomach, from 1.3 to 2 Gm. of the powdered ipecac may be given three times a day, provided the patient remains in bed. He should lie on his right side after taking the medicine and drink from 60 to 120 cc. of hot clear tea. The pills then will pass rapidly from the stomach. Half an hour after the pills have been taken, thirty drops of camphorated tincture of opium in 60 cc. of hot sweet water tends to allay retching and vomiting. If pills or capsules of ipecac are poorly borne, from 8 to 30 cc. of tincture or wine of ipecac may be given through a duodenal tube directly into the jejunum. At times, from 30 to 90 cc. of wine of ipecac given by rectum after colon lavage, through a high colon tube, proves efficacious.

If ipecac in various forms and by various routes of exhibition is poorly taken, then, in association with hypodermic injections of emetine or neoarsphenamine, one of the newer arsenic compounds, as acetarsone, may be given: two pills daily for twelve days usually proves efficacious.

It should be remembered that Amoeba histolytica is prone to localize in structures communicating with the alimentary tract, appendix or gallbladder, and that in this event recurrences of bowel infestation may be prevented only after appendectomy or cholecystectomy. Even if the protozoan does not migrate to these accessory structures, its systemic spread to liver, lungs, testis and epididymis or bone marrow may call for the long-continued exhibition of emetine or neoarsphenamine. The constitutional effects of chronic amebiasis—absent hydrochloric acid, deficient pancreatic secretion, anemia—demand recognition and treatment.

WASSERMANN REACTION IN SYPHILIS UNDER TREATMENT — ANTISEPTIC PROPERTIES OF ARSPHENAMINES

To the Editor:—1. In "Clinical Syphilography," by Stokes, page 424, figure 246, is given the incidence of a positive blood Wassermann reaction in primary syphilis. As far as I can learn by careful search through the whole book, there is nothing said about the difference in incidence of a positive reaction in treated and in untreated cases, and the exact relation, if known, between the kind and amount of treatment and the Wassermann reaction. I am referring specifically to first degree syphilis. I have in mind a case of typical hunterian penile chancre, positive for spirochetes with the Giemsa stain. Three blood tests have so far been negative, and the chancre is now about three weeks old. According to Stokes, in the third week 68 per cent of chancres show a positive blood reaction. Am I to assume that my case is one of the remaining 32 per cent, or am I keeping the Wassermann reaction negative by my treatment? I have been using neoarsphenamine twice a week. 2. Is anything known about the general in vitro antiseptic properties of the arsphenamines? I have heard that some syphilologists use tap water for their arsphenamine injections and use it without sterilizing it. They claim no more reactions to the injection. Could it be that arsphenamine solutions are self sterilizing, as are those of the soluble mercurials? Please omit name.

M.D., New York.

ANSWER.—1. The inquirer is in all probability keeping his patient's Wassermann reaction negative by treatment with two neoarsphenamine injections a week. The figures given by Stokes refer to untreated syphilis and represent the gradual increase in proportion of positive reactions which takes place with the increasing age of the infection as the systemic reaction to the disease develops. The suggestion that there should be a study of the incidence of positive reactions as a form of progression in patients who are under treatment for an originally seronegative primary infection, presumably in spite of treatment, is at first thought astonishing, but deserves consideration. Such investigations have already been made, by Moore and Kemp, with reference to the rate at which the positive Wassermann reaction is reduced to negative in early syphilis under treatment (serologic gradient), and figures for the incidence of relapse in seronegative primary syphilis which, however, deal with clinical lesions and not with examination of the blood, have been given by Stokes and associates in Venereal Disease Information, volume 12, no. 2, Feb. 20, 1931, issued as reprint 29 by the

Bureau of Venereal Diseases, U. S. Public Health Service. No published statement with regard to the percentage development of positive blood reactions in originally seronegative primary cases under the influence of treatment seems to be available. It is well known, however, that this shift to positive, as a form of progression, does occur, and precautions should be taken to recognize the situation early in the course of the treatment by taking several blood tests at intervals of a week after the initial negative reaction, on the basis of which treatment was begun. Patients in whom such positive reactions subsequently appear are to be regarded as having fully developed infections, and should not be treated by an abortive or short-cut technic.

2. The general in vitro antiseptic properties of the arsphenamines are known, including their spirillicidal action, to a certain extent. These drugs in solution are not sufficiently powerful bactericides to justify any reliance on their self sterilizing properties. In the light of experience with modern technic, the use of tap water for arsphenamine injection without previous sterilization can only be regarded as reprehensible.

ALBUMINURIA AND INSURANCE

To the Editor:—A few days ago I had occasion to examine a school boy in apparently perfect health and found a small trace of albumin. The boy was examined by his family physician, who did not confirm my test. However, a few days later I found the same condition present again, and the observation was confirmed by the laboratory. Microscopic analysis showed 4 white blood cells to the high power field, no red cells, no hyaline casts, some shreds and small waxy filaments. What is the condition present and what effect, if any, should it have on his insurability? Please omit name.

M.D., New York.

Answer.—The data submitted are insufficient to afford any definite deductions. Evidently the albuminuria is not constant. It would therefore be advisable to determine whether it is postural or orthostatic by examining the urine passed in the morning after a night's rest. The absence of albumin at this time and its appearance after the patient has been active would suggest this condition. Nephritis can hardly be considered here unless the child has recently had an acute infectious disease with a renal involvement. Nephrosis is associated with large quantities of albumin, waxy casts and doubly refractive lipoid bodies in the urine, while glomerular nephritis is associated with small amounts of albumin, red blood corpuscles and hyaline casts. The presence of a few white blood cells in the urine, if constant, would suggest the possibility of some irritative process in the genito-urinary tract. Repeated examinations of the urine and a careful physical examination should be made and a temperature record kept, as the possibility of a chronic renal lesion or even a calculus without any subjective symptoms must be considered.

Formerly the tendency for insurance companies has been to refuse insurance to applicants with albuminuria. Several companies realize that transient or orthostatic albuminuria need not necessarily interfere with life and health and are now insuring the applicant with little or no rating up of the premium.

ALLERGIC SWELLINGS

To the Editor.—I have a patient, a woman, aged 39, married, who has had swelling, stiffness and some pain in the metacarpophalangeal and first interphalangeal joints of both hands for the past seven or eight years. These symptoms are most marked early in the morning and tend to disappear during the day. *They are much more pronounced for several days* preceding her menstrual periods and during the time of menstruation. The condition is not severe enough to be disabling but is annoying. The cervix was amputated ten years ago. She had a miscarriage nine years ago. The menses are scanty (two days) with considerable pain on the first day. The general physical condition is essentially normal. There have been no other pregnancies. Could there be any relation between the menses and the rheumatoid condition? Please discuss this case as to etiology and treatment. Please omit name.

M.D., Alabama.

Answer.—From the description of the transitory character of the swelling, tending to disappear during the day, the trouble is probably not inflammatory, as would have been the case if it were a rheumatoid arthritis. Furthermore, a chronic arthritis of the type described would almost certainly have led to some permanent deformity and restricted movement of the joint. The history indicates, rather, an angioneurotic edema. This receives further support from the greater intensity of the symptoms at the menstrual period, when the average woman is more nervous. It would be interesting to know whether the patient or her immediate relatives suffered from any allergic disease, as urticaria, hay fever, asthma or migraine.

In regard to treatment, it might be wise to make some food skin tests and then withdraw from the diet those foods to which the patient is sensitive. This treatment is based on the assumption that the trouble is allergic.

LEVULOSE

To the Editor:—Referring to the editorial in The Journal, October 24, page 1230, entitled, "The Absorption of Levulose," improved processes of production of this sugar are mentioned. Could you send to me references to recent articles describing these new processes?

Veader Leonard, M.D., Baltimore.

Answer.—A semicommercial plant capable of producing 50 pounds (22.7 Kg.) of levulose a day has been in operation at Iowa State College, Ames, Iowa, during the past year, using the Jerusalem artichoke as the raw material because of its many good features from an agricultural point of view. By drying the artichokes, many advantages are obtained, including the operation of the plant throughout the year.

A continuous precipitation process has been developed, yielding granular lime levulate, which may be easily filtered and washed. The preparation of crystalline levulose in good yields has been accomplished at ordinary temperatures (15 C.) without the use of refrigeration.

The history of levulose up to the year 1923 has been summarized by Harding (*Sugar* **25:**406, 636, 1923). Later investigations have been published by Jackson, Silsbee and Proffitt (*Indust. & Engin. Chem.* **16:**1250, 1924; Scientific Paper 519, 614, Bureau of Standards, 1926). The latest review including the entire literature of the subject will be found in a paper by McGlumphy and Eichinger (*Indust. & Engin. Chem.* **23:**1202 [Nov.] 1931).

NEED OF PERSISTENCE IN TREATING CONGENITAL SYPHILIS

To the Editor:—A boy, aged 15 years, unusually strong and well built and apparently in perfect health was accidentally found a year ago to have a four plus Wassermann reaction. There are none of the usual signs of hereditary syphilis nor is there any history of acquired syphilis. No family history is obtainable, as the boy was adopted when a baby and nothing is known about his parents. I have known him since he was 4 years of age and he has had no sickness during that time except an attack of measles. For the past year he has received intensive antisyphilitic treatment by a competent physician, but he still has a positive Wassermann reaction. Would you advise further treatment? Please omit name.

M.D., California.

Answer.—Treatment should be continued as intensively and constantly as the health of the patient permits. Congenital syphilis yields slowly in most cases. A careful examination of the nervous system and the spinal fluid is indicated.

USE OF VIOSTEROL DURING PREGNANCY

To the Editor:—Please advise me whether administration of irradiated ergosterol to pregnant women could cause a premature calcification of the fetal head, resulting in dystocia, with possibly damage later to the child.

Hallie Earle, M.D., Waco, Texas.

Answer.—There is no danger to mother or child from therapeutic doses of viosterol (irradiated ergosterol) given during pregnancy. In fact, such medication probably would be of advantage, owing to the excessive drain of calcium and phosphorus that takes place during this period. This medication is especially indicated in cases in which the intake of calcium compounds has been insufficient.

NONSURGICAL TREATMENT OF RECTAL PROLAPSE

To the Editor:—An elderly woman is suffering from a complete rectal prolapse of several years' duration. She refuses to have an operation. Can you suggest any measures or devices that would help to keep the prolapsed rectum in its normal position? Please omit name.

M.D., Wisconsin.

Answer.—There is no mechanical device known that will keep in place the prolapse of the rectum appearing in an old person. Careful attention to diet to give regular bowel movements; above all, avoidance of cathartics and, lastly, pressure on the prolapse with warm moist dressings after bowel movements, followed by light compression obtained by a T binder over the area, are the most important palliative measures.

HEART DISEASE FOLLOWING TRAUMA

To the Editor:—The answer in Queries and Minor Notes (The Journal, October 24, p. 1245) on "Heart Disease Following Blow Over Sternum" leads me to offer an additional reference; namely, Tuohy, E. L., and Boman, P. G.: Trauma to Viscera from Nonpenetrating External Injuries, with Special Reference to the Heart, *Ann. Int. Med.* **4:** 1373 (May) 1931. These authors discuss three cases of auricular fibrillation following such trauma. One case was personally observed and the others were reported in two separate papers in the literature. This article is well worth reading for information on this little known subject.

William D. Reid, M.D., Boston.

Arizona October Examination

Dr. B. M. Berger, secretary, Arizona State Board of Medical Examiners, reports the written examination held at Phoenix, Oct. 6-7, 1931. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Fourteen candidates were examined, 12 of whom passed and two failed. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent
College of Medical Evangelists		(1930)	80.8
Stanford University School of Medicine		(1929)	89
Northwestern University Medical School		(1930)	89.6
Rush Medical College		(1931)	85.8
University of Illinois College of Medicine		(1929)	86
Indiana University School of Medicine		(1930)	82
University of Louisville School of Medicine		(1930)	84.5
University of Maryland School of Medicine and College of Physicians and Surgeons		(1930)	88.5
Harvard University Medical School		(1929)	81.2
University of Minnesota Medical School		(1930)	80.2
University of Cincinnati College of Medicine		(1930)	80.8
University of Toronto Faculty of Medicine		(1931)	76.6

College	FAILED	Per Cent
Osteopaths		64.1, 64.4

North Carolina June Report

Dr. John W. MacConnell, secretary, North Carolina State Board of Medical Examiners, reports the written examination held at Raleigh, June 15, 1931. The examination covered 16 subjects and included 70 questions. An average of 80 per cent was required to pass. Seventy-four candidates were examined, all of whom passed. Fifteen physicians were licensed by endorsement of credentials. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent
Howard University School of Medicine		(1930)	81, 88.6
Emory University School of Medicine		(1931)	86.3
University of Louisville School of Medicine		(1929)	82.3, (1931) 84.3, 92.4

Book Notices

The Influence of Diet on Caries in Children's Teeth. [Interim Report]. By the Committee upon Dental Disease. Medical Research Council, Special Report Series, No. 159. Paper. Price, 6d. Pp. 19, with 3 illustrations. London: His Majesty's Stationery Office, 1931.

This is a progress report of observations, extending over a period of about two years, made on 332 children receiving institutional care in and near Birmingham. The children were housed in separate cottages, which was a factor of assistance in carrying out the plan of investigation followed. All the children of a given cottage received test substances as daily additions to their regular diet. The administration of these supplements was carefully supervised by the foster mother. The diet of institution I was supplemented daily by treacle (golden syrup), from 28 to 42 Gm. (1 to 1½ ounces), according to the age of the child. At institution II, olive oil, from 14 to 21 cc. (1 to 1½ tablespoonfuls), according to age, was given as the daily supplement; later a second group at this institution received a similar amount of a solution of viosterol in olive oil. At institution III a group of children received a daily supplement of cod liver oil, the amounts being the same as for the olive oil experiments. Careful dental inspections were made at intervals of six months; the present report deals only with the number of erupted teeth and the presence and extent of caries. The data are treated statistically in order to determine the significance of the observations noted. There was an increase in the incidence and extent of caries in all groups, but in the case of those groups receiving fat-soluble vitamins (cod liver oil and viosterol solution) the increase was only about one-third that in the other groups. There was no significant difference in the rate of increase of caries between the children receiving olive oil and those receiving treacle. "The facts indeed seem to warrant the conclusion that the incidence and rate of progress of caries in teeth, either fully or nearly fully calcified, can be considerably retarded by the addition of fat-soluble vitamins to the normal diet. The general similarity of the results obtained from the use of cod liver oil and radiostol, respectively, suggests strongly that the potent factor in securing this retardation is vitamin D, inasmuch as it is common to both substances."

The Penalty: Must We Pay It? By Dr. Abraham Strachstein. Cloth. Price, $1. Pp. 136, with illustrations. New York: Good Health Publishing Company, 1931.

This book is labeled "a frank discussion of the social disease problem written so that whoever reads will understand." It is not especially well written. The words "luetic" and "lues" are used instead of "syphilitic" and "syphilis." The volume will not be understood by the vast majority of uneducated persons, who constitute the chief problem in control of venereal disease. The word "preventative" is used instead of "preventive," and in general the book is not quite up to what such a book ought to be.

Malaria Investigations in Some Parts of the Transvaal and Zululand. By N. H. Swellengrebel, Professor of Parasitology, University of Amsterdam, Holland, S. Annecke, M.A., M.B., B.S., Medical Inspector (Malarial), Public Health Department, Union of South Africa, and B. De Meillon, M.Sc., F.E.S., Acting Entomologist, South African Institute for Medical Research, Johannesburg. Publications of the South African Institute for Medical Research. Volume IV, No. 27. Edited by the Director. Paper. Pp. 245-274, with 18 illustrations. Johannesburg: South African Institute for Medical Research, 1931.

The only mosquitoes found to be concerned in malaria transmission were Anopheles funestus, Anopheles costalis and Anopheles pretoriensis. The natural index of infection in each case was: funestus, 15.9 per cent (340 examined); costalis, 15.6 per cent (205 examined), and pretoriensis, 1.7 per cent (114 examined). The conditions were found to be favorable to species control of the incriminated anophelines. A. funestus breeds in streams with grass-covered banks, especially where the current is not strong; it prefers water that is clear and fresh. A. costalis is a puddle breeder, being found in the most temporary mud puddles which are lacking in vegetation and without shade. A. pretoriensis is thought to play little part in natural transmission, probably because of its lack of contact with man. Evidence is presented which indicates that human gamete carriers (of estivo-autumnal malaria) with infections as low as 1 gamete to 1,500 leukocytes may infect anophelines. The native population in highly malarious areas shows a resistance to the disease. This is demonstrated by the lack of obvious signs of suffering in young children with heavy infection; by an acquired immunity later on, as shown by reduction of the parasite rate and a high spleen rate; and among adults by an acquired tolerance, as shown by a lessened spleen rate and a continued state of immunity, so that the parasites are kept low in numbers.

Gynecology and Urology for Nurses. By Samuel S. Rosenfeld, M.D. F.A.C.S., Adjunct Obstetrician and Gynecologist, Lebanon Hospital, New York City. Cloth. Price, $2. Pp. 230, with 97 illustrations. New York: William Wood & Company, 1931.

Because of the close relationship between gynecology and urology, the author presents a brief picture of these subjects. He falls short of making it of great value by devoting too little space to the subject of the nurse's responsibility in these conditions, and actual nursing care. The final chapter, written on postoperative care, appears to be a set of rules for hospital routine such as may be seen posted in the house staff room in some institutions. Lacking in this chapter is any discussion of postoperative complications and instruction to the nurse on how to recognize and evaluate untoward symptoms and signs. The book could be made more useful by revision in subsequent editions.

Atlas der Röntgenstereoskopie. Von Dr. Max Cohn, dirigierender Arzt der Röntgenabteilung am Städt. Krankenhaus im Friedrichshain-Berlin. 1. Serie mit 20 Filmdianegativen und einem Betrachtungsapparat. Cloth. Price, 22 marks. Pp. 26. Leipzig. Georg Thieme, 1931.

This collection includes a text by Dr. Max Cohn, a folding stereoscope and twenty stereoscopic negatives of roentgen appearances. Such conditions as tuberculosis of the kidney, appendicitis, gallstones, carcinoma, ulcers, echinococcosis, fractures, tumors of the brain, and various types of cysts are illustrated.

Exploration radiologique de l'appareil respiratoire. Par Émile Sergent, professeur à la Faculté de médecine de Paris, Francis Bordet et Henri Durand, chef du laboratoire de la clinique de la Charité. Avec la collaboration technique de J. Couvreux, chef du laboratoire de radiologie de la clinique de la Charité. Fascicule I et II. Cloth. Price, 350 francs per set. Pp. 465, with 639 illustrations. Paris: Masson & Cie, 1931.

This work is printed on excellent paper to bring out the roentgenographic illustrations to the best advantage. The scheme has been to publish the diagnosis and caption in close proximity to the illustration, to facilitate the intelligent study of the condition. The work is divided into three general parts: the first sets forth as briefly as possible the technical and roentgenologic exploration of the respiratory system, followed by general remarks on the value and interpretation of the results contributed to the clinical study by roentgenology. The second part is dedicated to the study of the basic principles, beginning with descriptions of the roentgenologic images of the normal respiratory tract. In the third part of the work there are described in order the roentgenologic appearances of the various respiratory disorders, classified under the following heads: thoracic cage, diaphragm, mediastinum, trachea and bronchi, pleura and the lungs. The text is adequate and not too brief. The captions contain the essential facts relating to each of the illustrations. The use of iodized oil in bronchiectasis is also described in detail, and certain other lesions are carefully described. This monumental work contains a veritable mine of information relating to the roentgenologic investigation of the respiratory tract.

Diseases of the Skin. By Richard L. Sutton, M.D., Sc.D., LL.D., Professor of Diseases of the Skin, University of Kansas School of Medicine. Eighth edition. Cloth. Price, $12. Pp. 1352, with 1301 illustrations. St. Louis: C. V. Mosby Company, 1931.

The first edition of Dr. Sutton's textbook appeared in 1916. The present edition includes a rearrangement of the illustrations, the use of a lighter and finer grade of paper, and much new material. The book is modern, and particularly safe as a guide for the general practitioner, since it does not offer to him technics involving roentgen or similar procedures suitable only for use by the specialist.

Die physikalische Seite des Blutgerinnungsproblems und ihre praktische Bedeutung. Von Dr. med. Heinrich Lampert, Privatdozent an der Universität Frankfurt a. M. Paper. Price, 10.50 marks. Pp. 127, with 45 illustrations. Leipzig: Georg Thieme, 1931.

This monograph presents results of studies of the physics of blood clotting. The function of surface forces in clotting receives especial attention. For blood transfusion, correct counting of thrombocytes and other purposes, it is desirable to use containers—syringes and vessels—the surfaces of which delay clotting. The author has made an effort to find substances that are more practical than paraffined glass for this purpose. Certain formaldehyde-phenol products delay coagulation, but the most promising substitute for paraffined glass appears to be amber, which, besides presenting surfaces which inhibit clotting for a time, also has the highly desirable quality of transparency. The author believes that his results will lead not only to valuable practical improvements in the handling of fresh blood but also to new and fruitful methods of investigating the blood itself.

Quantitative Estimation of Vitamin D by Radiography. By R. B. Bourdillon, H. M. Bruce, C. Fischmann and T. A. Webster. Medical Research Council, Special Report Series, No. 158. Paper. Price, 1s. Pp. 48, with illustrations. London: His Majesty's Stationery Office, 1931.

This is a detailed account of a method for the quantitative estimation of vitamin D, based on the roentgenographic examination of the healing of rickets in rats, for which an arbitrary scale of twelve different stages of healing is used. The curative effects of graded doses of the substance under examination are compared with the effects produced in a comparable series of animals by doses of a standard preparation, both being measured in terms of the roentgenographic scale described in this paper. Some of the factors taken account of in using this technic are breeding stock, age, weight, diet and caging of the young rats used for the test, and x-ray plant operated under specified conditions. A representative healing scale with detailed description is presented. Twelve roentgenograms comprise the series used in the scale, each picture being distinct enough to be distinguished from the others and to represent a definite state in the calcification process. The scale has been calibrated by tests on a large number of rats and found to be approximately logarithmic in nature. The chief sources of error in this technic prove to be variations in response of litter mates to vitamin, and mistaken judgment as to the degree of healing, the latter being responsible for nearly a third of the total error.

Bedside Interpretation of Laboratory Findings. By Michael G. Wohl, M.D., Associate Professor of Experimental Medicine, Temple University Medical School. With an introduction by Joseph McFarland, M.D., Sc.D., Professor of Pathology, University of Pennsylvania. Cloth. Price, $6. Pp. 321, with 133 illustrations. St. Louis: C. V. Mosby Company, 1931.

This book is noteworthy for its simplicity. It adds a few clinical interpretations of laboratory observations to those found in the ordinary textbooks on laboratory and clinical methods of diagnosis. In reality, the book is merely a summary of the work found in many textbooks and correlated for the purpose of clinical medicine and bedside teaching.

Medicolegal

Narcotic Addiction as Affecting Veracity

(Kelly v. Maryland Casualty Co. (U. S. D. C.), 45 Fed. (2d) 782; Maryland Casualty Co., Inc., v. Kelly (U. S. C. C. A.), 45 Fed. (2d) 788)

The Maryland Casualty Company, Inc., insured the Bank of Ivanhoe against loss by robbery or burglary. The bank was robbed. The plaintiff, J. M. Kelly, as receiver of the bank, thereafter sued the company, to recover under the insurance policy the amount lost through the robbery. In the United States district court for Western District of Virginia, Henry Clay McDowell, Judge, judgment was given in favor of the plaintiff, and the insurer thereupon appealed to the United States Circuit Court of Appeals, Fourth Circuit.

The cashier, a woman, was the principal witness for the plaintiff. She testified that while she was alone in the bank a masked man entered, pointed a pistol at her, and demanded the money in the bank. She handed him the money in the cash drawer, some $600 or $700, and then became unconscious. When she regained consciousness two hours later, she was locked in the vault, from which $5,600 was missing. She was in an hysterical condition and had hysterics and convulsions, which might have been either feigned or involuntary, from the time of her release from the vault until she was taken to the hospital about seven days later. On entering the hospital, she claimed to be suffering from an injury to the head, which she thought had been inflicted at the time of the robbery, either by a blow from the robber or by a fall. Her physician testified that during eighteen months he had personally administered to her from time to time, to relieve her from suffering, from 3 to 5 grains of morphine per week. The physician who saw her when she was admitted to the hospital testified that she was under the influence of morphine and was not suffering from a blow on the head. There was evidence that she had taken 4 grains of morphine and 5 ounces of chloroform the night before. There was, however, no evidence to show that she was under the influence of morphine either at the time of the alleged robbery or when she was testifying.

Counsel for the defendant insurance company, desiring to impair the credibility of the witness, offered to prove by a physician then present that she had for about eighteen months been addicted to the use of morphine. This physician, he said, would furthermore testify:

> My opinion is that an excessive use of morphine, such as indicated, might tend to undermine the morale of a person, especially for truthfulness, and make them cunning. It also tends to make them unreliable. I might also say that a drug addict might feign anything.

As the witness, the cashier of the robbed bank, had testified that her condition was due to her injuries, evidence of her addiction to the use of narcotic drugs, tending to contradict her testimony, was competent and admissible for that purpose. Such evidence was held incompetent and inadmissible, however, for the purpose of proving that the witness "was a dope addict, and that dope addicts are incredible."

In passing on the proffer of evidence to show that the witness was a narcotic addict and the effect of such addiction, Judge McDowell discussed elaborately and carefully the admissibility of evidence of narcotism, and more especially of evidence of morphinism, for the purpose of weakening the credibility of a witness. To that end he examined not only law books but every medical work that he was able to obtain from local physicians. In discussing this rather unusual resort to medical literature, Judge McDowell quoted Wigmore as follows:

> "Finally (and apart from the use, already referred to, of literary works and dictionaries) there is often found an open and deliberate citation by the court itself to encyclopedias, medical works, and the like, as giving a foundation of fact for subjects involved in their decisions."—3 Wigmore, Ev. (ed. 2), section 1700 d, page 651.

Several rules of law concerning the admissibility of evidence of drug addiction have been stated, said Judge McDowell, and,

> no court could have formulated, and no court could intelligently adopt or reject, any one of those rules, without having accepted as sound some theory as to the usual effect of narcotic drug addiction on the addict. And an intelligent adoption of one, rather than of some other, scientific theory makes necessary some knowledge of the different theories and of the reasoning supporting them. It seems to me to follow that it is the duty of a judge in my situation to inform himself as well as he reasonably may concerning the reasons for the differing medical opinions before he undertakes to make a choice between them.
>
> Again, it is to my mind much more satisfactory for the judge to read all the medical works he can reasonably obtain, rather than to rely wholly on the medical works selected by medical witnesses, whose selections might easily be influenced by conscious or unconscious partisanship.

Typical among the quotations from medical books, that Judge McDowell set forth to show what he found to be evidently, until recent times, the universal, or almost universal, medical opinion, and to be still the medical opinion of a very considerable body of writers, is the following:

> "Persons addicted to morphia are inveterate liars, and no reliance whatever can be placed upon their statements. In many instances this is not confined to matters relating to the vice."—William Osler and Thomas McRae, Principles and Practice of Medicine (ed. 9), p. 392.

Judge McDowell found, however, medical writers supporting "a more modern theory," and quotes effectively from what they have written. The following is typical of these quotations:

> "No addict who receives an adequate supply of opium and has money enough to live is converted into a liar or thief by the direct effect of the drug itself."—Lawrence Kolb, U. S. Public Health Service, Drug Addiction in Its Relation to Crime, Mental Hygiene **9:** 74-89.
>
> "That individuals may take morphine or some other opiate for twenty years or more without showing intellectual or moral deterioration is a common experience of every physician who has studied the subject."—Lawrence Kolb, U. S. Public Health Service, Pleasure and Deterioration from Narcotic Addiction, Mental Hygiene **9:** 699, 724.

In view of the conflicting statements in medical literature, Judge McDowell concluded:

> it is manifest that there is now no consensus of medical opinion to the effect that morphine addicts are usually abnormally untruthful in respect to matters not connected with the vice. And it follows that there is no justification for treating the older theory, or either theory, as a matter of common knowledge.

On the other hand, he found an agreement, practically universal, on two points:

> Nearly all drug addicts are untruthful in respect to the fact of addiction. This is also true in respect to obtaining, and in respect to retaining possession of, the desired drug, where there is any fear of a failure of supply.

On the whole, Judge McDowell concluded, an inference that morphinism usually causes abnormal mendacity in respect to matters in general is of such doubtful validity that it cannot be accepted as a matter of law.

The theory that narcotic addicts live in an unreal world and thus become unable to distinguish between images and facts, stated in *State* v. *Fong Loon*, 29 Idaho 248, 158 Pac. 233, and in Wharton and Stillé, Medical Jurisprudence (ed. 3), section 1111, Judge McDowell found himself unable to accept, arguing:

> But because a narcotic drug has some particular effect on people who are unaccustomed to such drug, it does not follow that the same drug has a similar effect on those who have become addicted to its use. . . . I cannot here do more than say that the impression left on my mind by the medical works I have read is that morphine addicts obtain from their usual dose merely freedom from "withdrawal pains," and that pleasurable sensations, including the dream state, can be obtained only occasionally and by means of a sudden increase in the size of the dose.
>
> At the least, there is certainly room for some doubt if narcotic drug addicts do live in an unreal world. And, even if they do, the assertion that long-continued day dreaming causes mendacity seems to me to require more supporting evidence than I have been able to find. Day dreamers are usually impractical people, but they are not generally understood to be more untruthful than are people who do not indulge in day dreaming.

The rule laid down in the Cyclopedia of Law and Procedure (40 Cyc. 2575) which authorizes the introduction of evidence to show that a narcotic drug addict was under the influence of the drug of addiction at the time of the occurrence about which the addict has testified, or is so at the time of testifying, Judge McDowell regarded as unsound. The rule is based on the theory that narcotic drug addicts are stupefied by such drugs, like people who are not accustomed to their use, and that their powers of observation, memory and narration are temporarily impaired. It would be contrary to all experience, however, if the usual dose of a morphine addict were to affect him exactly as that drug affects people who are not accustomed to it. There is much room for doubt if the usual dose of a morphine addict stupefies him, or if it has any effect except to prevent withdrawal pains. The medical writers seem to be agreed that whenever a morphine addict is not under the influence of at least his usual dose he is in a state which ranges from extreme discomfort to intense pain. In other words, morphine addicts should be mentally at their best when under the influence of their customary doses, and at their worst when in need of their drugs of addiction.

Evidence of morphinism on the part of a witness, if supported by competent evidence to the effect that the memory of that particular addict has in fact been impaired or by competent opinion evidence to the effect that the addiction of the witness has been for a sufficient period, or that amounts used have been great enough probably to impair the memory of the addict, clearly may be admissible. But, Judge McDowell concluded, evidence of drug addiction standing alone should not be admitted on the ground that it may have impaired the addict's memory. The addiction may have had such an effect, and it may not. There is medical authority for the assertion that long-continued addiction or a very large consumption of a narcotic drug does usually impair the memory. But not all drug addicts have been such for a long period, and some do not use and never have used large quantities of the drug of their addiction. Many medical works make no mention of impairment of memory as a result of narcotism. Evidence of addiction would, therefore, in many cases be admissible.

Nevertheless, in *Wilson* v. *United States*, 232 U. S. 563, 34 S. Ct. 347, 58 L. Ed. 728 (1913), a defendant in a criminal case, on cross-examination, admitted that she was addicted to the use of morphine and stated that she had taken her last dose of the drug at 10 o'clock that morning. The Supreme Court held that evidence was admissible. But whether or not that decision makes admissible further questions from the cross-examiner, to show that the witness is a morphine addict, is not clear. Judge McDowell thought that that was not the necessary effect of the decision. Owing to the popular belief that drug addicts are unveracious, knowledge by the jury of the bald fact of addiction would do an illegitimate injury to the credit of the witness; illegitimate, because the basis of the ruling in the case just cited was not a probability of mendacity but a probability of some degree of still continuing temporary stupefaction of the mental powers of the witness, due to the recent dose of morphine.

In affirming the judgment of the district court in favor of the plaintiff, the Circuit Court of Appeals, Fourth Circuit, said:

> As she (the witness) had testified that her condition was due to her injuries and the evidence tended to contradict her, it was competent for that purpose. But it is insisted that it should have been received for all purposes, principally for the purpose of showing she was a dope addict, and that dope addicts are incredible. Without entering upon a discussion of the tendency, if any, of the excessive use of morphine to undermine the moral attributes of the user, it suffices to say there is no sufficient evidence in the record to show that Mrs. Huddle had made such excessive use of it, and the court committed no error in restricting the evidence.

Workmen's Compensation: Hernia or Hydrocele.—About ten months after an alleged blow on the abdomen in the course of his employment, the claimant filed his application for compensation under the workmen's compensation act, asserting that the blow had caused a hernia. An order of the workmen's compensation board awarding compensation was affirmed by the circuit court, Harlan County, and an appeal was taken to the Court of Appeals of Kentucky. The claimant testified that after the injury he was examined by about thirty physicians, all of whom advised him that he had a hernia, but he was unable to give the name of any physician but one, who himself denied ever having examined the claimant after he was injured. A physician testifying on behalf of the claimant said that the claimant was not able to do manual labor, that his ruptured condition could have been caused by such an accident as the claimant described, that the claimant had a hydrocele near the hernia, and that because the claimant was anemic and had tuberculosis, it was his opinion that the claimant was not a good surgical risk and ought not to undergo a surgical operation. On the other hand, the physician named by the claimant as having examined him testified that he had never seen him nor treated him after the injury, but that his records showed that the claimant was examined before he entered the service of his employer from whom he was now claiming compensation and that at that time he was not ruptured, but had a hydrocele and some tenderness, which would not interfere with his work. Another physician testified that he had examined the claimant after the injury, preparatory to giving evidence, by the use of the x-rays and by physical examination, that there was no evidence of hernia, that he had a hydrocele of long standing which was not due to trauma, and that while his condition might interfere slightly with his work, it could be relieved by a simple operation. The Court of Appeals, however, affirmed the order of the circuit court, Harlan County, which had affirmed the order of the workmen's compensation board, awarding compensation to the claimant because of his alleged hernia arising from an injury in the course of his employment. —*Mary Helen Coal Corporation v. Hooker (Ky.), 35 S. W. (2d) 535.*

Wills: Testimony of Attending Physician Concerning Competence of Testator.—An attending physician may express an opinion concerning the competence of a testator without giving the reason on which his opinion is based. This rule applies with greater force when the witness is the family physician, one who has known and attended the testator over a period of years and has thereby become intimately acquainted with his physical and mental constitution and peculiarities. His testimony, under such conditions, is more than a mere opinion. It is equivalent to knowledge.—*Davidove v. Duvall (Md.), 153 Atl. 417.*

Frontal Sinusitis Attributed to Trauma.—The plaintiff in falling struck her head against a wall. The impact was so severe as to cause swelling and tenderness over her left eye and resulted in pus forming in the sinus above the eye. She was operated on for the sinus trouble. The wound healed quickly, but she was suffering at the time of the trial from conjunctivitis and impaired vision. The Kansas City Court of Appeals, Missouri, held that an instruction that allowed the jury to conclude that the injury was permanent was not erroneous.—*Burnison v. Saunders (Mo.), 35 S. W. (2d) 619.*

Wills: Criteria of Testamentary Capacity.—Neither sickness nor impaired intellect is sufficient, alone, to render a will invalid. If at the time of the execution of the will the testator was capable of recollecting her property and the natural objects of her bounty and their claims on her, and knew the business about which she was engaged and how she wished to dispose of her property, that is sufficient. Moreover, those who would impeach a will on the ground that the decedent was incompetent must clearly prove that incompetence.—*Tabb v. Willis (Va.), 156 S. E. 556.*

Evidence: Medical Witness's Discussion of Facts with Others.—In a personal injury suit, the defendant, over the plaintiff's objection, asked one of the plaintiff's medical witnesses if he had conferred with other physicians in attendance on the plaintiff. Objection was made on the ground that the inquiry sought to elicit an immaterial fact. We believe, said the Supreme Court of Oregon, that the information sought was material; it is always permissible to ask a witness whether he discussed the facts with any other person.—*Stotts v. Wagner (Ore.), 295 P. 497.*

Drunkenness: As Excuse for Delay of Trial.—Intoxication resulting from the recent use of ardent spirits is no excuse for crime and the court of criminal appeals of Texas doubted whether it would be justified in establishing a precedent that one who is drunk may rely on that fact as an excuse for not going to trial on a criminal charge.—*Perry v. State (Texas), 33 S. W. (2d) 1072.*

Society Proceedings

COMING MEETINGS

Mid-South Post-Graduate Medical Association, Memphis, Tenn., February 9-12. Dr. A. F. Cooper, Bank of Commerce Building, Memphis, Secretary.

Society of American Bacteriologists, Baltimore, December 28-31. Dr. James M. Sherman, Cornell University, Ithaca, N. Y., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Prognosis of Angina Pectoris.—White and Bland made a clinical study of 500 cases of angina pectoris and of 200 cases of coronary thrombosis. They present an analysis of certain factors the presence of which may or may not influence the gravity of the prognosis. The importance of the subject is evident because of the increasing frequency of angina pectoris and of the responsible position in the community of many of the patients. Of the series of 500 patients with angina pectoris, 213 are dead with an average duration of life of 4.4 years after the onset of the disease. The average duration of life to date for the total series of 500 patients was 4.9 years. Of the patients who died, death could be attributed to failure of the heart in 82 per cent, and a sudden exitus was frequently encountered. About one fifth (19 per cent) had normal hearts on physical examination, normal blood pressures, and normal electrocardiograms. This combination of observations was an unusually favorable sign. Coronary thrombosis, although frequently encountered, did not affect appreciably the duration of life, provided the patient survived the acute attack. The presence of hypertension appeared not to be of serious import. The electrocardiogram was of little help in predicting the outcome, although a "coronary" type of T wave in lead I or II was seen more often in the patients who died early. The presence of syphilis, angina decubitus, poor heart sounds, definite cardiac enlargement, congestive failure, or marked arteriosclerosis appears to be unfavorable, and the more of these factors present in the given case, the worse is the prognosis. A vital factor in the prognosis is the degree of care to which the patient can and will submit; the more careful the life of the individual, the longer as a rule will he live. Of the series of 200 patients with coronary thrombosis 101 are dead, with an average duration of life following the attack of 1.5 years. The average duration to date for the entire series of 200 patients was 2.4 years. The patients who died almost invariably succumbed to failure of the heart. The younger patients as a rule lived a little longer; the sex appeared to be unimportant. Neither the previous occurrence of angina pectoris nor its duration prior to the attack of coronary thrombosis seemed to matter. Hypertension was not important. Syphilis was rarely encountered. Cardiac enlargement of considerable degree was a somewhat unfavorable sign, while the presence of congestive failure and poor heart sounds added considerably to the gravity of the prognosis. The electrocardiogram did not help appreciably in this series. Good treatment was important.

Electrocardiogram in Heart Disease.—In a study of 100 cases of advanced cardiovascular syphilis, using like numbers of cases of arteriosclerotic and rheumatic heart disease for comparison, Friedlander did not note any electrocardiographic changes pathognomonic of syphilitic heart disease. The electrocardiographic picture in syphilitic and in arteriosclerotic disease shows a striking parallelism. The variations from the normal as found are due to the myocardial degeneration and are not characteristic of the syphilis alone. While it is true that certain of the arrhythmias and certain abnormalities of the T wave are of sinister prognostic import, it appears to be quite true that this is the case in the arteriosclerotic as well as in the syphilitic cases. There is thus no characteristic electrocardiographic picture of cardiovascular syphilis, and it is not justifiable to make definite forecasts of the prognosis in this disease from the electrocardiogram alone.

Familial Tendency of Coronary Disease.—Musser and Barton advance the thesis that there are two quite distinct expressions of coronary occlusion. The one is observed in elderly individuals, possessors of a well marked sclerosis of the arterial tree as a whole and in whom the etiologic factors are those of arteriosclerosis in general and represent largely the effects of senescence. The other occurs in men, as a rule, not past the sixth decade of life who do not have generalized arteriosclerosis, who may have relatively slight, but never exaggerated, hypertension, who have been singularly free from past infections, and who often give a history of coronary occlusion in several members of their family.

Ventricular Paroxysmal Tachycardia.—McMillan and Bellet report a case of ventricular tachycardia in which the following interesting features were noted: (1) the youth of the patient (sixteen years); (2) the absence of any definite evidence of a damaged heart; (3) the occurrence of the disturbance during pregnancy and its failure to disappear on the termination of gestation; (4) the ready abolition of the tachycardia by quinidine, and (5) the successful and uneventful outcome of a cesarean section performed during the tachycardia.

Occluding Thrombi of Left Auricle.—Schwartz and Biloon give the case histories of three patients in whom a clinical diagnosis of an occluding thrombus of the left auricle suspected during life was confirmed by postmortem examination. Two of these patients had mitral stenosis and one had hypertension. In one patient the diagnosis of a ball thrombus was suspected on the basis of the sudden and transitory appearance of peripheral vascular disturbances, such as uniform discoloration with cadaveric appearance of the extremities at a time when pulsations of the vessels to these limbs were totally absent. During such periods the sensorium was disoriented, the patient was in mild shock, the skin was cold, moist and clammy, and the first heart sound was inaudible, while oscillometric readings of the limbs affected did not reveal any movements. A diagnosis of an occluding auricular thrombus was based in one case on the rapid development of uniform discoloration with gangrene of the terminal phalanges of the ten toes and ten fingers, which persisted for more than a month until death. In the other case this diagnosis was based on the rapid progressive appearance of pain and gangrene of the legs and arms, with weak pulsations in the vessels supplying these limbs. All three patients showed auricular fibrillation with a rapid ventricular rate and were refractory to large doses of digitalis. It is probable that the irregular heart action favored the rapid development and increase in size of the auricular thrombi. The circumstances responsible for the formation of ball or pedunculated thrombi are still unknown. The mechanics of gangrene formation in the presence of an occluding thrombus of the left auricle is based on its obstruction of the mitral orifice causing a diminished blood flow to the periphery. This is enhanced by the further incomplete diastolic filling of the left ventricle because of the rapid and irregular heart action. The onset of such peripheral disturbances in patients with heart disease is of grave prognostic significance, for death takes place shortly after their appearance.

*Skin Temperatures of Children. F. B. Talbot, Velma Bates, Eleanor Bates and Alice J. Dalrymple, Boston.—p. 965.

Skin Temperatures of Children.—Studies of skin temperatures of children made by Talbot and his co-workers by means of a thermocouple showed the following facts: 1. There is a local variation of the temperature of the skin over different parts of the body, even in normal children, the temperature of the trunk being highest, the face next and the extremities lowest. The temperature of the feet tends to be lower than the temperature of the hands. 2. Surrounding temperature has a definite effect on the temperature of the skin of the body even when the child is clothed. The cooler the room is, the lower the temperature of the skin. 3. There is also a seasonal effect on the temperature of the skin. 4. This investigation showed that humidity within the limits of room temperature and room humidity studied had no effect on the temperature of the skin. 5. There is a rapid loss of heat from the surface of the body on exposure. This affects the face least, the body next and the extremities most. There is a greater variation in the reaction of the extremities to different surrounding temperatures than in other parts of the body. This suggests that the extremities act as safety valves for the conservation or the elimination of heat. 6. During fasting the temperature of the skin, as well as that of the body, becomes reduced. 7. Exercise has a definite effect on the skin temperature. During the first few minutes of exercise the temperature of the skin falls and later rises. This may be of profound physiologic importance and suggests that when exercise is first commenced heat is retained in the body in order to increase the efficiency of the muscles. 8. This work gives further evidence that the heat-regulating apparatus of the premature infant is not developed. The temperature of the skin, as well as that of the body, is affected directly by the surrounding temperature and to a greater degree than it is in normal babies. 9. Studies were made of the effect of fever on subjects with different body temperatures. These were grouped in such a way that the skin temperature for different fevers and different room temperatures are now available and are presented as possible standards of expected skin temperatures for different body and room temperatures. 10. The skin temperature was recorded in a number of cretins with lowered basal metabolism. Some of them were also studied after the metabolism had been elevated by the use of thyroid extract. When heat production was found increased, the temperature of the skin was increased. 11. A variety of pathologic cases were studied without showing any relationship between the temperature of the skin and the type of illness which the patients were suffering.

Anterior Pituitary Luteinizing Substance in Treatment of Functional Uterine Bleeding.—Novak and Hurd describe the results they obtained in the treatment of fifty-one women with functional uterine hemorrhage by an anterior pituitary luteinizing principle derived from the urine of pregnant women. In forty-four of these the treatment was successful in checking the bleeding, even though some of the patients were treated with preparations of somewhat uncertain luteinizing potency. Most of the failures were in this group. Previous efforts at the organotherapy of this condition have been unsuccessful. Radiotherapy is highly undesirable in young women, so that, because of the frequent intractability of functional hemorrhage, many patients have had to submit to repeated curettage. With strongly luteinizing preparations, it was possible to check functional hemorrhage in twenty-seven of twenty-nine cases. In fourteen of the fifty-one cases the bleeding ceased after a single injection, and in twelve after two injections. A large proportion of these were of the intractable and recurrent type, many of the patients having had from one to four or more curettages. With less potent luteinizing preparations the results were less impressive but, on the whole, satisfactory. The authors' experience with the entire group has convinced them of the value of the treatment in functional hemorrhages, and of its even greater future possibilities.

Rabbit Ovulation Test in Diagnosis of Pregnancy.—Wilson and Corner present results obtained from the urines of 196 women on whom the rabbit ovulation test as suggested by Friedman was made. The observations correspond closely to those reported in the use of the Aschheim-Zondek reaction, with apparently a small percentage of error. Its advantages over the latter are found chiefly in the much shorter time necessary, its simplicity, and a possible economy of laboratory animals. From their experience the authors believe that it should prove to be an extremely valuable and practical method for the early diagnosis of pregnancy. In their series, with the exception of a single case of endometrial hyperplasia, a positive reaction always indicated the presence of active fetal tissue in biologic contact with the maternal blood stream, or recently (not over seventy-two hours) separated from it. A negative reaction does not entirely exclude the possibility of a pregnancy being present, since the intra-uterine or extra-uterine ovum may have perished and been retained for some period of time. The test may prove to be of some value in determining the life or death of the ovum in the early months, though not its immediate death, and not in the later months of pregnancy.

Study of Postoperative Value of Barbituric Acid Hypnotics.—Maxwell calls attention to the fact that opium and its derivatives increase the frequency and severity of postoperative distention and vomiting and are not necessary to relieve pain. Barbituric acid hyptonics are satisfactory from a pharmacologic and clinical standpoint when combined with an analgesic (amidopyrine). It is illogical to combine these agents in fixed proportion, because of the marked difference in their rate of elimination; it is rational to administer them separately according to clinical indications. Barbital, by virtue of its simple chemical structure, is less toxic and clinically as effective as its more complex and toxic modifications. The author recommends these hypnotics because their action is limited to the central nervous system and their use is followed by a high incidence of amnesia and by little disturbance of organic function.

Length of Labor.—Calkins and his associates believe that a more accurate observation of the resistance of the cervix (and the pelvic floor), as well as more accurate determination of the effectiveness of the labor pains, will be necessary in order to analyze the causes for the extreme variations in the length of labor so commonly encountered. More accurate determination of the resistance would likewise enable one to predetermine the probable duration of the labor. Deliberate appraisal of the various factors present in any given labor, when balanced against a more definite knowledge of the forces present and functioning, might also serve to reduce the present high rate of operative intervention. To this end, it is suggested that the consistency of the cervix, as well as the thickness of its wall and the length of its canal, be accurately determined and recorded before labor begins or as early in labor as possible. Such a record on a scale of five (one being a very soft cervix, three one of average softness, and five a firm resistant cervix) has been kept in a few hundred cases with surprisingly satisfactory results. It is suggested that the effectiveness of labor pains be more accurately determined and recorded for the purpose of increasing one's ability to determine the probable length of labor in each given case. Experience with a small series thus estimated on a scale of five (with one and two representing poor pains, three average pains, four hard pains, and five abnormally hard pains), has proved highly suggestive. In the grading of labor pains, more attention is paid to the intensity of the contraction than to duration or frequency, although all three factors must be given consideration. Intensity of first stage contractions can be satisfactorily estimated by digital (not palmar) palpation of the fundus or by palpation of the tension, and amount of stretching, produced in the cervix. Likewise, in the second stage, digital palpation of the fundus is preferred to the determination of the amount of descent or the amount of stretching of the pelvic floor. It is believed that accurate determination of the effectiveness of the labor pain balanced against the resistance of the cervix and pelvic floor is the all important factor in determining the length of labor. The other variants, as analyzed by the authors, are of only minor importance.

Manifestations of Rheumatic Fever in Relation to Climate.—According to Longcope, the available statistics concerning the geographic distribution of rheumatic fever indicate that the disease is rare or almost unknown in the tropics, and much less commonly observed in the warmer portions of mid-temperate zones than in the colder portions. In some regions where rheumatic arthritis is said to be rare, mitral stenosis is quite frequently observed. At the Johns Hopkins Hospital in Baltimore the admission rate to the adult medical wards for rheumatic fever, in all its forms and in all its stages, over a period of five years was 1.37 per cent. The necropsy rate for rheumatic heart disease over a period of twenty-one years was 1.66 per cent. The disease, therefore, is comparatively common. An analysis of 142 cases of rheumatic fever studied during this period showed that symptoms or signs of cardiac disease appeared in the past histories of 50 per cent of the cases. Cardiac disease was present on admission to the hospital or was detected during observation in 95 per cent of these cases. Only 6 of the entire 142 patients presented symptoms and signs of arthritis alone, but in more than 77 per cent arthritis, often of mild degree, occurred at some time during the illness for which they were admitted to the hospital. Rheumatic fever, as it is seen at the Johns Hopkins Hospital, is essentially a disease of the heart, frequently preceded or accompanied by arthritis, often of mild degree, or by chorea. Severe acute arthritis is rarely seen, but acute pericarditis and pleurisy are not very infrequent. The author suggests that the infrequency of severe acute arthritis, the great frequency of carditis and the comparative insidiousness of the disease during the acute and subacute stages render the clinical picture of rheumatic fever somewhat different in Baltimore from that generally described for more northerly sections of the United States.

Colonic Changes in Chronic Arthritis. — Dickson gave barium enemas to normal rats, well nourished and fed on a diet rich in vitamin B. After this examination a diet deficient in vitamin B was exhibited for several weeks, when a second enema was given. The diet was again returned to one high in vitamin B and a third enema administered in a month's time. The colon underwent marked changes during the observation. The second examination showed the bowel elongated and markedly atonic, so atonic in fact that the pressure from the flow of the enema was great enough to rupture the colon, and the enema poured out into the abdominal cavity. The rats not lost by this accident were at once placed on a diet again rich in vitamin B, and further observation was made in a month's time. At the third observation the tone of the intestine had returned to normal, and the intestine was much shortened in its total length. In some of the rats it was difficult to demonstrate any difference between appearances at the first and at the third enema. With this point in mind, the author assumed that some of the abdominal disturbances of chronic arthritis might be associated with nutritional deficiency, and investigation was undertaken in an attempt to prove or disprove the theory. The first step was to demonstrate the incidence and type of colonic abnormalities in arthritic cases. When this had been done, periodic examinations were made to demonstrate the effect of suitable diet on the clinical progress and the roentgenologic appearance of the large intestine. In many cases the return to a normal appearance was indeed amazing. In others, and these were complex cases in which nutrition alone played only a minimum part, the changes were slight or absent. It was, however, extremely interesting to note that in the majority of cases the improvement noted on the film bore a close relation to the improvement noted clinically. Latterly, the author has been able with a fair degree of accuracy to state from the roentgenologic examination the amount of improvement, shown clinically, without any progress history being supplied from the clinician. Also it has been possible after the first examination in some cases to give a prognosis pointing toward failure that has been borne out by the patient's subsequent course.

Occlusion of Right Branch of Pulmonary Artery by Thrombus.—Means and Mallory report a case which illustrates the fact that total thrombotic occlusion of a main branch of the pulmonary artery may occur without damage to the lung, provided it develops slowly enough to allow for the development of collateral circulation through the bronchial system. Such a lesion may not produce local signs in the lungs, but the presence of cyanosis and right-sided heart failure without other obvious cause may suggest its presence. The case is interesting from the point of view of morbid physiology in that it proves that an entire lung may be separated from its pulmonary artery supply and suffer no injury of any sort provided the occlusion is gradual, allowing time for the establishment of collateral circulation from the aorta. The situation reminds one of those cases of chronic total occlusion of both coronaries without history of the characteristic picture of coronary occlusion. The effect of slow closure of the pulmonary artery is evidently different from sudden shutting off, as from embolism or ligation, in which cases the picture of infarction is produced.

Use of Oxygen in Heart Disease.—Barach studied the therapeutic use of oxygen in eight patients with congestive heart failure due to primary cardiac disease, in five cases of cardiac insufficiency developing as a sequela to chronic pulmonary diseases, in four cases of acute coronary thrombosis, and in three cases of coronary arteriosclerosis with chronic cardiac pain. In the cases of congestive heart failure the most striking effects observed were relief of dyspnea and orthopnea, diuresis and disappearance of edema, and a marked rise in the carbon dioxide content of the arterial blood. Other observations noted were relief of cyanosis, increased arterial oxygen saturation, decreased pulmonary ventilation, lowered pulse rate, and decrease in the lactic acid content of the blood. In cases of acute coronary thrombosis, life appeared to be prolonged by the inhalation of an oxygen-enriched atmosphere until the heart was able to recover from its acute functional disturbance. The cases of coronary arteriosclerosis with chronic cardiac pain were relieved by residence in a high oxygen atmosphere. These results indicate that oxygen want is the primary factor in the production of many forms of cardiac dyspnea. The increase in carbon dioxide content of the arterial blood occurs as an adaptative change which facilitates the elimination of carbon dioxide. The clinical improvement which patients suffering from the various forms of heart failure experience suggests a new employment of oxygen therapy by effective methods in these conditions.

Reaction to Nitrites in Arterial Hypertension.—Burgess states that, except for a transient fall in blood pressure after amyl nitrite, neither it nor glyceryl trinitrate when used in the usual therapeutic doses causes any consistent blood pressure changes in normal human beings or in persons with arterial hypertension with or without severe renal damage or retinal arteriolar sclerosis. The fall occurring after the use of amyl nitrite is so rapid and transitory and so independent of subjective symptoms that it is impossible to measure it accurately by taking blood pressure determinations in the ordinary way. This fact greatly decreases its usefulness as a test for arteriolar relaxability in estimating the prognosis in arterial hypertension. In persons suffering from attacks of angina pectoris of the usual ambulatory type, a rapid fall in systolic and usually in diastolic pressure takes place after the use of these drugs. The pain relief that occurs in these cases of ambulatory angina is independent of the pressure levels, and therefore apparently independent of the action of the nitrites on the peripheral vessels, but due to their action in increasing coronary circulation. The cause of the pain in ambulatory angina is probably an ischemia of the myocardium dependent on an insufficient blood supply due to disease of the coronary arteries.

Auricular Flutter and Complete Heart Block: With Restoration of Sinus Rhythm and Auriculoventricular Conduction.—Gager restored a patient with complete heart block to sinus rhythm and auriculoventricular conduction by the use of quinidine sulphate. Physical and mental improvement resulted. Fifteen cases were found in the literature showing the association of auricular flutter and total block, and the clinical phenomena and criteria for diagnosis are reviewed. From experimental and clinical observations in partial block and from the results in three cases of complete block, the author shows the value of restoring sinus control in cases of auricular flutter.

Sulphur for Production of Fever in Peripheral Vascular Diseases.—Waller and Allen made observations on pain at the site of injection, on relief of pain in ulcerated or gangrenous regions, on healing of ulcers, on height and duration of fever, and on chill and leukocytosis in fifteen cases of peripheral vascular disease, in which thirty-two intramuscular injections of sulphur, 2 per cent, in olive oil were given. Fever began about seven hours after the injection; the temperature reached an average maximal level of 102 F. and lasted an average of fifty hours. Chills occurred following approximately 50 per cent of the injections, but they were mild when doses of suspension of sulphur of 1.5 or 2 cc. were given. The most satisfactory dose in the treatment of peripheral vascular disease was 1.5 or 2 cc. Greater amounts were rarely necessary to produce effect even later in the course of the injections. Clinical improvement was as marked following intramuscular injection of sulphur as that induced by intravenous injection of typhoid vaccine, and occasionally it was more striking. The pain at the site of the injection varied from moderate to severe and constituted the greatest disadvantage to intramuscular injection of sulphur in olive oil. Sulphur in olive oil, injected intramuscularly, in the treatment of peripheral vascular disease, is most satisfactory for persons of advanced age, for those who are resistant to treatment by vaccine, and for those in whom the pain from the injection is not excessive.

Mediastinal Displacement in Pneumothorax.—Pollock gives roentgen evidence that a disturbance of the normal physiologic intrathoracic pressure during the course of artificial pneumothorax therapy may produce mediastinal displacement when the mediastinum is sufficiently flexible. Mediastinal displacements eventrating into the contralateral lung during the phase of expiration are not of clinical significance. However, fixed displacements in the presence of a relatively nonelastic mediastinal pleura produced by excessive pressure in the pneumothorax cavity may give rise to respiratory embarrassment and a sense of pressure to the stage of discomfort. A reduction of the displacement results in comfort to the patient. Mediastinal displacement depends on flexibility of the mediastinum, the intrathoracic pressure in the pneumothorax cavity, and the relative fixation of the mediastinal contents. A relatively flexible mediastinum usually occurs in younger adults early in artificial pneumothorax treatment, and the mediastinum tends to become less and less flexible as pneumothorax therapy is continued.

Protein Fever in Rabbit Syphilis.—Kolmer found that the intravenous injection of typhoid-paratyphoid vaccine into syphilitic rabbits in doses of from 1,000,000 to 100,000,000 per kilogram of weight produced a rise of rectal temperature of from 2 to 4 or 5 degrees Fahrenheit, lasting several hours and reaching the preinjection level within twenty-four hours. The treatment of rabbits with acute testicular syphilis with ten intravenous injections of increasing amounts of typhoid-paratyphoid vaccine at intervals of seventy-two hours did not result in complete cure in any of the animals. Ten intravenous injections of the vaccine at intervals of seventy-two hours, together with five intravenous injections of arsphenamine in doses of 0.002 Gm. per kilogram at weekly intervals, did not result in the complete cure of any of the rabbits with acute testicular syphilis. Ten intravenous injections of the vaccine at intervals of seventy-two hours, together with five intramuscular injections of potassium bismuth tartrate in doses of 0.001 Gm. per kilogram at weekly intervals, did not result in the complete cure of any of the rabbits. The intravenous injection of from 0.008 to 0.4 cc. of Coley's fluid per kilogram of weight into syphilitic rabbits produced a rise of rectal temperature of from 3 to 5 or 6 degrees Fahrenheit which lasted several hours and which reached the preinjection level within twenty-four hours. None of the rabbits with acute testicular syphilis that received ten intravenous injections of increasing amounts of Coley's fluid at intervals of seventy-two hours were completely cured. The rabbits with acute testicular syphilis that received ten intravenous injections of arsphenamine in doses of 0.002 Gm. per kilogram or five intramuscular injections of potassium bismuth tartrate in doses of 0.001 Gm. per kilogram at weekly intervals were not completely cured. In the rabbits given intravenous injections every two days of 1 cc. of citrated blood taken from human beings from twenty-four to thirty-six hours after malarial paroxysms there was no rise in temperature, and demonstrable effects on the course of the acute testicular syphilis were not noted. Therefore, the fever of from 2 to 5 degrees Fahrenheit, which lasted several hours and which was induced in rabbits by intravenous injections of increasing amounts of typhoid-paratyphoid vaccine and Coley's fluid, showed much less effect on the course of acute testicular syphilis than the fever induced by hot baths. While the treatment for acute and chronic syphilis in human beings with intravenous injections of typhoid-paratyphoid vaccine and Coley's fluid alone or in combination with chemotherapy has yielded encouraging results, these agents have been without pronounced curative activity in the treatment for acute testicular syphilis in rabbits.

Gingivitis of Pregnancy.—Monash reports several cases in which growths were observed on the gums of pregnant women. They began to form at a variable time during pregnancy, usually during the earlier months, increased in size unless treated, and spontaneously diminished or disappeared after delivery of the child. The growth is usually part of a generalized gingivitis and represents simply an exaggerated degree of the condition. The name "proliferative gingivitis of pregnancy" is proposed. The growth is inflammatory in origin and should not be classed as a true tumor. Prophylactic measures and treatment are discussed.

Syphilitic Bursopathy. — Garner and Schoch report two additional cases of the syphilitic bursopathy of Verneuil, bringing the present number of cases in the literature to thirty-eight. The prepatellar bursae were involved in each case, both patients being women with late syphilis. The chief clinical features of the conditions are discussed, with especial emphasis on the indolence and frequent symmetry of the process, the negative roentgenographic study, the positive Wassermann reaction and the early response to conservative antisyphilitic therapy. In one of the patients the type of scar deserves emphasis. Unlike the usual thin, atrophic scar of a cutaneous ulcerating gumma, it was depressed, dimpled and adherent to the underlying tissue, and did not give a suggestion of the configuration of the original gummatous ulcer.

Dermatitis Venenata from Shoe Leather.—Lewis reports two cases of dermatitis venenata from shoe leather, which point to the fallacy of considering all dermatoses of the feet to be of fungus origin. The condition may have escaped recognition or it is extremely rare, as it is not mentioned in any of the standard textbooks on dermatology or monographs on dermatitis venenata. A review of the literature failed to yield any reports of cases. However, it seems logical to keep the possibility of such a condition in mind when one is dealing with dermatoses of the feet, especially those that have proved refractory to ordinary methods of therapy.

Secondary Anemia.—In a study of the treatment in 126 cases of anemia due to various causes, Keefer and Yang noted the following facts: The recovery from anemia due to chronic loss of blood may be accelerated following the administration of liver and iron. In some cases, transfusion of blood was necessary owing to the severity of the anemia. Continued loss of blood in small amounts and sepsis retard recovery. Anemias resulting from inadequate or faulty diets were often associated with the avitaminoses or other deficiency disorders. Many of these patients recovered following a well balanced diet, and in some regeneration of the hemoglobin was accelerated by the use of liver or iron. The anemia associated with chronic dysentery usually appeared in patients who had been on inadequate diets and who had had active dysentery for two months or longer. Hemorrhage, infection and gastric anacidity played a minor part in the production of the anemia. In the group as a whole, all the clinical features that are said to be characteristic of pernicious anemia were observed, including atrophy of the lingual papillae, subacute combined sclerosis, gastric anacidity and anemia responding to liver extract. These observations lend support to the hypothesis that pernicious anemia is a deficiency disease. Anemia associated with infestation due to hookworm may be cured with iron, or liver and iron, while the patients continue to carry the worms. Malnutrition and faulty diets are important factors in predisposing such patients to anemia. Women with the anemias of pregnancy recover following the transfusion of blood or following the administration of liver and iron. In some cases, iron alone is positive; in others, liver or liver extract is potent in increasing the rate of recovery. Recovery from the anemia associated with kala-azar may be extremely slow in spite of treatment with antimony compounds, transfusions of blood and ingestion of liver and iron. In this condition it appears as if the damage to the bone marrow were responsible for the anemia. When recovery occurred in many of the foregoing types of anemia, the reticulocytes were increased. Generally speaking, the number of reticulocytes depends on the level of the red cell count at the beginning of the treatment, although there were exceptions in cases in which one observed relatively large increases in reticulocytes with a high red blood cell count. In most of these cases the hemoglobin content was low. In other cases an increase in the reticulocytes was not observed following treatment. In some of these cases the reticulocytes had been increased before treatment was begun; in others, they were never increased. When liver ash was given in amounts equivalent to 300 Gm. of whole liver a day, containing 21 mg. of iron, striking results were not observed. In several instances there was a moderate increase in the hemoglobin, red blood cells and reticulocytes, and this response was usually observed in patients who subsequently recovered promptly on larger doses of iron. In some cases of anemia, liver and iron were more effective than when either one was given alone. In others, the maximum effect was observed following the use of iron. Liver extract was of demonstrable value in some of the nutritional anemias of childhood, in some of the anemias associated with pregnancy and in chronic dysentery. It was of little value in posthemorrhagic anemia. From the authors' observations, it was not possible to predict in every case which form of treatment would be most beneficial. If complete recovery is not observed in patients following the use of iron, liver should be added. In many patients who do not respond to liver or iron there is usually an adequate cause to explain their failure. Infection and pathologic processes of the bone marrow are of the greatest importance. The response in various clinical anemias following the ingestion of food substances other than liver, kidney or iron needs further investigation.

Tuberculous Meningitis.—Kramer and Stein give the case history of a Negro who had evidence of syphilitic meningitis; subsequent observations of tuberculous meningitis were made, and a favorable termination is reported. A review of the literature revealed a number of contributions on the curability of tuberculous meningitis and numerous reports of cures. This number was considerably reduced because of insufficient scientific data. Seventy-three cases of presumably authentic cures were collected. A study of this group of cases does not enlighten one with information that may be of value in the

direct treatment for this disease in the future. Cures have been attributed to various factors, such as the age and the resistance of the patient and a low virulence of the organism. Statistics of the collected cases show the highest percentage of cures among patients above 20 years of age (33 per cent), and the lowest percentage in infants. The authors believe that the traditional and fixed idea that a patient with tuberculous meningitis must die should be reconsidered. No doubt, a recovery is extremely rare, but no one can foretell when this unexpected favorable termination may occur. The tendency to discard the diagnosis of tuberculous meningitis and disregard such laboratory observations as the presence of tubercle bacilli and successful inoculation into guinea-pigs, merely because the patient recovered, seems unscientific and illogical.

Exophthalmic Goiter.—Reveno advances the hypothesis that exophthalmic goiter is primarily a disturbance resulting from a long continued toxic process in the intestinal tract. This process not only damages the thyroid to the end that varying amounts of its functioning tissue are destroyed but causes a faulty and irregular metabolism of the amino-acid tyrosine, so that an excess of thyroxine, epinephrine and tyramine is produced. These conclusions are reached in view of (1) the inadequacy of the thyrogenic theory of the disease; (2) the work of McCarrison on the effects of toxic material in the intestinal tract on the thyroid; (3) the close relationship between the chemical constitution of thyroxine, epinephrine and tyramine; (4) the common source of these three substances, viz., tyrosine; (5) the changes in the normal tyrosine-tyrosinase reaction and the decarboxylization process for conversion of tyrosine to phenols, with resulting overproduction of the base tyramine, and (6) the pharmacologic action of tyramine.

Phenolsulphonphthalein Test.—Hanner and Whipple describe experiments from which it is clear that in dogs with necrosis of the liver due to chloroform poisoning there is a distinct rise in the elimination of phenolsulphonphthalein by the normal kidney. A rise in the elimination of phenolsulphonphthalein from a control level of from 75 to 78 per cent to from 90 to 97 per cent may be noted. With repair of the hepatic injury, the elimination of phenolsulphonphthalein returns to normal. Phosphorus poisoning gives a similar but less striking reaction. With experimental biliary obstruction in the dog, the same general reaction is noted, with a definite increase in the elimination of phenolsulphonphthalein by the normal kidney. After hepatic injury due to chloroform, the dog's liver does not remove phenolsulphonphthalein from the blood stream and does not excrete it in the bile, whereas in a normal dog the liver removes much phenolsulphonphthalein from the blood, and about 10 per cent of the injected phenolsulphonphthalein may by recovered from the bile within two hours. A chronic biliary fistula and an Eck fistula may permit a smaller excretion of phenolsulphonphthalein in the bile and a corresponding rise in the elimination of the dye in the urine. There is no evidence that a cholagogue, whether in the normal dog or in one with a biliary fistula, increases the elimination of phenolsulphonphthalein by way of the bile, and consequently the urinary excretion of phenolsulphonphthalein is unchanged. Phenolsulphonphthalein given by mouth is absorbed and reappears in the urine only in quantities equal to from 3 to 5 per cent of the amount administered. Reabsorption, therefore, is a negligible factor when applied to the phenolsulphonphthalein eliminated through the bile into the duodenum. From these experiments and the observations of other workers, it may be concluded that the elimination of phenolsulphonphthalein by the liver and kidney under these conditions is identical in the dog and man. Clinically, an unusually high renal elimination of phenolsulphonphthalein should suggest pathologic changes in the liver. Combined renal and hepatic disease calls for cautious analysis of the renal elimination of phenolsulphonphthalein.

Tumors of Heart and Pericardium.—According to Yater, the symptomatology of tumors of the heart and pericardium may be divided into two classes—that which is not suggestive of tumor of the heart and that which is. In the first class are those cases in which there are no symptoms referable to cardiac dysfunction, those in which there is terminal cardiac breakdown, those in which symptoms of simple congestive heart failure dominate the clinical picture, those in which sudden death occurs with or without previous cardiac symptoms, and those in which the clinical picture is that of subacute bacterial endocarditis. In the second class the clinical types may be quite diverse but should serve to call to mind the possibility of tumor of the heart. Any case of heart block in which no satisfactory explanation of the arrhythmia is obtainable may be one of tumor breaking through or originating in the main portion of the conduction apparatus. When symptoms referable to disturbance of function of a portion of the heart occur, tumor of that part of the heart is a diagnostic possibility. In the case of pedunculated intracavitary tumor obstructing a cardiac orifice, usually the mitral or tricuspid, certain deviations from the usual symptomatology of endocarditis are often present. The history of rheumatic infection is absent; the course of congestive failure is progressive; there is little or no response to digitalis, and the physical signs may change remarkably with change of posture. In every case in which tricuspid stenosis seems to be present, tumor should be suspected because inflammatory stenosis of that orifice is exceedingly rare. Acquired pulmonic stenosis should be considered the result of neoplastic obstruction. If in a person who is known to harbor a malignant neoplasm cardiac symptoms develop which cannot be otherwise explained, it is reasonable to assume that metastatic invasion of the heart has occurred. Accumulations of hemorrhagic fluid in the pericardium are suggestive of subepicardial or pericardial neoplasm, and hemorrhagic pleural effusions are not uncommon in malignant disease of the heart or pericardium. A localized enlargement of the heart or an irregularity of outline associated with enlargement as shown in the roentgenogram is suggestive of tumor of the heart as well as aneurysm and mediastinal tumor.

Regenerated Hepatic Tissue.—Althausen states that, in toxic cirrhosis of the liver, vigorous regeneration of tissue maintains the carbohydrate metabolism-regulating function and probably other metabolic activities of this organ. Owing to a loss of the original structure of the liver in this disease, the new hyperplastic nodules lack connection with bile channels, accounting in this manner for marked impairment in the excretion of dye. This information can be utilized by the clinician for differential diagnosis of toxic cirrhosis of the liver by the use of two suitable tests of hepatic function.

Gastric Secretion After Histamine.—Gammon and Miller noted that the maximal free gastric acidity after histamine and after Liebig's extract in a miscellaneous group of patients varied to a far greater extent from the mean value than it did after the gruel meal in a similar group. No correlation could be recognized between the maximal free acidity after histamine and after a gruel meal when the two tests were done on the same group of patients. The variations in the acidity after histamine could not be correlated, except in the achlorhydrias, with the diagnoses of the cases. No significant variations in acidity or volume secretion after histamine were noted in correspondence with the age or the sex of the patients. The volume of secretion after histamine was greatest on the average in the group of cases of duodenal ulcer and duodenitis, but it bore no direct relationship to the degree of acidity, except that it was lower in those cases with zero acidity. On the basis of their observations the authors conclude that the histamine test, though valuable to determine the ability of the stomach to secrete acid, is not serviceable as a routine method of gastric analysis, because the variations in its results are great without obvious cause. The gruel meal has an advantage as a routine test of gastric acidity in that its results may be more nearly correlated with the clinical diagnoses. The explanation for the superiority of the gruel meal probably lies in the fact that it contains buffer substances which permit the stomach to adjust the acidity of its total contents to a more definite level, a level that is correlated with existing conditions.

Insulin Absorption by Conjunctiva.—Christie and Hanzal describe experiments in which they found that insulin instilled into the conjunctiva is absorbed with great rapidity and gives rise to a fairly constant and consistent fall of blood sugar levels in rabbits. The drop in blood sugar level persists for from four to five hours as against from five to six hours by the subcutaneous route. Apparently it requires about 60 per cent more insulin by this method of administration than by the subcutaneous route. The authors have seen nothing to make them believe that commercial insulin is irritating to the eyes of animals.

Angina Pectoris.—Siegel and Feil report electrocardiographic observations in eleven cases made during transient attacks of angina pectoris. In eight of these patients there was inversion of the T wave and (or) inversion of the S-T segment of the curve. In some instances a negative T became more deeply depressed. These changes disappeared after subsidence of the pain. This evidence supports the conception that transient anginal attacks are due to myocardial ischemia, presumably due to alteration in coronary artery flow. Electrocardiograms taken during other types of paroxysmal pain (labor pains, renal and gallstone colic) did not show any changes in the T wave or S-T portion of the curves.

Nutritional Edema.—Weech and Ling discuss the relation of serum protein deficiency to various types of edema, both experimental and clinical. Attention is called to other factors and in particular to the rôle of several inorganic salts in modifying the effect of protein deficiency alone. In a series of patients suffering from nutritional edema, who were studied during both the active and the convalescent stages, it was found that when the level of serum albumin was greater than 2.9 Gm. per hundred cubic centimeters edema was never observed and that when the level fell below 2.5 Gm. per hundred cubic centimeters edema was invariably present. The correlation with total serum protein, although not so close, was sufficient to indicate a critical level for edema close to 5 Gm. per hundred cubic centimeters. Serum globulin was exceedingly variable: decreased, normal and increased values all were found in association with edema. Decreased globulin generally occurred only when the albumin was also decreased and thus was usually present in association with edema. No relation of cause and effect was considered, however, to exist between lowered globulin and edema. The results of metabolism observations on two of these patients are given. In both cases the combined administration of sodium chloride and sodium bicarbonate led to rapid gain in weight, marked increase in edema and depression of chloride excretion in the urine. In one of the patients these effects could not be reproduced after feeding of an adequate diet had resulted in a return to normal of the serum protein. The impossibility of offering an exact explanation of all the effects observed is pointed out, although it is stated that the results are in harmony with the view that the cation sodium is more intimately related to the causation of edema than the anion chloride.

Water in Epilepsy.—McQuarrie and Peeler present experimental and clinical data to show the effects of sustained pituitary antidiuresis and water drinking on mildly epileptic as contrasted with nonepileptic children. It is shown that typical grand mal seizures can be induced within twelve to forty-eight hours in the epileptic, but not in the nonepileptic subject, by giving water at the rate of from 2 to 5 cc. per kilogram of body weight hourly while maintaining effective pituitary antidiuresis. This difference in response between epileptic and nonepileptic patients may be helpful in establishing the diagnosis early in an obscure case. Under the conditions of the experiments described by the authors, dilution of the extracellular body fluids appears to be an essential factor in the induction of seizures since administration of an amount of sodium chloride just sufficient to prevent this tends to interfere with their occurrence. The results presented lend strong support to the view that the mechanism for controlling semipermeability of the brain cell membranes is inherently defective in the epileptic patient.

direct treatment for this disease in the future. Cures have been attributed to various factors, such as the age and the resistance of the patient and a low virulence of the organism. Statistics of the collected cases show the highest percentage of cures among patients above 20 years of age (33 per cent), and the lowest percentage in infants. The authors believe that the traditional and fixed idea that a patient with tuberculous meningitis must die should be reconsidered. No doubt, a recovery is extremely rare, but no one can foretell when this unexpected favorable termination may occur. The tendency to discard the diagnosis of tuberculous meningitis and disregard such laboratory observations as the presence of tubercle bacilli and successful inoculation into guinea-pigs, merely because the patient recovered, seems unscientific and illogical.

Exophthalmic Goiter. — Reveno advances the hypothesis that exophthalmic goiter is primarily a disturbance resulting from a long continued toxic process in the intestinal tract. This process not only damages the thyroid to the end that varying amounts of its functioning tissue are destroyed but causes a faulty and irregular metabolism of the amino-acid tyrosine, so that an excess of thyroxine, epinephrine and tyramine is produced. These conclusions are reached in view of (1) the inadequacy of the thyrogenic theory of the disease; (2) the work of McCarrison on the effects of toxic material in the intestinal tract on the thyroid; (3) the close relationship between the chemical constitution of thyroxine, epinephrine and tyramine; (4) the common source of these three substances, viz., tyrosine; (5) the changes in the normal tyrosine-tyrosinase reaction and the decarboxylization process for conversion of tyrosine to phenols, with resulting overproduction of the base tyramine, and (6) the pharmacologic action of tyramine.

Phenolsulphonphthalein Test. — Hanner and Whipple describe experiments from which it is clear that in dogs with necrosis of the liver due to chloroform poisoning there is a distinct rise in the elimination of phenolsulphonphthalein by the normal kidney. A rise in the elimination of phenolsulphonphthalein from a control level of from 75 to 78 per cent to from 90 to 97 per cent may be noted. With repair of the hepatic injury, the elimination of phenolsulphonphthalein returns to normal. Phosphorus poisoning gives a similar but less striking reaction. With experimental biliary obstruction in the dog, the same general reaction is noted, with a definite increase in the elimination of phenolsulphonphthalein by the normal kidney. After hepatic injury due to chloroform, the dog's liver does not remove phenolsulphonphthalein from the blood stream and does not excrete it in the bile, whereas in a normal dog the liver removes much phenolsulphonphthalein from the blood, and about 10 per cent of the injected phenolsulphonphthalein may by recovered from the bile within two hours. A chronic biliary fistula and an Eck fistula may permit a smaller excretion of phenolsulphonphthalein in the bile and a corresponding rise in the elimination of the dye in the urine. There is no evidence that a cholagogue, whether in the normal dog or in one with a biliary fistula, increases the elimination of phenolsulphonphthalein by way of the bile, and consequently the urinary excretion of phenolsulphonphthalein is unchanged. Phenolsulphonphthalein given by mouth is absorbed and reappears in the urine only in quantities equal to from 3 to 5 per cent of the amount administered. Reabsorption, therefore, is a negligible factor when applied to the phenolsulphonphthalein eliminated through the bile into the duodenum. From these experiments and the observations of other workers, it may be concluded that the elimination of phenolsulphonphthalein by the liver and kidney under these conditions is identical in the dog and man. Clinically, an unusually high renal elimination of phenolsulphonphthalein should suggest pathologic changes in the liver. Combined renal and hepatic disease calls for cautious analysis of the renal elimination of phenolsulphonphthalein.

Tumors of Heart and Pericardium.—According to Yater, the symptomatology of tumors of the heart and pericardium may be divided into two classes—that which is not suggestive of tumor of the heart and that which is. In the first class are those cases in which there are no symptoms referable to cardiac dysfunction, those in which there is terminal cardiac breakdown, those in which symptoms of simple congestive heart failure dominate the clinical picture, those in which sudden death occurs with or without previous cardiac symptoms, and those in which the clinical picture is that of subacute bacterial endocarditis. In the second class the clinical types may be quite diverse but should serve to call to mind the possibility of tumor of the heart. Any case of heart block in which no satisfactory explanation of the arrhythmia is obtainable may be one of tumor breaking through or originating in the main portion of the conduction apparatus. When symptoms referable to disturbance of function of a portion of the heart occur, tumor of that part of the heart is a diagnostic possibility. In the case of pedunculated intracavitary tumor obstructing a cardiac orifice, usually the mitral or tricuspid, certain deviations from the usual symptomatology of endocarditis are often present. The history of rheumatic infection is absent; the course of congestive failure is progressive; there is little or no response to digitalis, and the physical signs may change remarkably with change of posture. In every case in which tricuspid stenosis seems to be present, tumor should be suspected because inflammatory stenosis of that orifice is exceedingly rare. Acquired pulmonic stenosis should be considered the result of neoplastic obstruction. If in a person who is known to harbor a malignant neoplasm cardiac symptoms develop which cannot be otherwise explained, it is reasonable to assume that metastatic invasion of the heart has occurred. Accumulations of hemorrhagic fluid in the pericardium are suggestive of subepicardial or pericardial neoplasm, and hemorrhagic pleural effusions are not uncommon in malignant disease of the heart or pericardium. A localized enlargement of the heart or an irregularity of outline associated with enlargement as shown in the roentgenogram is suggestive of tumor of the heart as well as aneurysm and mediastinal tumor.

Regenerated Hepatic Tissue.—Althausen states that, in toxic cirrhosis of the liver, vigorous regeneration of tissue maintains the carbohydrate metabolism-regulating function and probably other metabolic activities of this organ. Owing to a loss of the original structure of the liver in this disease, the new hyperplastic nodules lack connection with bile channels, accounting in this manner for marked impairment in the excretion of dye. This information can be utilized by the clinician for differential diagnosis of toxic cirrhosis of the liver by the use of two suitable tests of hepatic function.

Premedication. S. Rowbotham.—p. 41.

System of Anesthesia for Dental Anesthetist.—De Caux believes that nitrous oxide, properly administered, is the safest anesthetic agent for all ages and conditions. It is ideal for all operations on the mouth and pharynx. It is best administered undiluted until the patient is anesthetized. Asphyxial symptoms should never be allowed to persist but should immediately be relieved by oxygen either from the air or from a cylinder. Oxygen can easily be administered by the nose without interference with the surgeon. For extensive surgical work on the mouth it is best administered by way of a tube passed through the nose into the trachea. Every opportunity should be taken to make use of premedication, especially in children.

On Manipulative Treatment of Tendon Lesions. I. H. Lloyd-Williams.—p. 148.
Radiologic Diagnosis. B. Leggett.—p. 151.

Hyperpyrexia.—According to Neymann, hyperpyrexia can easily be produced by diathermy and will undoubtedly prove to be a beneficial procedure in many acute and chronic diseases. At present its value in the treatment of dementia paralytica exceeds that of any other known form of therapy. With correct technic this method of producing fever can be controlled with accuracy. It permits of dosage both in time and in quantity elements. The dangers are exceedingly slight and can be entirely overcome by proper care and attention.

Relationships Between Chronic Rheumatism and Throat Infection.—The careful analysis of approximately 500 cases in which chronic rheumatism was a prominent symptom during the last three years has led Hindley-Smith to certain conclusions. First, chronic rheumatism is a symptom and not a disease *sui generis*. In about 75 per cent of cases the causal factor is the streptococcus of the viridans and hemolyticus varieties. Of the remaining 25 per cent of cases the primary cause is due to some form of chronic infection such as bacillary dysentery and gonorrhea, when any cause has been demonstrable. The evidence indicates that in the streptococcal cases the condition begins in early childhood, usually between the ages of 3 and 6. The infection appears to begin with a primary stage of invasion in the throat, with sore throats, septic tonsils, and so on, a secondary stage with constitutional disturbances affecting the blood, heart and nervous system, beginning at the ages of 9 to 14; and later in life a tertiary stage which manifests itself as chronic rheumatism and fibrositis. There is no clearly defined interval between these stages (as, for instance, in syphilis), but each stage is always recognizably represented in each case history, and in each successive stage the throat and nasopharyngeal symptoms appear to play a decreasingly obvious but none the less active part.

Low Voltage Radiography. A. B. McLean.—p. 500.
Reflex Phenomena in Chronic Appendicitis. G. C. Field.—p. 504.

Treatment of Granuloma Inguinale.—Greenwood presents an analysis of twenty-two cases of granuloma inguinale in which he used diathermic fulguration. He states that this form of treatment is easy to carry out, is not attended by shock, and, if general anesthesia is given at the time of operation, the patient experiences hardly any discomfort. The average time taken to heal the ulcer in the series of cases was seventy days, the greater part of the ulcer being healed in most cases in about four or five weeks. This is a very much shorter period than that taken by the antimony tartrate treatment in most cases. There were no failures in the series. Judging from the appearance of the scar and from the one follow-up case seen, the author believes that the cure is lasting. The fact that treatment merely of the edges of the ulcer is sufficient goes to confirm the work of Castellani and Mendelson that it is not the Leishman-Donovan body, found only in smears from the ulcer but a nosoparasite which is the causative organism. It also seems to indicate very strongly that the true causative organism should be looked for in the active edges of the ulcer.

American Impressions of British Tuberculosis Conference. Louise Strachan.—p. 175.

Bovine Tuberculosis.—Rabagliati suggests the following policy pending a determined attempt to eliminate tuberculosis in its entirety from herds of cattle in England, a measure perfectly feasible but at the present time beyond the hope of practical politics: 1. Encouragement of the use of and therefore the production of "certified" and grade A milks. These classes of milk, if produced under proper supervision, are practically safe. 2. Milk should be produced from cows under careful veterinary supervision. Experience shows that when cows are examined quarterly or, if possible, more frequently (though this can rarely be done in a large county) the percentage of tuberculous milk sold is exceedingly small. This supervision insures that not only are many cows with tuberculosis of the udder detected but also many animals excreting tubercle bacilli by the respiratory, alimentary and even the urinary tracts, which may be responsible for infecting the milk, though such infection may only be of intermittent character. These may easily be missed if merely bulk samples are taken. 3. The use of pasteurized milk when the source of supply cannot be properly controlled. For large cities pasteurization has undoubtedly many advantages, but in advocating it its many disadvantages must not be lost sight of, and the methods by which it is carried out ought to be much more closely supervised than is usual at the present time.

Similarity of Cervical Abscesses and Branchial Cysts.—Bailey calls attention to the fact that the physical signs of a branchial cyst and a tuberculous abscess are practically identical. The patient presents himself with a cystic swelling in the upper third of the neck, deep to the upper third of the sternomastoid, coming around the anterior border of that muscle. This is the commonest location of a tuberculous abscess [illegible] also the constant situation of a branchial cyst. The [illegible]

*Various Colonies of Hemolytic Streptococci in Scarlet Fever. Ruth Tunnicliff, Chicago.—p. 357.

Artificial Fever and Experimental Poliomyelitis.—The different types of data obtained by Jungeblut and Kopeloff are somewhat conflicting, which makes it difficult for them to draw conclusions. Within the limitations of the experimental material, it appears to be proved that noninfectious fever of considerable intensity applied during the period of incubation, but maintained only over comparatively short periods of time, is not capable of altering the course of experimental poliomyelitis in the monkey to any significant extent. The same holds true for infectious fever produced by inoculation with Trypanosoma equiperdum, when the two infections are induced simultaneously. With a poliomyelitic infection superimposed on an existing febrile trypanosomiasis there may be a distinct prolongation of the period of incubation of the poliomyelitic infection, undoubtedly indicating some attenuation of the virus. Since the latter observation is based on one monkey alone, the authors do not know how regular this occurrence is. With syphilis a definite spirocheticidal effect in vivo may apparently be obtained by febrile temperatures that cause no obvious damage to the host. As regards poliomyelitis, it would seem that the production of a sufficiently intense fever to bring about destruction of the virus in vivo is not possible within a safe zone of raised temperature.

Hemolytic Streptococci in Scarlet Fever.—During the course of scarlet fever, especially during convalescence and in complications, Tunnicliff isolated atypical hemolytic streptococci alone or associated with typical Streptococcus scarlatinae. They appeared to have dissociated from the typical, or "normal," slightly granular, conical scarlatinal colonies and differed from them by forming on heated blood agar (chocolate agar) granular or smooth convex colonies and the rough conial colonies did not change chocolate agar; the granular convex colonies turned it green, while the smooth convex colonies varied in this respect. By the opsonic test, the cocci from dissociated colonies were not opsonified like the group of streptococci specific for scarlet fever, but by subculturing they were reverted, both colonically and immunologically, to typical scarlatinal streptococci.

Results of Specific Treatment in Type I Pneumococcus Pneumonia.—Lord has noted that specific serum treatment of type I pneumococcus lobar pneumonia lowers the mortality when used during the first three days of the illness but is ineffective after this interval. Humoral immunity is to be regarded as an important cause of recovery from pneumococcus lobar pneumonia. The discrepancy between the small amount and inconstant presence of protective substances in the blood and the decisive nature of crisis, occasional recovery at the usual time in spite of the early appearance of protection, and the ineffectiveness of serum treatment after the third day of the disease, suggest that other factors may also be concerned in the defensive mechanism.

Note on Tuberculosis and Suicide. A. N. Cox.—p. 173.
American Impressions of British Tuberculosis Conference. Louise Strachan.—p. 175.

Bovine Tuberculosis.—Rabagliati suggests the following *policy pending a determined attempt to eliminate tuberculosis* in its entirety from herds of cattle in England, a measure perfectly feasible but at the present time beyond the hope of practical politics: 1. Encouragement of the use of and therefore the production of "certified" and grade A milks. These classes of milk, if produced under proper supervision, are practically safe. 2. Milk should be produced from cows under careful veterinary supervision. Experience shows that when cows are examined quarterly or, if possible, more frequently (though this can rarely be done in a large county) the percentage of tuberculous milk sold is exceedingly small. This supervision insures that not only are many cows with tuberculosis of the udder detected but also many animals excreting tubercle bacilli by the respiratory, alimentary and even the urinary tracts, which may be responsible for infecting the milk, though such infection may only be of intermittent character. These may easily be missed if merely bulk samples are taken. 3. The use of pasteurized milk when the source of supply cannot be properly controlled. For large cities pasteurization has undoubtedly many advantages, but in advocating it its many disadvantages must not be lost sight of, and the methods by which it is carried out ought to be much more closely supervised than is usual at the present time.

Similarity of Cervical Abscesses and Branchial Cysts.—Bailey calls attention to the fact that the physical signs of a branchial cyst and a tuberculous abscess are practically identical. The patient presents himself with a cystic swelling in the upper third of the neck, deep to the upper third of the sternocleidomastoid, coming around the anterior border of that muscle. This is the commonest location of a tuberculous abscess, and also the constant situation of a branchial cyst. The skin overlying the swelling may or may not be slightly inflamed. In either case this is not of assistance, for branchial cysts are subject to recurrent attacks of inflammation; indeed, the patient nearly always first presents himself with a branchial cyst thus complicated. A syringe is taken and some of the contents of the swelling aspirated. The unwary will say at once "pus," but branchial fluid and tuberculous pus in a syringe have precisely the same appearance. The fluid is sent to the bacteriologic laboratory, and the usual report in the case of a tuberculous abscess is: "No tubercle bacilli found. Cultures sterile." This report is also the most likely one to be received in the case of a sample of branchial fluid. In less than 10 per cent of cases are tubercle bacilli found in the aspirated contents of a tuberculous cervical abscess. The similarity between these two conditions is truly remarkable, and it is easy to appreciate why it is so common for a branchial cyst to be diagnosed as a tuberculous abscess, and how an erroneous diagnosis can be upheld by the authority of scientific laboratory investigation. If the following suggestions and tests are applied it is possible to segregate branchial cysts, which are comparatively rare, from tuberculous abscesses connected with the upper jugular chain, which are common: 1. Branchial cysts most often appear between 17 and 25 years of age. While their appearance may be delayed until much later, they are rarely seen before puberty. 2. On carefully palpating the sternocleidomastoid with the muscle in physiologic activity, as is occasioned when the chin is forcibly pushed against the palm of the hand, one finds that the sternocleidomastoid will be thinned and flattened over the cyst, but it is unaltered when the swelling is a tuberculous abscess. This test requires some practice before the results can be relied on. 3. If a drop or two of the aspirated fluid is placed on a glass slide, covered with a cover-slip, and examined immediately under the microscope with one-sixth power lens, the presence of numerous cholesterol crystals at once makes the diagnosis of branchial cyst certain. It is unwise, and quite unnecessary, to send the specimen to the laboratory, unless one is certain that the examination will be made at once, and one specifies that the information sought is with regard to the presence of cholesterol rather than bacteriologic characteristics. The foregoing test is so reliable that it is safe to predict that if it were applied generally the majority of branchial cysts would be correctly diagnosed as soon as they appeared. As it is, even after these tests have been applied conscientiously, a few cases escape detection. The reason for this is that therapeutic aspiration, and particularly the injection of medicated preparations, as is at present fashionable, robs branchial fluid of its characteristic cholesterol. Acute, or subacute, inflammation of the cyst sometimes has the same effect.

Gangrene of Skin of Diphtheritic Origin. J. S. Anderson.—p. 800.

Problem of Child in Tuberculous Household.—Wingfield believes that the general practitioner must view the problem of the child in the tuberculous household mainly as a clinical problem; his duty is to the child and its parents rather than to the community at large. He should not have to examine all the contact children in his practice by the Mantoux reaction for evidence of infection and by the roentgen ray for evidence of lesion. He should not have to deal with these patients personally; these investigations should be made for him, and he should have a knowledge of their results. His duty is to watch and to turn his attention to the proper hygiene of the home. He must realize the danger not of exposure but of continuous exposure; that is to say, he must use every effort to sterilize the open case which is the source of contact, and to dilute the infection either by treatment or by segregation, partial or complete. Contact infants must be his especial care in this direction. He must teach the parent and the adult how by attention to a few simple hygienic rules they can minimize the danger to the children almost to the vanishing point. It is not his duty, and would be a waste of his time and injurious to his practice, if he were to say to the tuberculous mother that she must never see her child again. When the contact children of his practice reach adolescence is the time he must be most wise and wary. That is the time when the parent and child need guidance in the choice of work, mode of life and environment. That is the time when the roentgen ray will be particularly useful, for apical infiltration in childhood and adolescence, although apparently latent, always goes on to definite clinical pulmonary tuberculosis if untreated.

Broken Nose.—According to Williams, the common type of "broken nose" is due to lateral (but not backward) displacement of both nasal bones with imbrication. Treatment consists of disimpaction, free mobilization of both bones, and symmetrical molding together. No splints are needed. When the nose has been crushed, internal splinting is required to restore the profile; the author describes a convenient form of splint. Resection of the septum may be needed. When a portion of the maxilla is impacted in the antrum, access is obtained by the canine fossa route. If much damage has been caused to skin and soft parts, every effort must be made to conserve tissue, limit sepsis, and prevent adhesions.

Pituitary in Etiology of Cancer.—On the basis of the hypothesis that in cancer cases the anterior pituitary was overactive, and the posterior pituitary underactive, two patients with advanced cancer were treated by Susman with solution of pituitary alone, and five with solution of pituitary and theelin. All were placed on a diet low in carbohydrate. An epithelioma began to separate off and was enucleated after seven weeks of this treatment. The growing edge disappeared in five days. All the patients showed regressive changes in the tumors, and life appeared to be definitely prolonged.

Torsion of Ovarian Cyst in Children.—Steel reviews more than twenty-five cases of torsion of ovarian cyst in children and gives an illustrative case. Ovarian tumor, though rare, increases in frequency with the age of the child and is most commonly encountered between the ages of 10 and 14. Torsion, although very rare, is the commonest complication of these tumors. A correct diagnosis of the condition is decidedly more often the exception than the rule, in spite of the fact that a constant clinical picture is found in almost every case. The typical features present are a history of similar but less severe attacks, the sudden onset of pain, an increase of temperature and pulse rate, the palpable abdominal tumor with overlying tenderness and rigidity, and the tender cystic mass, which can be made out by rectum. The diagnosis is sometimes very difficult, the lesion for which torsion of a cyst is most often mistaken being an appendical abscess.

*Surgical Treatment of Constipation. H. C. Trumble.—p. 405.
*Hodgkin's Disease: A Treatise. L. Utz and Leila Keatinge.—p. 412.

Surgical Treatment of Constipation.—Trumble believes that it is possible that section of the hypogastric nerve alone would be sufficient to permit of relaxation of the sphincters and to cure some patients with Hirschsprung's disease, but until more is known about the subject it would probably be wise to adopt a more radical procedure. The simplest way to do this is to divide the lumbar splanchnic nerves just proximal to the inferior mesenteric ganglion. The author gives reports of three cases in which this was done with satisfactory results.

Hodgkin's Disease.—According to Utz and Keatinge, tuberculous lymphadenitis, which is so often mistaken for Hodgkin's disease, can be differentiated by serologic tests in children and by biopsy in adults. The histologic appearances in the tuberculous lymph nodes are not in any way similar to those found in Hodgkin's disease. True splenic anemia can be identified clinically, as a rule by the absence of palpable abdominal lymph nodes, by the absence of ascites or jaundice, or many of the pressure symptoms directly due to the presence of enlarged lymph nodes in Hodgkin's disease. To differentiate Gaucher's disease, which is incidentally often associated with enlarged superficial nodes, is a different matter. The familial occurrence of Gaucher's disease is practically the only guide short of biopsy of the nodes, which, however, may also demonstrate some resemblance to Hodgkin's disease. In spite of all that has been written about the differentiation of lymphosarcoma from Hodgkin's disease, the authors are inclined to agree with Ewing by stating that the lymphocytoma type of lymphosarcoma in which the lymphocyte and not the endothelial cell is proliferated can be differentiated at a glance by microscopic examination. But when the endothelial elements of lymph nodes proliferate to produce a so-called lymphosarcoma of the endothelial type, differentiation either clinically or on histologic grounds is practically impossible. In differentiation one relies solely on the appearance of the Dorothy Reed cells, but a great number of cases of Hodgkin's disease are then classified as lymphosarcoma. Clinical differentiation between these two diseases is well nigh impossible. Leukemia can be identified in practically all instances by the blood picture and, as the pseudoleukemia of Sternberg is still a disease without a clinical entity, differentiation is impossible.

Lymphatic Reaction in Trypanosomiasis.—White rats experimentally infected with Trypanosoma brucei were studied histologically by Hu, at different stages of infection. It was found that this infection produces a massive hyperplasia of the reticulo-endothelial system, increased intramedullary and extramedullary erythropoiesis and myelopoiesis and a striking hyperplasia of the lymphoid tissue. There is no evidence, however, to show that one element can be transformed into the other. The lymphatic hyperplasia, which takes place chiefly in the spleen and the lymph nodes, consists of a great increase in number of large and medium sized lymphoblasts which, in the early stage of infection seem to be formed directly from certain small lymphoid cells in the lymphoid tissue of these organs. These lymphoblasts, once formed, may either undergo rapid cell division, forming other lymphoblasts, or become transformed into plasma cells. Although the lymphoblasts of the germinal centers and the rest of the lymphoid tissue participate in this generalized hyperplasia, the large and medium sized lymphocytes and a certain number of the small lymphoid cells do not undergo significant change. Especially striking are the small lymphoid cells of the thymus, all of which remain practically unaltered in the whole course of infection. The failure of these cells to take part in this reaction is interpreted by the assumption that they are true small mature lymphocytes which, with the ordinary histologic methods, are indistinguishable from the small primitive cells capable of forming larger lymphoblasts.

Tinea of Nails.—Kurotchkin and Ch'in report that a study of eighteen cases of onychomycosis revealed two clinical forms of the disease. The most common form was characterized as a rule by considerably thickened and brittle nails which were also either ridged or otherwise deformed. In the second form the nails were smooth and had an abnormally dull white color, characteristic of leukonychia. In the later type of case the fungus was found in abundance in the scrapings from the surface of the nail. Three species of Epidermophyton were isolated from thirteen cases. Cultural examination of the remaining five cases was negative for fungi. Epidermophyton rubrum was present nine times among the thirteen cases. This fungus was also responsible for the infection in the two cases with leukonychia. It was observed that onychomycosis is a secondary infection in the majority of cases. It may develop as a result of the extension of the infection from cutaneous mycotic lesions such as occur in tinea of the feet and hands. It may also accompany tinea cruris, in which case infection of the nails is probably due to self inoculation. This conclusion is based on the fact that in cases of coexisting mycoses the same organism has regularly been isolated both from the nails and from the skin.

Changes in Digestive Tract Due to Parasitic Worms.—Of the various histologic changes in the intestinal tract of vertebrates due to parasitic worms, the following are briefly described by Hoeppli and Hsü: superficial lesions of the mucosa due to mechanical action of organs like suckers, rostellum, and buccal capsule; changes mechanically produced in the glands, and lesions of the deeper layers of the intestinal and stomach wall. The changes of the first group are very similar in principle; an inflammatory reaction and ulcer formation occur usually only in cases in which the parasite anchors in one position for a long time. The mechanically produced changes of the glands consist in a torsion and widening, which vary from a very slight degree (Strongyloides species) to a very high degree (Tetrameres species and Cotylaspis species). Lesions of the deeper layers are represented by nodules of different structure, ulceration which depends for its histologic picture on the development of the esophageal glands, and tunnel formation (Spiroxys japonica).

*Pain Syndrome of Fifth Lumbar Vertebra in Young Women. D. C. Rœderer.—p. 354.

Pain Syndrome of Fifth Lumbar Vertebra.—For several years, Rœderer has been noting a pain syndrome, not accompanied by contracture, which affects the region of the fifth lumbar vertebra in young women at the end of puberty. These young women range in age from 13 to 25 years (the oldest still have the exterior habitus of adolescents). The pain is fixed and constant, never very acute, but annoying by its persistence. Some patients complain simply of inconvenience; there is sometimes a sensation of burning or pricking and almost always a sensation of heaviness. The pains are spontaneous, with periods of eclipse. A prolonged upright or sitting position sometimes brings on the symptoms. The pain does not radiate to the buttock, thigh, groins or organs in the true pelvis. The menses usually aggravate the condition. The evolution of the syndrome is irregular; several weeks of latency are often followed by a reappearance of symptoms without apparent cause. Generally after from twelve to eighteen months the pains disappear either gradually or suddenly. The recovery seems absolute; a follow-up of old cases proved that it is permanent. The syndrome resembles that of painful occult spina bifida of the fifth lumbar vertebra reported by other workers. However, the author's syndrome appears in women only, while the related syndrome occurs in both sexes. Palpation localizes a painful spot in the region of the spinous process of the fifth lumbar and the first sacral vertebra; but the sensitive region is sometimes more extensive and includes the articular processes between the fourth and fifth lumbar vertebrae and even the transverse processes of the sacral vertebrae. However, the spinous process of the fifth lumbar or the first sacral vertebra always responds with the maximum of pain on pressure. The diagnosis of the syndrome is very delicate and is sometimes uncertain for weeks and even months; there is no indication of Pott's disease or sacral osteitis, and the roentgenograms are negative. The therapy is only palliative. The author recommends rest, with local and general sedatives. He believes this syndrome is sufficiently characteristic to be designated as an entity.

Mean Hypertension During Exertion.—Vaquez and his co-workers believe their researches demonstrate that the mean arterial pressure constitutes a true physiologic constant. In a previous paper (*Presse médicale* **39:**1309 [Sept. 5] 1931; abstr. The Journal, November 7, p. 1419), Vaquez and Gomez described the method for the oscillometric determination of the mean blood pressure. Subsequent researches led to the following conclusions: In well compensated cardiac disease the mean pressure is similar to what it is under normal conditions; that is, following exertion there is no change or very slight change in the mean pressure. It is otherwise when cardiac insufficiency is present and the right ventricle is affected. An elevation of the mean pressure is not due to acceleration of the pulse, since there is often acceleration of the pulse in the compensated condition. In dextrocardiac insufficiency, moreover, the elevated mean pressure subsequent to exertion returns but slowly to its former level. In persons with compensated cardiac disease an elevation of the mean arterial pressure following exertion may be a premonitory sign of approaching cardiac failure. The authors believe that a consideration of the extreme pressures is not sufficient. To determine the exact functional capacity of the heart, the mean arterial pressure should be ascertained both in a state of rest and in a state of action.

Action of Hypertonic Solutions of Sodium Chloride.—Chiariello studied the effects of intravenous injections of hypertonic solutions of sodium chloride on dogs in which both ureters were ligated experimentally. He observed that the dogs so treated and doomed to die survived longer than the controls that were not so treated. Such survival amounted, on the average, to 21.8 hours. It is difficult to explain the mechanism of the action, but the author is inclined to assume a direct antitoxic action of the hypertonic solutions.

Injections of Calcium Salts into Tissues Adjacent to Fractures, Under Pathologic Conditions. — Rollo reports that, from his experiments on animals (rabbits and guinea-pigs), it appears that injections of calcium glycerophosphate into the tissues immediately adjacent to a fracture serve to stimulate the focus to greater activity. They cause the early and abundant formation of new connective tissue and favor the ossification of the bone. While the second fact was established by previous experiments on sites of fractures under ordinary physiologic conditions, the first is proved especially in cases of partial diaphyseal resection and the interposition of muscle tissue between the bone fragments, in which (through parvicellular infiltration and the ample formation of new connective tissue) the destruction and replacement of the muscle tissue, and the formation of callus, inducing ossification, were facilitated. In the controls the interposed muscle tissue, preserving its integrity longer, impeded the normal evolution of the callus.

Effects of Pulmonary Tuberculosis and of Artificial Pneumothorax on Glutathione of Blood. G. Borsalino.—p. 1057.

Pulmonary Hyperventilation; Behavior of Lactic Acid in Blood and Alkali Reserve.—Lucchi and Manfredini, continuing their researches on pulmonary hyperventilation, studied in twenty subjects the behavior of lactic acid of the blood and of the alkali reserve in voluntary hyperpnea. They found a notable and almost constant diminution of the alkali reserve and an increase of the lactic acid, both being more marked the more intense and the more extensive the muscular spasms were. The authors consider that the diminution of the alkali reserve is due partly to an increased elimination of carbon dioxide through the respiratory passages and partly to the hyperlacticemia provoked by the effort of the musculature and, above all, by the muscular spasms.

Prophylactic and Therapeutic Value of Antidiphtheritic Serum.—Pontano studies the diphtheria problem in its three fundamental aspects: experimental, statistical and clinical. Experiments on the guinea-pig have led to wrong interpretations of human diphtheria. The prophylactic and therapeutic experiments with serums on the guinea-pig show only the prophylactic and noncurative value of the serum. The author took up the experiment by infecting the guinea-pig with bacilli and not merely intoxicating it with a toxin. He confirms the prophylactic value against the bacterial infection, both as to local manifestations and as to toxemia. He accords the serum no action on the established disease as regards either the local infection or the toxemia. An unbiased examination of the statistics led him to conclude that the reduction in the mortality from diphtheria is due to other causes than to the use of serotherapy. Clinical evidence in a large number of personal cases does not point to a curative action of the serum. In grave cases the mortality was the highest when the serum was employed. The serum does not have any effect on the local lesions. With serum, the mortality from diphtheria is high when the seat of the disease is laryngeal. In the ordinary cases of the disease the mortality is the same without serum as with serum.

*Action of Histamine on Hydrogen Ion Concentration and Alkali Reserve. V. González Calvo and J. Martinez Bruna.—p. 508.

Action of Histamine on Hydrogen Ion Concentration and Alkali Reserve.—González Calvo and Martinez Bruna made determinations of the hydrogen ion concentration and the alkali reserve in patients with several pathologic conditions, either during rest or during work, and before and after eating, to ascertain what the modifications of the acid-base equilibrium are under the influence of histamine. One of the patients had diabetes. The work was preceded by determinations of the same nature in rabbits. The dose of histamine given to man was 1 mg. administered subcutaneously. From their observations the authors reach the following conclusions: Histamine has a marked action on the hydrogen ion concentration and on the alkali reserve both of man and of rabbits. Because the mechanism controlling the acid-base equilibrium is better developed in man than in rabbits, thus permitting in the former a partial inhibition of the action of histamine, the changes in the hydrogen ion concentration and in the alkali reserve under the influence of histamine are more marked in rabbits than in man. They are of a transient nature, lasting no longer than an hour and a half, and are manifested in rabbits by the appearance of alkalosis. The processes of digestion, muscular work and the like cause marked changes in the acid-base equilibrium, and these changes are more marked when the determinations of hydrogen ion concentration and alkali reserve are made simultaneously. The action of histamine varies according to the conditions of the given individual, although histamine affects more intensely the hydrogen ion concentration than the alkali reserve. The authors cannot as yet give a conclusive statement on the action of histamine on the acid-base equilibrium of diabetic patients, since the number of observations is not sufficient (only one diabetic patient was observed by them). Further determinations of the same nature in diabetic patients are planned.

Surgical Treatment of Cicatricial Stenosis of Esophagus. G. Suárez Aguirre.—p. 1217.

Cancerous Degeneration of Tubuloracemose Gland of Cervix Uteri.—The most interesting fact in Votta's case is the important information given by the biopsy, done in a patient with chronic erosive hypertrophic cervicitis, by which the presence of a malignant degeneration of a tubuloracemose gland of the cervix uteri was discovered and treated early by exeresis of the cervix, containing the degenerating tissues, and by radium therapy. Clinical symptoms of the presence of a malignant process in evolution had not been previously discovered. The patient is observed at frequent intervals for recurrences, which up to the present have not appeared. The microscopic characteristics of the tumor, a plasmodial epithelioma, are given in detail in illustrations. The neoplastic degeneration of the glandular epithelium in the author's case supports the theory of the common glandular origin of epitheliomas of the cervix uteri.

Lymphocytic Meningitis Simulating Tuberculous Meningitis.—Silberstein states that there is a type of epidemic benign meningitis in which the differential diagnosis from certain diseases or conditions, such as syphilis, epidemic encephalitis, trauma, acute poliomyelitis or some other disturbances, is easy. The disease attacks adults (usually young men). It simulates so closely tuberculous meningitis that a differential diagnosis between these two forms of meningitis is difficult. The cerebrospinal fluid in this type of meningitis contains a large number of lymphocytes. Its sediment is negative for tubercle bacilli and when inoculated into a guinea-pig gives negative results. The disease follows an evolution to spontaneous recovery without leaving any sequelae, an occurrence which is rarely observed in cases of tuberculous meningitis. The author states that the performance of the biologic test and the isolation and cultures of the causal bacteria are necessary to include this new entity of meningitis in the pathology of the nervous diseases.

Normal Size and Form of Heart in Man.—In the introduction, Moritz points out that at necropsy the determination of the dimensions of the heart is usually limited to measuring the thickness of the walls, the median length and the basal circumference of the ventricles, and to weighing the heart. In the main part of the article he aims to show what size of the heart can still be considered normal or is already abnormal. He considers as the best method the determination of the correlations of the heart measurements to the other body measurements. The size of the heart is determined by orthodiagraphy. The author reaches the conclusion that, for the determination of the normality of the size of the heart, the body height is the best correlative.

New Treatment of Typhoid Bacillus Carriers.—Since the typhoid bacilli in carriers usually lodge in the biliary tract and since halogen compounds have a bactericidal effect, Onodera and his associates treated seven typhoid bacilli carriers by giving intravenous injections of tetiothalein sodium and after a certain time the region of the gallbladder was irradiated with roentgen rays. Of seven patients who were treated in this manner, three became free from bacilli (bile and feces), two remained free from bacilli for a month following the treatment, and in the other patients, who are still under clinical observation, the treatment was without effect. Considering the ineffectiveness of the other therapeutic measures that have been recommended for bacillus carriers, the authors think that since their method produces favorable results in some cases it justifies further investigation.

Function of Stomach Following Removal of Antrum Pylori.—Johnson performed on dogs resection of the antrum pylori and gastro-enterostomy, and, immediately below, a duodenal fistula was made. It was found that the secretion of such a stomach is reduced, especially if porridge and soups are fed; but even if meat, bread and vegetables are given, the gastric secretion is reduced. If soups and porridge are fed, the stomach retains the food only for a short time, but solid foods are retained much longer. As soon as the food enters the duodenum there takes place, even under these unphysiologic conditions, a complete mixture with the duodenal secretions, and thus the hydrochloric acid is largely neutralized.

Aspects of Diabetes with Insulin Resistance.—Serio states that patients with the form of diabetes which is resistant to insulin usually appear well nourished, have only slight acidosis and are influenceable only slightly by dietetic measures. He then describes the clinical history of such a patient. Since dietary measures as well as insulin therapy failed in their effect and since the patient showed slight symptoms of hyperthyroidism, an antithyroidal preparation was administered in increasing quantities. After forty days of this medication the insulin resistance had completely disappeared, so that 14 units of insulin was now sufficient to reduce the glycemia considerably and even to produce hypoglycemic symptoms. The sugar content of the blood during fasting became normal and could be kept in normal limits in spite of a free diet and of tolerance tests, even after the treatment had been discontinued. The renal elimination of sugar continued. This was probably due to a renal factor, which became evident after the hyperglycemia had disappeared.

Intracutaneous Injection and Basal Metabolism.—Crecelius describes experiments which prove that intracutaneous injection, that is, irritation of the sympathetic nervous system, causes changes in the basal metabolism, whereas if the injection is made subcutaneously or intramuscularly there is no such effect. However, not all persons react in the same manner. To what causes it may be ascribed that in some persons there is an increase in the basal metabolism while in others there is a decrease has not been detected as yet. A careful control of the blood pictures gave no explanation, since a certain uniformity was not detectable.

Membranous Colitis a Disappearing Disease.—Boas points out that membranous colitis, which thirty years ago was one of the most discussed intestinal disorders, in recent years has hardly been mentioned, and he is convinced that the reason for this is the decreased frequency of the disease. In the last decades of the last century, when the incidence of membranous colitis was greatest, the various forms of colitis were usually treated by medicated and especially by astringent enemas. Modern medicine has done away with the habitual enema treatment and particularly with the medicated and astringent enemas, and the author thinks that membranous colitis has decreased in the same ratio as the use of enemas. Another reason why he considers enemas and especially medicated ones as the etiologic factor of membranous colitis is that in the rare cases of membranous colitis which came under his observation in recent years the anamnesis always revealed the habitual use of enemas. When the enemas were discontinued and a dietary treatment was introduced instead, the patients no longer complained of the discharge of membranes. On the basis of past experiences, the author concludes that the cause of the membrane formation is a simple colitis, for the treatment of which unreasonable methods, such as enemas, were prescribed. In this manner a simple mucous colitis developed into a membranous colitis. Since colitis is no longer treated in this manner, and since likewise the use of cathartics has diminished, membranous colitis has almost disappeared.

Apple Diet and Intestinal Flora.—Schreiber shows that in acute and catarrhal intestinal diseases, such as Flexner's dysentery, paratyphoid B and the common dyspepsias, an apple diet causes a change in the intestinal flora, which manifests itself in a considerable increase in the coli bacteria and in a decrease in the pathogenic intestinal flora. At the same time, the clinical manifestations disappear. The virulence of the coli strains neither increases nor changes as the result of the treatment, so that a predisposition for the disease may persist in spite of the clinical cure.

Intramuscular Calcium Therapy in Pulmonary Tuberculosis.—Undritz employed intramuscular injections of calcium gluconate in sixty patients with tuberculosis. The injections are given every other day, alternating into the right and left gluteal muscles. In some cases the injections can be interrupted for some time, and later another series may be given. Intravenous injections of calcium gluconate are advisable in cases of hemorrhage, and a prolonged intramuscular administration may be followed by a series of intravenous injections. The author gives a tabular report, showing the results of the treatment in sixty cases, and a detailed report of three cases. He concludes that intramuscular calcium therapy is advisable in all forms of pulmonary tuberculosis, but in patients with high temperature and poor general condition the injections of calcium gluconate should be postponed until the active manifestations have somewhat subsided and the general condition has been improved by camphor therapy. Especially suitable for parenteral calcium therapy are patients with pleural exudation, and also patients who receive pneumothorax treatment, for in these cases the inhibiting action of calcium on the exudation is of especial value. A prophylactic administration of calcium is advisable from one to two weeks before the pneumothorax is induced. In the summary the author stresses that the calcium administration cannot be considered as a causal therapy and that not all patients are benefited by it. However, he considers it a valuable adjuvant. Its efficacy is due to transmineralization of the organism; that is, it does not form calcium deposits, but, in passing through the organism, it displays pharmacodynamic actions, such as increasing the phagocytosis and checking the inflammation and exudation.

Pathogenesis and Therapy of Leukorrhea.—Pulay's observations indicate that leukorrhea is a manifestation of avitaminosis. Clinically considered, leukorrhea belongs to the group of seborrheal eczema, urticaria, chronic rhinitis and hay fever. In many cases of leukorrhea the anamnesis reveals that disorders of the skin existed in earlier years. Since it is possible to counteract seborrheal eczemas in children by administration of vitamin A, the author tried vitamin treatment in cases of leukorrhea. In some of the cases, administration of vitamins A and D effected a rapid improvement, but other cases were at first refractory. In the majority of the cases belonging to the latter group, severe seborrhea existed. Soon after a protein-free diet was instituted, these cases yielded to vitamin therapy. In order to determine the correlation between these factors, the author studied the blood chemistry of these patients and detected a reduced alkali reserve, acidosis and low magnesium content. In patients in whom the cholesterol content was normal or somewhat reduced, the vitamin treatment became rapidly effective; however, in the patients with severe seborrhea, in whom vitamin therapy was at first ineffective, the cholesterol content of the blood was considerably increased. Only after the cholesteremia had been counteracted by the proper dietary treatment did the vitamins become effective. These observations indicate the significance of the metabolic conditions in the pathogenesis of leukorrhea and show that the leukorrhea problem is largely dietary.

Unnoticed Biologic Law and Its Significance for Research and Practice.—Wilder describes the results of his clinical experimental researches on the autonomic nervous system. He investigated the Eppinger-Hess theory of vagotony. The usual doses of atropine, epinephrine and pilocarpine were administered subcutaneously, and especial attention was given to the pulse rate and the blood pressure. On the basis of his observations he concludes that it is incorrect to assert that in the individual the usual manner of testing reveals a characteristic reaction to atropine, epinephrine and pilocarpine. There are differences in the quality and even in the types (vagotonic and sympathicotonic) of the reactions in the same person. In all types of experiments it was found that in about 75 per cent of the cases the difference in the outcome of the tests concurred with a difference in the initial values of pulse rate and blood pressure. It was observed that the higher the initial values the less the tendency to increase but the greater the tendency to decrease. If the initial value is high, the increase is slight but the decrease is marked; on the other hand, if the initial value is low the increase is great, while the falling off is slight. This is the biologic law to which the author has reference, and he terms it the law of the initial value (ausgangswertgesetz). The already existing state of irritation influences the irritability; that is, the higher the existing irritation or degree of activity, the lesser the responsiveness to increasing influences and the greater to inhibiting influences. In the second part of the article the author discusses the practical significance of this law. It explains many apparent contradictions; for instance, that the same person may react differently to the same dose of the same pharmaceutic preparation, or that the pulse rate reacts differently from the blood pressure, or that the reaction does not correspond to the dose. Knowledge of this law is also important for therapeutic measures, especially in spheres in which the vagosympathetic antagonism is involved. The author discusses the basal, sugar and calcium metabolism; also diuresis, temperature, iodine and the thyroid, the pharmacodynamic actions of cardiac remedies, the reactions of the pupils, the uterus, the stomach and the mechanism of perspiration.

Hormonal Sterilization of Female Mammals.—Mandelstamm and Tschaikowsky report that injections of 10 mouse units of prolan B (hormone of the anterior lobe of the hypophysis effecting luteinization) and even as much as 50 units are tolerated by white mice, without injurious effects. A single injection of prolan B produces temporary sterility in a large number of the animals. Of seventy-three mice, only eleven became pregnant during three estrual cycles. In mice that had been sterilized by hormonal treatment, a single injection of prolan prevented ovulation during five or six estrual cycles, and in some the sterility even lasted fifteen cycles. A repeated injection of 10 mouse units of prolan B effected sterility in all the examined animals (observation time of six mouse cycles). The authors conclude that injection of prolan B may prove to be helpful in inducing temporary sterilization of the female organism.

Psychic Influence on Female Genitalia.—In the introduction to his paper, Zempléni points out that the influence of the functional phases of the female genitalia (menarche, menstruation, pregnancy, labor, puerperium, lactation and menopause) on the psyche is generally recognized, for, in connection with those phases, serious psychic reactions and even psychoses have been observed. However, the influence of psychic factors on the genital functions is not so frequently recognized, yet two cases described by the author show that this is possible. In one case, premature menstruation set in as the result of apprehensiveness before a ball and thereafter always set in prematurely under the same conditions. The second case reported by the author concerns a woman who had an abortion as a result of a severe influenza during the tenth week of her first pregnancy. Because she had been told by her friends that all subsequent pregnancies would terminate during the tenth week, her apprehensiveness during the two following pregnancies actually had this effect, although there was apparently no cause for an abortion. During the next pregnancy her physician at first denied that she was pregnant and later this pregnancy was carried to term. The author also cites other conditions, such as war amenorrhea, which are probably due to psychic factors.

Reaction of Nongravid Human Uterus to Extracts of Posterior Lobe of Hypophysis.—Contrast roentgenoscopy of the uterus for diagnostic purposes gave Schultze the opportunity to make observations on its motor functions. However, he is convinced that the roentgenogram alone does not permit definite conclusions and that quantitative estimates should be based on the pressure registrations. If the reaction of the uterus following injection of extract from the posterior pituitary is determined by means of pressure registration, it is found that it corresponds to the menstrual cycle. At the beginning of the menstrual cycle the uterus reacts not at all or only slightly to the injection of extract of the posterior lobe of the hypophysis. About fourteen days after the menstruation, the contractions become stronger and of longer duration, and beginning with the twentieth day until twenty-four hours before menstruation sets in again the reaction capacity is very strong. Besides these observations on the dependence of the uterine reactivity on the ovarian cycle, the author made yet other observations on the course of the reaction. He found that in case of intravenous application the action of the extracts sets in half a minute after completion of the injection. First there is a pressure decrease, which in turn is followed by a marked increase. The intensity of the reaction is likewise dependent on the dose. In estimations of the uterine contractions it is also significant to consider other factors that are of influence. There are "spontaneous" contractions caused by the contrast medium. The woman's excitement during the injection also causes strong contractions, and only after these have passed should the influence of the extract be estimated. The discharge of some of the contrast material and whether the tubes are open or closed is also of influence on the contractions. If large doses of the extract are injected there are certain unpleasant general reactions, such as a feeling of anxiety, severe headache, extreme paleness, enlargement of the pupils and retardation of the pulse. If small doses are given, the general reactions are slight.

Relation Between Pituitary Body and Female Genital Organs. Seidler.—p. 838.

Function of Ovaries After Hysterectomy.—Bochenski divides the clinical symptoms ascribed to hysterectomy into two groups: those resulting from loss of the organ and those attending retrogressive degeneration of the ovaries. The first group embodies all local symptoms due to anatomic changes in the pelvis, plus removal of the internal secretion of the uterus; the occurrence of an internal secretion in the uterus is not, however, a generally accepted theory. Nine rabbits in which the uterus was removed and oophorectomy was performed six to twelve months later, did not show any macroscopic or microscopic changes in the ovaries as compared with control animals. The symptoms frequently encountered in women, and ascribed to hysterectomy, may be due to preexisting pathologic changes in the ovaries.

Lymphadenoma and Amyloid Degeneration (Hodgkin's Disease).—Kostrzewski and Ciechanowski discuss in detail this rare combination, of which only three cases are on record, two reported by Lichtwitz and one by Matthes. The case under discussion is of particular interest because of insignificant pseudoleukemic changes, general advanced amyloid degeneration and rare possibility of premortal diagnosis. The authors state that (1) the complication of lymphadenoma by amyloid degeneration is proved beyond doubt by this case; (2) there is no relation between the location or extent of the two diseases; (3) the presence of amyloid degeneration does not throw any light on the etiology of pseudoleukemia, and (4) the complication of lymphadenoma by amyloid changes proves that Hodgkin's disease is not a local disorder of the glandular system but a systemic disease with glandular symptoms.

Transient Benign Coxitis.—Belmonte calls attention to a transient, benign infection of the hip joint, apparently little known in the Netherlands but frequently described in foreign journals. Coxitis fugax occurs chiefly in children and sometimes presents peculiarities that make early diagnosis possible. This is especially important for differentiation from tuberculous coxitis with a serious prognosis. Special treatment is not necessary. With rest in bed, the subjective and objective symptoms disappear after a few days or, at the most, a few weeks. The course is entirely favorable. A similar disorder occurs in the knee joint and there appears to be a similar spondylitis.

Occurrence of Diastase in Blood and Urine of Patients with Acute Infectious Diseases. Cont'd. K. Germer.—p. 405.

Investigations on Excised Human Thyroids.—Krogh and his associates find that cytologic examinations show exophthalmic goiter, unlike simple goiter, to be characterized by cellular hyperactivity, collapse of storage secretion, and proliferation. In patients treated preoperatively with iodine, the storage secretion is frequently restored but the morphologic signs of cellular hyperfunction, particularly the hypertrophy of the Golgi apparatus, are unchanged. The administration in adult male guinea-pigs of dried glands from simple goiters and from successfully treated exophthalmic goiters, in doses based on their iodine content, led to an increase in metabolism nearly equivalent to that caused by the administration of normal guinea-pig thyroids; glands from nontreated exophthalmic goiters and from unsuccessfully treated ones showed a biologic activity definitely below normal.

*Genuine and Postencephalitic Narcolepsy: Clinical Investigation. S. Wohlfahrt.—p. 342.
*Scorbutic Ménière's Symptom and Otosclerosis. H. Öhnell.—p. 358.

Some Less Common Forms of Torsion of Adnexa.—Marcus describes three cases of torsion of normal uterine appendages. In the first, in the third month of pregnancy, removal of the twisted adnexa did not affect the pregnancy, and normal delivery occurred at term. Excision was also done in the second case, and in the third the twisted adnexa were untwisted. Analogous cases from the literature are cited. The prognosis was good in all cases.

Spasmodic Torticollis and Operative Treatment.—Olivecrona reports six cases in which operative treatment resulted in marked improvement or in complete recovery. He states that recurrences are seldom to be feared and that, in cases of incomplete recovery, further improvement may be expected during the following years, probably because of the tendency of the condition to spontaneous recovery. He emphasizes that surgical division of the intraspinal portion of the accessory nerve should not be considered sufficient but that peripheral exeresis of the accessory nerve should as a rule be done. He advises against waiting for spontaneous recovery, as it usually takes years before the condition becomes somewhat endurable. When internal treatment, psychotherapy and so on are ineffective after six months, operative treatment is advocated. If, however, torticollis is only a partial phenomenon of some extrapyramidal syndrome, operative treatment is considered only in exceptional cases.

Genuine and Postencephalitic Narcolepsy.—Wohlfahrt reports four cases of true narcolepsy, all in younger men, two cases showing definite signs of disturbances of internal secretion closely resembling hypothyreosis. The administration of thyroid resulted in improvement. In three other cases reported, the symptoms are apparently related to a previous epidemic encephalitis.

Scorbutic Ménière's Symptom and Otosclerosis.—In Öhnell's case of Ménière's symptom in a patient with latent scurvy, the abundant administration of vitamin C resulted in marked improvement. The definite improvement in four other patients with Ménière's symptom after vitamin C had been given is believed to support the assumption that Ménière's symptom is in certain cases due to scurvy.

SALT-RESTRICTED DIETARY

WITH PARTICULAR APPLICATION TO TUBERCULOSIS THERAPY *

EDGAR MAYER, M.D.
SARANAC LAKE, N. Y.

Attention at the moment is being redirected to nutritional therapy, especially for cutaneous diseases, disturbances of the sympathetic, and advanced tuberculosis.

EXPERIMENTAL

The general question of curative diet for disease is, of course, an old one. To mention a single experiment, zomotherapy (raw meat and meat juices) was once strongly advised for tuberculosis; but the results showed so little uniformity that no clear deductions could be drawn. In recent years, experimental and clinical attempts have been made for the direct purpose of altering the organism's blood and tissue reactions by means of food. The difficulties involved in any such experiment are easily understood when one recalls how tenaciously the organism retains its blood and tissue reactions, and how stubbornly the regulatory mechanisms of the body prevent displacement of the acid-base equilibrium to one side or the other.

Among recent experiments in this field have been those of Harvey and Howe, who reported from their study of white rats that the complete ration unusually rich in protein favored a more rapid rate of growth of fibroblasts in a healing wound than did a diet with the usual concentration of protein. They made a simple incision in the stomach wall; at later intervals they tested the strength of the wound by inflating the stomach and using the pressure at which the wound broke as an index of the rate of healing, which is proportional to the rate of growth of the fibroblasts. In the first four days after the initial incision, no influence of the high protein diet was manifest, but from the fifth to the tenth day there was a decided advance in the rate of healing in the group given the protein-rich food.

Nutrition is stated to affect coagulability of blood in such a manner as to cause persons to bleed or the blood to clot more readily. Kugelmass and Samuel[1] found that prolonged feeding of a diet containing protein increased the coagulability of blood, maintaining the clotting factors at a high level. Injury of the tissues by surgical intervention induced an overproduction of blood fibrinogen and hence an increased coagulability of the blood. "The introduction of heterologous protein into the vascular system increases the blood-clotting function transiently, with a rapid return to normal."

Experiments have been made also with alkaline and acid ash diets. Schade and others reported a definite influence on the blood reaction from the persistent administration of basic or acid diet with the addition of corresponding salts. An attempt to reduce the blood buffers by a concentration of acid in wounds was made by Hermannsdorfer.[2] He discovered that acid-ash food produced a marked decrease of secretion; the wound shrank, flabby granulations became cornified, and fresh red coatings were quickly cleared away. Briefly, the wound dried up and had better circulation. An opposite effect was noticed after an alkaline-ash diet; the entire wound developed a smeary appearance, often accompanied with the formation of pseudomembranes and fresh epithelial desquamation, and the entire region of the wound showed increased and often edematous swellings. Within the wound the granulations were glassy and the secretions increased, with offensive smell. Parallel with the increased moisture in the wound there were noticeable pathologic changes: With the acid diet, the drying wound gradually lost some of its germs; Bacillus pyocyaneus, Bacillus proteus and other bacilli decreased; streptococci and staphylococci changed in quantity but remained the most persistent. On the other hand, the moist wound resulting from alkaline food was swamped with germs; Bacillus proteus, anaerobes, streptococci and staphylococci all grew abundantly, and there were cases of wound diphtheria. In this connection it is valuable to recall that, during the World War troops from countries with more acid nutrition in the regular diet avoided the epidemics of wound diphtheria which were common among troops with vegetarian food.[3]

Hermannsdorfer further noted that superficial wounds in guinea-pigs fed on oats and phosphoric acid showed marked tendency to granulation, contraction and healing, while those fed on sodium bicarbonate and green vegetables presented torpid wounds and little inclination to healing.

Sauerbruch holds that shifting of tissue reaction to the acid side induces leukocytosis and improved phagocytosis, and changes dissociation of calcium and potassium ions. Spiro[4] showed that calcium caused increased acidity and noticeable depletion of water content of tissues. Dubois and Stolte[5] showed that vegetable diet, rich in potassium, increased retention of calcium.

Bogert and Kirkpatrick demonstrated that acid-forming foods increased while base-forming foods retarded calcium absorption and retention.

---

Variations in the acid-base value of diet have been shown by many [6] to influence the absorption and excretion of calcium and phosphorus in rickets and tetany. Acid-forming diets lacking in vitamin D produced rickets in young white rats; base-forming diets under similar conditions produced a very mild degree of rickets; the former shifted the acid-base mechanism of young rats to the acid side, and base-forming diets to the basic side of equilibrium. "Acid-forming diets inhibit and base-forming diets accelerate the rate of growth, metabolism and activity."

In direct opposition to Hermannsdorfer's "acidifying" diet, others have advised, in cases of hypertension, that an alkaline ash diet be stressed and that fruit be increased to replace cereals and meats. With such varying opinions, it is difficult at present to be dogmatic on these points, when proof is so clearly lacking.

DIETARY COMPONENTS

Let us consider the knowledge of the separate constituents of a diet, taking first the question of carbohydrates. Eskimos in their cold climates have been known to thrive on the low total sugar intake of no more than 30 Gm. a day without exhibiting any unusual tendency to arteriosclerosis or kidney disease. The minimum amount of sugar that a person may take and still retain perfect health has not been ascertained, but it is known that, to effect any appreciable metabolic change in the ordinary patient, an increase of at least 20 Gm. over the accustomed amount is necessary.

Proteins.—Definite advice concerning proteins is difficult to give. It would seem that a high protein ration in a great many instances can be carried very well, and for nephrosis, or for convalescents or growing children, 120 Gm. a day or even more may be indicated. In the treatment of disease the exact amounts are hard to fix; perhaps 120 Gm. a day would be an advisable maximum, and 50 a good minimum. In certain cases, such as nephritis, the amount is sometimes cut below this minimum, especially in nitrogen retention cases this may be wise, but ordinarily if such a low amount is supplied in the diet the patient will draw from his bodily resources any additional amount needed.

Fats.—The regulation of fats goes beyond the ordinary diet, for no minor changes in diet-fat will affect metabolism. Dubois relates that he has made sudden changes of 200 Gm. in fat intake without finding any evidence of change in metabolism. It is well known that the human body can hold in reserve large amounts of fat and draw on them at will.

Weigert [7] found that animals overfed on fat showed an increased resistance to tuberculous infection in contrast to the lessened resistance manifested by animals fed chiefly on carbohydrates. Vogt [8] believed that he corroborated this in children. McCann [9] found that for one unit of heat produced from dextrose there is nearly 30 per cent more carbon dioxide than that gotten from the same energy production from fat; so he advises a diet composed largely of fats up to the limits of digestive capacity as one that will produce the least demand on the function of the damaged lungs.

Calcium.—Through the use of parathyroid extract and viosterol, changes in calcium can be effected, but as yet clinical experiments with these have yielded clarifying results only in the treatment of such definite diseases of calcium metabolism as rickets and tetany and osteomalacia. In tuberculosis the calcium metabolism remains yet to be thoroughly investigated; for the proof of a deficiency of serum calcium and tissue calcium in this disease has not yet been established. Experiments on animals have been made to throw light on this point, and in some cases of tuberculosis the serum calcium has been found to be low, but only in the final stages of the disease. We are equally uninformed about the final effects of calcium ionization. But these experiments with animals have yielded certain positive knowledge: it was found that in calcium-normal blood the amount of calcium is not noticeably increased by an addition of calcium to the diet; and in tuberculous organs the amount of calcium in the food did not determine the calcification; furthermore, the calcification did not seem to have any changes which could be brought into ratio with the tuberculous changes.

Sodium Chloride.—In the past, opinions about mineral salts in a patient's diet have been very contradictory. Reduction in the amount of table salt was once strongly advised to reduce edema of the heart and kidney disease, but recently calcium chloride has been advantageously substituted, especially when it has been combined with mersalyl (salyrgan). In cases of hypertension and edema, the sodium and chloride ions of sodium chloride have alternately been considered the chief contributing causes.

Salts can be deposited in the skin, especially in sodium chloride overfeeding. Keining and Hopf [10] found that certain patients, who were first kept for several days on a salt-free diet and then flooded daily with 20 Gm. of sodium chloride in four doses of 5 Gm. each, showed increased urticaria and eczema, almost without exception. This treatment frequently gave the patients severe shock, so that the salt had to be promptly discontinued. The itching became unbearable. Furthermore, in some of the cases, isotonic salt solution produced wheals at the site of injection. An osmotically equilibrated dextrose solution did not cause any wheals in the same cases. A study of the components of sodium chloride responsible for the irritation showed that the anions were not concerned. The sodium was proved to be responsible for the irritation, so that a cation action was involved. Antagonistic cations, potassium, calcium, magnesium and strontium, administered simultaneously overcame the action of producing wheals. It is known chemically that these cations often act favorably on diverse skin disorders. The cations must stand in perfectly definite quantitative relationship to overcome the irritation or to lessen it, and the relative proportion of the constituents of the salt mixture corresponds closely to the cation relationship of the blood plasma.

Functional disturbances have been observed to follow large subcutaneous or intravenous injections of sodium chloride. Instances are those of increased metabolism with simultaneously diminished respiratory quotient, salt glycosuria and so-called salt fever. Some workers report that the addition of suitable amounts of calcium detoxicates the sodium sufficiently to prevent sodium chloride fever. Also surviving organs as nerve and muscle preparations have been injured and have shown considerable changed irritability in pure isotonic sodium chloride which was removable by adding antagonistic cations. Single celled organisms have been severely injured and their development disturbed in pure sodium solutions, but they found optimal conditions only with definite cation proportions.

Meyerowitsch,[11] in a study of sodium chloride metabolism in tuberculosis, found salt retention with rising temperature, exudation and edema, but increased salt excretion with fever remission.

Von Bunge[12] believes that sodium chloride inanition can be produced by a vegetable diet and that the normal sodium chloride balance can be maintained in the average person on 2 Gm. of table salt a day. In cases of restricted sodium chloride intake, the normal osmotic pressure is preserved by decreased renal excretion of salt.

Man alone takes salt as a denatured and artificial product as a daily constituent of his food, but severe health injuries do not occur, as the body possesses mechanisms which are capable of detoxicating it to some extent. It is assumed that this is done by the antagonistic cations of the body.

Excess sodium has especially been alleged to cause liquefaction of colloids, as on the surface of all body cells, all these cells being bathed by the fluid which is disturbed in its cations. Such changes in the physiologic conditions at the cell membranes simultaneously alter the response of the cells to stimuli and disturb the conduction of stimuli. All stimuli that reach the cells depend on the chemical colloidal conditions at their surfaces and hence, in the first place, on the relationships of the cations which surround the cells.

The salt relations in the inside of the cell come in contact with the relations in the body fluids at the cell membranes. Conduction disturbances are said to be most marked at the insertions of the sympathetic nervous system, this being the most delicate indicator for all electrolyte displacements. If an abnormal cation relationship surrounding the cells carries abnormal stimuli conduction, a sympathetic disturbance is involved.

As salt-poor nutrition restores the body's normal cation relationship, it is to be expected that there is simultaneous restoration of the normal sympathetic cell functions.

The attempts to increase artificially disease symptoms that represent a disturbance of the sympathetic are considered to show the dependence of the degree of irritability on the normal salt relationship, and, after prolonged use of salt-free nutrition, chemical analysis can show that not only do the abnormal cation values disappear but the symptoms also.

So the indications for salt-poor diet are the manifold sympathetic disturbances and not specifically tuberculosis. Sympathetic disturbances are the result and not the cause of abnormal cation relationships. These can be conditioned by alimentation.

There are only small amounts of antagonistic cations to sodium in the blood. Serum contains almost the maximum of sodium and furnishes only small amounts of antagonists, but the salts of the cell interiors furnish the antagonists; namely, potassium, calcium and magnesium.

The condition of the colloids and therefore also of the cation mechanism determines greatly the activity of vitamins. Vitamin action is intimately related to electrophysical processes, so that some workers practically identify vitamin action and surface tension. In the case of physiologic salt relations the surface tension conditions in the body's colloidal system are the most favorable, and so the conditions for the assimilation of vitamins are optimal.[10]

Calories.—There is not much more certainty possible when one considers a diet from its caloric or vitamin standpoint. In the question of calories, the bodily activity of the individual patient must determine to some extent the caloric values of the advised diet. One must, of course, first arrange for the patient's basic metabolism; then the calories may be increased to take care of bodily activity; but where one person will require for this a doubling of caloric value, another will need only an increase of, let us say, 25 per cent. The additional amount needed for the dynamic action of his food will usually be under 10 per cent. If the normal caloric intake has been high, the amount needed to induce any change will be correspondingly large. Dubois says that a patient receiving 2,000 calories would probably not react to any increase smaller than 200.

Vitamins.—In the question of vitamins, it is still to be satisfactorily demonstrated that any large increase over the usual amount is advisable, even for persons in good health. If it is certain that a definite lack of vitamins exists, it is obvious that they must be supplied, but, as a matter of fact, clear adult cases of a deficiency of vitamins are not common. From his wide experience in New York, Dubois asserts that only rarely does he encounter such diseases as adult scurvy and osteomalacia. Symptoms of pellagra occurred occasionally, but they were usually found in chronic alcoholic addicts who lived on doughnuts and coffee. It is yet questioned whether pellagra may not be evidence equally well of a deficiency in iron and of a lack of vitamin G. Dubois has not seen xerophthalmia or beriberi in his New York clinics.

But caries and defective growth of the teeth have been attributed to a lack of vitamins, and an increase in vitamins C and D has been prescribed for its prevention and healing as well as of vitamin A for building up general resistance to infection. Also, McCarrison's experiments in the production of gastric ulcers under diets deficient in vitamins B and C are well known. It is even possible that diets rich in vitamins A, C and D may help to forestall or heal secondary ulcerative tuberculosis of the intestine. It is certainly difficult to fear any great harm from an excess of vitamins (or the usually attendant increase in mineral salts), except in the extreme excesses that have produced hypercalcemia in experimental rickets. However, an abnormal increase of one vitamin over the others may disturb the vitamin balance and be detrimental. Also, large amounts of raw food taken to increase the vitamin value may offset their efficacy by producing bad effects from their indigestible residues. For cooked food, it must be remembered that the vitamin content is affected by the incidental processes of preparation; vegetables cooked in open containers lose many of their vitamins; canned vegetables are often quite as rich in vitamins as home cooked ones.

DIETARY FOR TUBERCULOSIS

In the face of existing uncertainties, it is clear that any conclusion about a diet for tuberculous patients must rest on large clinical experiments properly controlled over a considerable period of time. From such experiments and subsequent theoretical interpretations, a diet has recently been promulgated by Gerson, Sauerbruch and Hermannsdorfer. The principles of their recommendations embrace the whole field of body chemistry and involve a change in the soil in which the tubercle bacillus grows.

[11] Meyerowitsch, Nadeschda: Ueber den Kochsalzstoffwechsel bei fiebernder Tuberkulose, Zurich, Gebr. Leemann & Co., 1911.

[12] von Bunge, Gustav: Lehrbuch der Physiologie des Menschen, Leipzig, F. C. W. Vogel, 1905.

The essentials of this diet are:

1. The all but complete exclusion of sodium chloride, with a sodium-poor but calcium-rich salt compound being used as a substitute.

2. (*a*) A large percentage of uncooked fresh vegetables in the diet, either in the form of vegetable extracts prepared by pressing uncooked vegetables, such as carrots, beets, spinach and turnips, or in the form of salads with added fruit juices similarly prepared. (*b*) Preparation of cooked vegetables in their own juices in waterless cookers.

3. Marked restriction of meats; Hermannsdorfer and Sauerbruch allow 600 Gm. weekly, Gerson much less. (The table shows the differences.)

Comparison of Suggested Diets for Tuberculous Patients

	Gerson Diet	Hermannsdorfer-Sauerbruch Diet
Proteins	About 55 to 67 Gm. daily	About 90 to 120 Gm. daily
80% Animal	Meat....... 100 Gm. weekly	600 Gm. weekly
20% Vegetable	Fish........ 70 Gm. weekly	About the same
	Viscera..... None (sweetbreads, etc.)	Rather freely permitted
	Legumes... None	Permitted
Fats	About 170 Gm. daily	About 170 Gm. daily
	Cream...... None	About 250 cc.
	Eggs....... Yolks only	Whole egg
Carbohydrates	Total—250 Gm. carbohydrates given daily	
	Sugar...... 20 Gm. weekly	About the same amount
	Honey...... 50 Gm. weekly	About the same amount
Fluids	1,400 cc. vegetable juices; fruit juices 600 cc.	Restricted vegetable and fruit juices; about 2½ pints in form of milk, cream, soup, juices, etc.
	Milk........ 250 cc.	About 1,000 cc.
	Soup....... None	
Sodium chloride	About 1.56 Gm. in food About 1.15 Gm. in juices About 2.7 Gm. of sodium chloride intake daily	
	Ratio of protein to fat to carbohydrate is about 1 to 5.6 to 3.4	Ratio of protein to fat to carbohydrate is about 1.5 to 2.7 to 3.7
Aim	Dehydration of tissues and altering body's mineral metabolism. Rich in fat, vitamins and minerals (perhaps protein). Poor in salt and carbohydrate. Vegetables steamed; much raw food given, with cod liver oil with phosphorus, and mineral compound (chiefly calcium). Calories: 21 to 23 calories per pound of body weight; 2,770 or 3,030 if patient weighs 132 pounds (60 Kg.). In Hermannsdorfer diet, calories furnished are 15 per cent by protein, 53 per cent by fat and 32% by carbohydrates.	

4. Restricted water intake, but fairly liberal amounts of freshly expressed juices of fruits and vegetables.

5. Various spices to increase the flavor of the dishes.

6. A mineral compound chiefly of calcium lactate and calcium phosphate, with calcium and magnesium combinations in the form of double salts; strontium, aluminum and silica in colloidal albumin combination, and a cod liver oil, each of these given three times a day.

7. Rich fat and protein, but low carbohydrate elements.

The theories of the mode of action of this diet entail a long and detailed discussion. In this paper I can merely review a few reported conclusions on the value of this diet and add my own impressions resultant from the observation of my own cases and of the cases of others which I was privileged to study in the past two and a half years.

The diet has been both vigorously attacked and enthusiastically supported. Each of the individual dietary factors has been singled out as advantageous by certain workers and just as strongly denounced by others. Some have found that the diet acidifies, others that it alkalizes. Proponents of the diet have aimed at desiccation of tissue through withdrawal of sodium chloride, while others claim a resulting tissue hydration as the cause of extravagant gains in weight.

Dörffel[13] recently found by skin section of treated cutaneous tuberculosis a dehydration of normal and diseased skin as well as a mineral displacement. Potassium was increased, and calcium and magnesium were diminished, while sodium was greatly diminished. These changes were particularly marked in the disease foci.

The withdrawal of table salt has been objected to also on the ground that it is needed for the production of hydrochloric acid of the gastric mucosa, yet actual test has proved the presence of sufficient hydrochloric acid and has shown about 3 Gm. of sodium chloride output in the urine. Its withdrawal has been urged as a measure of healing lupus, by reducing a cutaneous irritant that is stored and excreted by way of the skin. In some cases the diet has been said to increase and in others to decrease the sodium chloride of the blood. Some investigators further report a decrease in the blood calcium level, or an augmented alkali reserve, or high cholesterol values in the blood. The relative percentages of sodium chloride and protein content in the blood have been stressed, and some experimenters have considered sodium chloride as a sort of vitamin, an aid to restriction of protein decomposition. Phosphorus (as given in cod liver oil with phosphorus) has been objected to as dangerous in such dosage to the liver.

Despite the variations in the reported results of separate trials with this diet, many of its most violent opponents have admitted that this therapy is an advance. My own experiences very largely agree with the evaluation of it made by the Hamburg Medical Congress, that the diet is a distinct therapeutic advance as an aid generally effective in the treatment of lupus vulgaris, and occasionally in bone and joint tuberculosis, but that its value in other forms, more particularly pulmonary tuberculosis, is yet to be determined. I have discerned in it an alterative therapy. Symptomatic improvements, even in pulmonary tuberculosis, have been common, but the effective factor, even the psychotherapeutic one, cannot be evaluated here. However, the diet seems directly responsible for many relieved cases of functional disturbances attendant on pulmonary tuberculosis, especially with chronic constipation or gastric hyperacidity. And tuberculosis with the rare toxic nephroses or essential hypertonia or vasoneuroses has been helped by it.

The leading authorities report favorable effects from this diet in the treatment of lupus vulgaris: retrogression of swelling, flattening of the foci, and absorption and disappearance of the individual nodules. Lupus of the mucous membrane reacts even better than lupus of the skin. Foci of the nasal mucosa, the hard palate, the pharynx and the larynx have been benefited; the lupus foci about the gums of the teeth have been the most resistant. Noteworthy influence on exudative processes is clearly shown; the dry squamous forms react less favorably. The best results are seen when light treatment by general exposure in minimal doses is added. My conclusions are arrived at from the

---

13. Dörffel, J.: Deutsche med. Wchnschr. 57:268 (Feb. 13) 1931.

observation of sixteen lupus cases whose treatment I directed others to carry out.

In an occasional sinus in genito-urinary and in bone and joint tuberculosis that has come under my observation, the diet has helped to bring about favorable closure where other therapeutic procedures had failed for from one to two years. Frequently there was a large gain in weight, which was not reduced by the administration of table salt (as a control test of hydration).

CONCLUSIONS

In this question of the mineral salt metabolism, it is possible that certain constitutions will react favorably to the withdrawal of table salt. And it is equally possible that some individuals will improve on a larger vitamin intake, the two factors correlating in some way biochemically. But any schematization of the dietary therapy for all constitutions must be rejected. A universally efficacious curative treatment for tuberculosis does not exist, but the resistance of inferior constitutions and of defective or deficient organic functions can be raised by correct dietary treatment, and the raising of this resistance represents the meritorious aspect of these new endeavors. Evaluation of specific factors must be held in abeyance.

108 Main Street.

ROENTGENOGRAPHIC APPEARANCE OF THORAX AFTER RIB RESECTION FOR PULMONARY ABSCESS*

JOHN T. FARRELL, JR., M.D.
PHILADELPHIA

While much has been written concerning the postoperative roentgenographic appearance of the abdominal viscera, particularly the stomach, there is little in the literature on the roentgen appearance of the chest organs after operations on the thorax. This is probably due to the infrequency of thoracic operations compared to the great number performed on the abdominal organs. It is important that the roentgenographic changes following operation be recognized because roentgenographic study may be the only form of postoperative examination possible. Adequate physical examination is often prevented by the skin incision and bulky dressings, and frequently the patient is too ill to be subjected to thorough auscultatory and percussion procedures.

This study is based on the postoperative roentgen observations of twenty-three patients on whom rib resection was done for pulmonary abscess. The patients ranged in age from 8 to 50 years; sixteen were males and seven females. In thirteen patients the abscess followed operation (in twelve tonsillectomy, in one hemorrhoidectomy); in nine patients it followed an acute respiratory infection (in two pneumonia, in one pneumonia and empyema, and in six nonspecific respiratory infection), and in one patient the abscess developed as a sequel to fracture of the mandible. The abscess in fourteen patients was on the right side and in nine on the left.

It is often impossible to determine just how much of the altered roentgenographic appearance is due to surgical procedure and how much to the disease itself. It is safe to say, however, that so far as the patient's condition is concerned the more serious changes are due to disease, and that changes wholly secondary to operation are trivial from the clinical point of view.

FACTORS DETERMINING THE POSTOPERATIVE ROENTGENOGRAPHIC APPEARANCE OF THE CHEST

1. *The number and portion of ribs resected.* Except in cases in which the surgeon finds the pleural cavity obliterated by inflammatory adhesions, drainage of pulmonary abscess* is conducted in two stages. The first is removal of the ribs and the placing of a gauze pack against the pleura to form obliterating adhesions; the second is incision of the abscess and excision of part of the abscess wall.

Swelling of the skin and subcutaneous structures after operation is readily recognized when the side operated on is compared with the sound side. It is conspicuous following both stages. Sometimes air can be seen in the subcutaneous tissues. The duration of the skin and subcutaneous changes varies; in most instances it requires about a month after the second stage for the swelling to subside entirely.

The most apparent change after rib resection is the absence of rib shadows over the area of operation. When resected posteriorly or in the axilla, the absence of the ribs is readily detected; but after removal close to the chondrosternal junction anteriorly, the absence is not so striking. In some instances, absence of a portion of a rib anteriorly may go undetected; this is particularly true when the pulmonary changes which might draw the examiner's attention to the absence have disappeared.

Removal of any considerable portion of several ribs leads to sinking in of the chest wall over the area. Pronounced deformity is brought out on anteroposterior roentgenograms when resection has been done in the axillary line (fig. 6). The skin and chest wall sink in to form a V-shaped cleft with the apex directed centrally. This retraction is most marked on roentgenograms made shortly after operation, but it persists in some degree forever.

Retraction of the anterior or posterior thoracic wall following resection of these portions of the ribs does not produce striking deformity in the outline of the chest on roentgenograms made in the anteroposterior direction (fig. 4 *B*). The deformity may be detected in lateral roentgenograms, though usually the shadows of the normal lung overlap and hide the retraction to a considerable degree.

Absence of the ribs anteriorly or posteriorly may be hidden by a large abscess or by extensive pleural changes unless the Potter-Bucky diaphragm is employed.

Osteomyelitis sometimes develops in the rib ends after resection. It is not a common complication. The changes are identical with those of the disease in any bone, but in the ribs differentiation from the changes of operative trauma uncomplicated by infection may be difficult. The pathologic changes in the ribs are sometimes hidden by pulmonary or pleural densities.

Ribs usually regenerate after resection if the periosteum is left intact. In children this is a rapid process and may be recognized roentgenographically as early as three weeks after removal. In adults a longer time is required. A man, aged 30, showed no evidence of regeneration at seven weeks and only slight regrowth at eleven weeks. When the periosteum remains in the rib bed, new bone may bridge the gap between the cut ends and form a smooth rib that cannot be differentiated from normal rib. Bridges of bone often join two or more ribs.

---

* From the X-Ray Department, Jefferson Hospital.

* Read before the Section on Radiology at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 12, 1931.

* The patients forming the basis of this study were operated on by Dr. John B. Flick, to whom the author is indebted for the operative and clinical notes.

Linear shadows resembling those seen in the lung at the site of an abscess and similar to some types of tuberculous fibrosis may develop anteriorly along shreds of periosteum left after resection. They are occasionally difficult to differentiate even in stereoscopic films from pulmonary changes. Usually, however, the markings due to periosteal regeneration pass downward almost at right angles to the end of the resected ribs, whereas pulmonary fibrosis due to inflammatory change develops in the direction of the spread of the bronchial branches. In the apical portion of the lungs this is upward and lateral, and in the middle and lower portions downward and lateral, in any case being more nearly parallel to the ribs or at a less acute angle to them than the linear markings of periosteal regeneration.

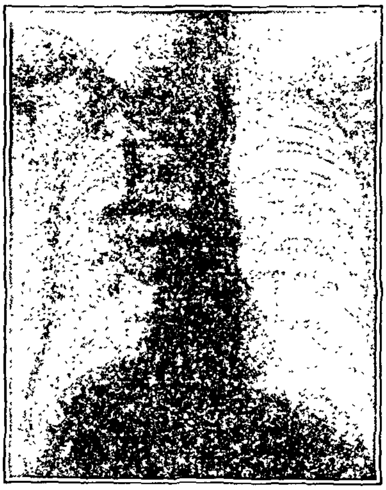

Fig. 1.—Indentation of the lung by gauze packed against the pleura in a man, aged 23, Jan. 30, 1930: Abscess of the right upper lobe, resection anteriorly one week earlier; deformity slight; swelling in the soft tissues.

When the wound is packed with plain gauze at the first stage, the shadows of the lung are not altered unless, as is the case in deep-seated abscesses, a strip of sound lung lies between the abscess and the pleura. The normal lung tissue overlying a deeply seated abscess is compressed by the packing, and a dense crescentic shadow forms at the perimeter of the lung with its concavity peripheral and convexity central (fig. 2). Iodoform gauze used as packing casts a distinct shadow.

It is important for the roentgenologist to know the operative procedure employed, for compression of a lower lobe may simulate an interlobar empyema. Figure 2 illustrates the roentgenographic appearance of a chest in which lobectomy was contemplated for bronchiectasis secondary to pulmonary abscess. A rubber dam placed between the under surface of the lower lobe and the diaphragm and packed with gauze has compressed the lung. The airless compressed lower lobe casts a shadow which might be mistaken for an interlobar empyema.

2. *The character of the pleural changes.* Both preoperative and postoperative changes in the pleura influence the roentgenographic appearance. Edema of the pleura or fluid in the pleural cavity, when present before operation, may obscure the abscess and normal lung and, when occurring postoperatively, hide the rib and pulmonary changes.

Preoperative pleural edema sometimes simulates the density of empyema and may be mistaken for it. It occurs complicating peripherally located abscesses and produces a homogeneous shadow resembling that of fluid. A diagnosis of fluid in the pleural cavity was made in two instances in this series and at operation only a markedly thickened and edematous pleura was found without free fluid (fig. 3).

The commonest roentgenographic finding immediately after operation is an increase in the size of the shadow of the diseased area accompanied by a slight increase in density (fig. 4). It is due to swelling of the pleura secondary to the operation, and is particularly well defined over the axillary border of the chest on the anteroposterior roentgenograms. Return to normal is usually rapid and follows absorption of the edema, though occasionally marked pleural edema may leave a residual thickening persistent for months.

Fluid occasionally develops in the pleura after operation. It is practically always due to extension of the disease to the pleura and is usually independent of the operative procedure. In most instances a pyopneumothorax develops and presents the classic signs of the condition, displacement of the heart and a horizontal fluid level on roentgenograms made with the patient erect. Encapsulated collections of fluid sometimes form, and interlobar collections are occasionally seen. Drainage leads to regression of their shadows.

There is nothing in the appearance of empyema developing postoperatively to set it apart from empyema occurring independently of operation. It usually masks the underlying pulmonary condition. Drainage lessens the density of the shadow, but, even after it has been done, it may be impossible to determine which of the remaining shadows are due to pulmonary disease and which arise from the pleural changes.

3. *The postoperative course of the disease and time after operation that the roentgenogram is made.* Many postoperative alterations are due to the disease and not to the operation. Extension of the lesion may take place, or new abscesses may develop. Their shadows depend on the extent and character of the new changes. Occasionally, small inflammatory foci develop in sound lung tissue and disappear by absorption without actual abscess formation.

In uncomplicated abscess going on to recovery, a gradual diminution in the density of the markings at the site of the abscess takes place. This begins at the periphery and progresses to the center. Usually there is left only an annular scar of fibrous tissue or radiating linear densities taking the direction of the vessels and bronchi. In time these ordinarily disappear and leave a normal pulmonary parenchyma. In the upper lobe fibrous tissue strands course upward and outward, in the lower lobe downward and outward. Scars in the upper lobes may be diagnosed as tuberculous in origin unless one is familiar with the patient's history. Lower lobe scars are similar to the shadows of bronchiectasis; indeed, they are sometimes due to

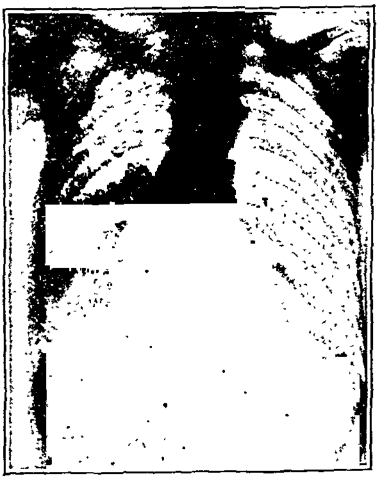

Fig. 2.—Compression of the lower lobe by a pack placed between it and the diaphragm simulating an interlobar collection of fluid, in a man, aged 44.

bronchiectatic dilatations at the site of the abscess. Bronchoscopic pneumography is necessary to differentiate residual interstitial fibrosis from bronchiectasis.

Multilocular abscesses or abscesses with indurated lung about the cavity show no change immediately after the second stage. This is due to the fact that it takes some time for the atelectatic lung to reexpand, and a dense shadow is cast until the lung is fully aerated.

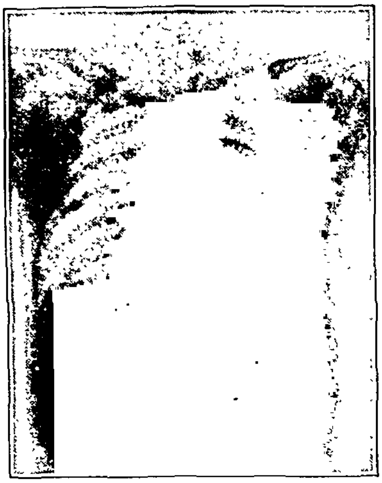

Fig. 3.—Edema of the pleura occurring preoperatively simulating an empyema, in a man, aged 31, Dec. 23, 1929: Abscess of the left lower lobe. At operation no free fluid was found in the pleura.

4. *Technic of examination.* Accurate comparative studies require similar exposure technic preoperatively and postoperatively. As a routine, preoperatively, stereoscopic postero-anterior exposures and a lateral view with the patient erect are made. In addition, exposures should be made anteroposteriorly and laterally with the patient in the horizontal plane. The latter preoperative exposures are necessary because after operation the patient is often too ill to permit the examination to be made with him sitting up or standing.

For some days after rib resection the patient is unable to raise his arm on the side of operation above his head as is necessary for the best lateral views. During this time he can extend it only at right angles. This position of the arm obscures the area of the upper lobe anteriorly, and in some cases may cast a shadow simulating interlobar changes.

5. *Sex and age.* Sex influences the appearance of the postoperative roentgenograms only in that the soft tissues of the female breast are disturbed. An incision above the breast may cast a finger-like shadow of lessened translucence. When this extends laterally to the axilla the condition is readily recognized, but when the incision is wholly anterior the area of lessened density often resembles a pocket in the lung. These translucent areas are due to separation by the packing of the skin edges of the wound at the site of the incision. A similar shadow is occasionally seen in males with well developed pectoral muscles.

Age is an unimportant factor unless the patient is not fully grown. In this group of patients, all but one had obtained practically mature growth. In a boy, aged 8 years, in whom an abscess developed in the right upper lobe after empyema, rib resection in the axillary line was followed by fusion of the regenerated ribs. The abscess entirely disappeared but the affected half of the chest has not developed normally, and three years after recovery its diameter is only half that of the normal side (fig. 5).

TYPES OF POSTOPERATIVE ALTERATIONS ROENTGENOGRAPHICALLY OBSERVED

Two types of alteration are seen roentgenographically after rib resection, structural and positional. The structural changes concern, first, the external conformation of the chest and follow the effects of the operation on the skin, subcutaneous tissues and ribs, and they also concern the intrathoracic organs, the pleura and lungs.

Alterations of position affect the diaphragm, heart, trachea and other mediastinal structures.

Structural changes of the skin, subcutaneous tissues and ribs alter the external conformation of the chest. The degree of deformity is determined by the length and portion of the ribs excised and by the time subsequent to operation that the roentgenogram is made. Swelling of the thoracic wall, sometimes accompanied by air which entered the tissues at the time of operation, and absence of rib shadows without evidence of osseous regeneration are the changes in the chest wall detected immediately after operation (fig. 4). The swelling lessens rapidly and the chest wall returns to normal thickness, the extent of the final deformity depending on the degree of retraction. If the periosteum has been left intact, rib regeneration usually takes place; in some cases it follows the bed of the resected ribs and in others produces osseous bridges spanning intercostal spaces to join two or more ribs together. The most marked roentgenographically recognizable deformities occur when resection is done in the midaxillary line (fig. 6). Resection posteriorly produces less distortion (fig. 4 *B*). After removal of ribs anteriorly, the deformity may not be roentgenographically recognizable on anteroposterior views and in lateral exposures may be obscured by the overlying shadows of the sound lung.

Structural changes of the pleura and lung have little effect in adults on the external conformation of the chest but produce roentgenographically recognizable changes within the chest. Pleural abnormalities are due either to edematous swelling or to the formation of fluid. Edematous thickening of the pleura as well as edematous swelling of the subcutaneous tissues practically always occurs after rib resection. The edema may be very slight and seen only along the axillary margin as a shadow a few millimeters thick, or it may be so marked as to obscure the entire side of the chest and hide the underlying pulmonary disease. In the latter cases the pleura is often a centimeter or more thick. Swelling of the pleura occurs preoperatively (fig. 3) and may be mistaken for empyema, as was done in two of our cases. Empyema sometimes develops during the postoperative course of lung abscess; the pus may be free or encapsulated.

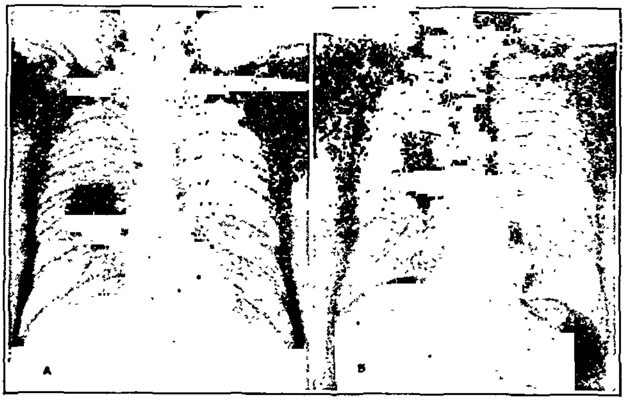

Fig. 4.—Abscess of the right lower lobe in a man, aged 50: *A*, before resection; *B*, eight days after the first stage. The size and density of the diseased area have been increased owing to swelling of the pleura. The subcutaneous tissues are swollen and contain air.

It is difficult to separate the component shadow densities when an abscess is accompanied by extensive pleural reaction. Regression of the abnormal shadows in both the lungs and the pleura takes place gradually, and usually the shadows finally disappear entirely.

Bronchopulmonary fistulas sometimes remain after external drainage of a pulmonary abscess. Their presence cannot be detected by direct roentgenography. They may be outlined by injection through the skin opening of an opaque medium such as iodized poppyseed oil. Bronchoscopic pneumonography is frequently helpful in determining the relation of the sinus to the bronchial tree of the lobe involved.

The pulmonary changes depend on the site and size of the abscess, on the condition of the pleura, and on the time elapsed after operation. When peripherally located, a unilocular abscess unaccompanied by pleural complications will lessen in density and extent immediately after evacuation, but if it has a well organized wall an annular shadow will persist unless the wall is excised at operation. An abscess surrounded by a zone of increased density due to indurated lung undergoes peripheral clearing which finally reaches the center of the area. Similar gradual regression follows evacuation of multilocular abscess with an encompassing pneumonitis, but return to normal takes longer and may be followed by a persistent scar of fibrous tissue resembling, when in the upper lobes, tuberculous fibrosis, and, when in the lower, bronchiectasis.

Abscess associated with pleural disease requires a longer time for complete disappearance of the abnormal roentgenographic shadows than uncomplicated abscess.

Change in the position of the thoracic viscera plays but a minor rôle in the postoperative roentgenographic appearance of pulmonary abscess. It is not the prominent feature of abscess that it is of such intrathoracic conditions as bronchial new growth, bronchial foreign body, postoperative pulmonary collapse or pleural effusion. The position of the diaphragm is altered more than that of the heart, trachea or other mediastinal structures; this, too, contrasts with the observations in other conditions. In empyema and obstructive emphysema displacement of the heart, aorta and trachea away from the affected side is pronounced; and in postoperative collapse or atelectasis secondary to bronchial foreign body or new growth, drawing of these structures toward the diseased side is characteristic. The position of the diaphragm in these conditions is often an unimportant diagnostic point; but in roentgenograms made after rib resection for pulmonary abscess the altered position of the diaphragm may be the only evidence of displacement, the heart, trachea and mediastinum maintaining their normal relations (fig. 6).

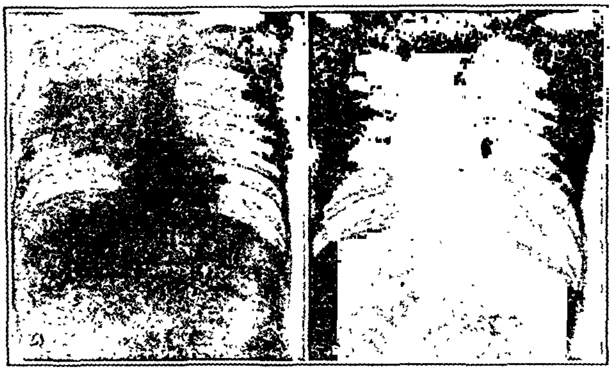

Fig. 5.—Abscess of the right upper lobe complicated by empyema, in a boy, aged 8 years: *A*, before resection for abscess; deformity of the eighth rib posteriorly resected for an earlier empyema is apparent. *B*, thirty-three months after resection. The right half of the chest is less well developed than the left. Dense bridges of bone unite the resected ends, but there is still retraction of the soft tissues. A small scar remains in the lung.

This study has demonstrated that the positional change of the diaphragm after rib resection is directly proportional to the extent of the accompanying pleural changes. In patients without pleural complications, no change takes place. Mild reaction in the pleura causes the half of the diaphragm on the diseased side to rise slightly (fig. 4 *B*) and to remain elevated until the reaction subsides. Extensive pleural thickening or the development of an empyema always leads to marked elevation of the diaphragm on postoperative roentgenograms. After subsidence of the edema or evacuation of the fluid, this persists for a long time; in fact, the affected half of the diaphragm may remain above the normal long after the scar in the lung has disappeared. This persistent elevation is secondary, I believe, to fibrous tissue formed at the site of the abscess. After the empyema is drained or the edema absorbed, the lung is prevented from fully expanding by the scar, and the diaphragm remains elevated. The mechanism of the diaphragmatic elevation differs from that of the elevation seen in extensive fibrotic tuberculous lesions in that the pulmonary fibrosis in tuberculosis is directly responsible for the contraction of the lung, and elevation of the diaphragm follows without intermediary pleural changes. Pulmonary fibrosis is not an outstanding roentgenographic characteristic of pulmonary abscess postoperatively. It is pronounced only in those cases in which there have been marked changes in the pleura. Similarly, and probably for the same reason, bronchiectatic changes occur postoperatively more commonly in abscess complicated by pleural disease than in uncomplicated cases.

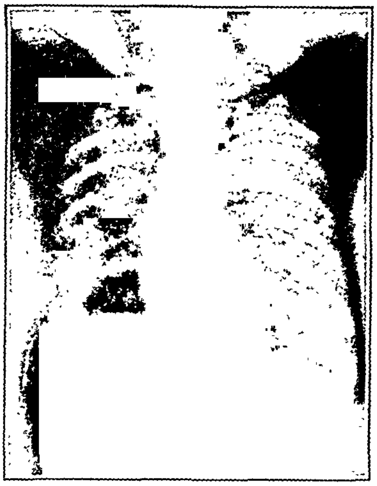

Fig. 6.—Retraction of the subcutaneous tissues five months after resection in the midaxillary line in a man, aged 33; abscess of the middle lobe; regeneration of ribs, residual thickening of the pleura, and scar in the lung at the site of the abscess. Note elevation of the diaphragm. Empyema, probably interlobar, complicated this abscess.

SUMMARY

1. In the study of a series of twenty-three patients, on whom rib resection was done for drainage of pulmonary abscess, it appears that the postoperative roentgenographic appearance of the chest is determined principally by the number and portion of the ribs resected, the character of the pleural changes, and the postoperative course of the disease.

2. Changes in the postoperative roentgenogram are structural and positional.

(*a*) Structural changes involve the skin, subcutaneous tissues, pleura and lungs and are influenced by the type of operation, the size and location of the abscess, the character of pleural complications and the postoperative course.

(*b*) Positional change is not the marked feature of abscess either before or after operation that it is of other pulmonary diseases. It affects the diaphragm more than the heart or trachea. Elevation of the diaphragm is seen in those cases associated with pleural edema or empyema. It is probably due to fixation of the lung by fibrosis developing at the site of the abscess while the lung is compressed by the pleural complication.

235 South Fifteenth Street.

ABSTRACT OF DISCUSSION

Dr. Merrill C. Sosman, Boston: I think the last thing Dr. Farrell said is probably the most important, namely, that the changes due to the disease are of great import to the patient and to the surgeon, whereas those due to the operation are, with the exception of the rib deformity, of much less importance. There is great difficulty in distinguishing between the changes due to the operation and those occurring as the natural sequence of disease. I think one thing of value in the differentiation is the rapidity of change. The conditions resulting from the operation are usually of short duration and they change rapidly. They are either edema or hemorrhage in the majority of cases. Those due to the disease are of much longer duration and change much more slowly. Dr. Farrell stressed the postoperative edema of the pleura, which at times is difficult to differentiate from pneumonia, from intrapulmonary hemorrhage and from empyema following operation on a lung abscess. There again the rapidity of change, I think, is one of the important, decisive factors in determining what is present. A third point he brought out was the necessity of getting a roentgenogram before operation in the position in which the patient is going to be after operation. It is difficult to get stereoscopic roentgenograms before operation and then try to estimate the change in the lung that has occurred when one has a portable apparatus, the patient lying on his back in bed and surrounded by a large number of dressings. It is difficult to compare lesions in the first set of films with the portable film. For that reason I am in favor of his suggestion of getting a roentgenogram before operation with the patient lying on his back. It is always wise when one is dealing with lesions in the right lung to look carefully for the interlobar septum between the upper and middle lobes. That sometimes is of great help in determining how much change in position of the lung, how much shrinkage or expansion is occurring from day to day. It has amazed me to find how variable the interlobar septum is. It may be as high as the first rib or it may be way down within an inch of the diaphragm. Its position may change rapidly from day to day, depending on the amount of the atelectasis or fibrosis present.

Dr. Samuel Brown, Cincinnati: I should like to recommend that the interlobar pleura be studied in the lateral view. Such a study may often help one to differentiate between a pulmonary abscess and an encapsulated interlobar empyema. These two conditions are often confused if one confines oneself to the anterior view.

Dr. John T. Farrell, Jr., Philadelphia: Dr. Sosman was very good to emphasize a point which I failed to make regarding the technic of operation. The last case was that of a small boy. At operation the empyema was not interlobar. The pus was free in the pleural cavity.

Insight into Womankind.—Gynecology has moreover a feature that is not shared with any other branch of medicine in that its practice is limited to one sex, and my contention is that those professing it should be much more than surgeons with a special flair for the female pelvic organs. Their insight into womankind should surely be something more than that disclosed by their inspections of the varying anatomical and pathological appearances met with in the reproductive apparatus. It is in this regard that the gynecologist has, in my opinion, failed to make the most of his undoubted opportunities, and I will follow the matter a little further.—Fairbairn, J. S.: The Medical and Psychological Aspects of Gynecology, *Lancet* 2:999 (Nov. 7) 1931.

THE TREATMENT OF EMPYEMA *

CARL A. HEDBLOM, M.D.
CHICAGO

The course and outcome of an empyema is determined not only by treatment but also by type and virulence of infection, pathologic anatomy, age and general condition of the patient, and the nature and gravity of the primary infection of which it is almost always a complication.

From the standpoint of treatment, empyema may be classified as pyogenic and tuberculous. The pyogenic form is subdivided into the acute and chronic; the tuberculous, which practically always becomes chronic, into that form in which there is, and that in which there is not, clinical evidence of pulmonary tuberculosis. The treatment of these several types will be discussed in order.

ACUTE PYOGENIC EMPYEMA

Empyema is recognized as pyogenic by the demonstration of the organism in a smear or culture of the aspirated pus. The pneumococcus, streptococcus and staphylococcus are the most common infective organisms, in the order named. These, and other bacteria, occur in pure culture and with anaerobes in varying combinations. Their virulence varies seasonably, and among individual patients, to a marked degree.

Pneumococcic empyema in adults is usually metapneumonic, developing after the pneumonia has subsided; the streptococcic is often synpneumonic, forming during the course of pneumonia. In infants pneumonococcic empyema is most common as in adults but, like the streptococcic, is usually synpneumonic.

An ordinary mild metapneumonic empyema is usually encapsulated by adhesions at the time it is first recognized. A streptococcic empyema may require two or three weeks for encapsulation. In the stage before adhesions have formed, the pus is characteristically thin; when it has become thick and creamy the presence of adhesions may be assumed. In any type of virulent infection the effusion accumulates rapidly and is at first seropurulent.

Empyema cavities vary greatly as to position and size. The usual position is in the lower posterolateral portion of the pleural cavity, but it may be in the paravertebral gutter, anterolateral, diaphragmatic, mediastinal, apical or interlobar. Multilocular and multiple isolated pockets occur. Occasionally both pleural cavities are involved. In size they vary from 30 cc. or less to 3,000 cc. or more, occupying then the whole pleural cavity, and, by bulging the mediastinum, encroaching on the opposite lung. Empyemas following pneumothorax, and those due to virulent infection are characteristically large.

Bronchial fistulas may result from an etiologic rupture of a pulmonary abscess into the pleural cavity, or from perforation of an empyema into a bronchus.

The fundamental principle in the treatment of empyema is complete drainage, obtained early and maintained until the cavity is obliterated by reexpansion of the lung. The ideal method, in any given case, is that one which brings this about at the least risk to the individual patient, and with a minimum sacrifice of structure and function. A short convalescence is highly desirable but is of distinctly secondary importance.

---

* Read before the Section on Surgery, General and Abdominal, at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

Since empyemas vary so greatly etiologically, structurally and clinically, it follows that no one method is universally suitable. The treatment to be most effective must be individualized.

Drainage may be accomplished by the so-called closed or open method, with or without irrigation, of which the various drainage devices, operative procedures, and irrigating solutions periodically rediscovered and advocated are simply variations.

After decades of discussion there persist the most divergent and even diametrically opposed views as to the relative merits of the closed and open method, and as to the usefulness of irrigation. Their attempted evaluation has been based chiefly on a comparison of statistics, in which sufficient account has not been taken of the many variable factors that influence the results of any given method. The age and general condition of the patient, the virulence of the infection, and the nature and severity of the underlying disease, as well as treatment, influence mortality. All play a part in the development of complications, which are so frequently the cause of death.

Chronicity may be attributable to the method as such, but also to the failure to carry out the principles involved. If an empyema cavity is kept empty of pus all the time, there will be a minimum of chronicity; while if drainage is not efficient, there will be a relatively large incidence of chronicity, regardless of the method of treatment. Duration of convalescence based on incomparable standards is used as a criterion in comparative studies of methods of treatment. A sinus may persist for months after the patient is discharged and may represent a persistent cavity. The degree of loss of function and of deformity should enter into the evaluation of any method.

Improvement of results and an increasing approachment of opinion regarding methods would seem to lie not so much in the study of inconclusive and incomparable statistics as in the direction of more attention to fundamental principles and more individualization of treatment.

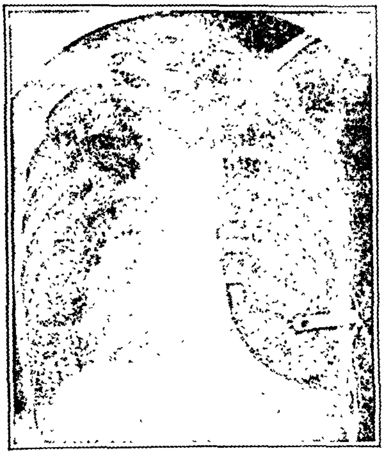

Fig. 1.—Traumatic empyema: fractured ribs with total collapse of lung of three months' duration. The patient is seemingly in a hopeless condition.

The fundamentals of treatment would seem to be drainage without embarrassment of respiration and circulation, reexpansion of the lung and general supportive measures.

The principle of drainage, kept adequate until the cavity was obliterated, established by Hippocrates, and more or less followed up to the time of the Arabian ascendency in medicine, was then, with few exceptions, discarded, up to a half century ago;[1] it is even now not sufficiently appreciated, as evidenced by the discussions as to when a tube should be removed and by the constant succession of chronic cases from insufficient drainage.

Reexpansion of the lung is essential to the normal obliteration of the empyema cavity. The chief mechanism by which it occurs in the presence of an open pneumothorax was explained by Weissgerber,[2] in 1879, as dependent on the paradoxical expansion of the collapsed lung by positive intrabronchial pressure, incident to forced expiratory effort, as in straining or coughing, by which the lung edge may be forced even into the wound. During this oft repeated expiratory expansion the lung gradually becomes adherent to the chest wall, first at the points of firmest and most prolonged contact. Its further expansion is favored by the same mechanism, and by the constantly progressing scar tissue formation and contraction along the angles of contact between visceral and parietal pleura, as pointed out by Roser[3] in 1878. These mechanisms may fail, and the lung then remains collapsed, unless its expansion is assisted by the development of a temporary or continuous, greater or lesser degree of negative tension in the cavity.

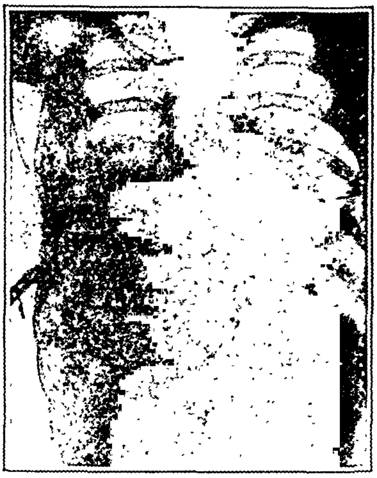

Fig. 2.—Same patient as in figure 1, showing degree of reexpansion of the lungs following irrigation with surgical solution of chlorinated soda through draining sinus.

The possible unfavorable influence of open pneumothorax in the treatment of acute empyema was recognized by the ancients. The simplest unpremeditated device for producing a negative tension in the cavity was the pus soaked dressing, around which air escaped during expiration, but which in part prevented its reentry during inspiration. This principle of the valve, more perfectly applied, is represented in the various skin muscle flaps, which are shaped at drainage operation, and in the numerous mechanical drainage devices that are now in use. Forced respiration by the use of the Wolf blow bottles and by other devices, including carbon dioxide rebreathing,[4] enhance their effectiveness as well as promoting reinflation of collapsed alveoli.

Valve action plus active suction is embodied in the siphon drainage of Buelau,[5] by which suction is kept up to the weight of the column of pus filling the rubber tube, inserted into the cavity through a more or less air tight stab wound. The valve action is provided by keeping the open end of the tube under water. The suction theoretically amounts to the length of the column in terms of water pressure, i. e., from 30 to 40 cm., but it must be recognized that the resistance of thick, more or less sticky, pus against the tube wall greatly reduces this pressure.

Perthes[6] further increased the negative tension by introducing a water suction pump into the drainage system, regulated by a water valve, so as to produce a suction equal to from 40 cm. to 120 cm. of water pressure. The various other suction devices are modifications of this method.

Perhaps the most fundamental and important contribution to the treatment of acute empyema, since Hippocrates, was the demonstration by Graham and Bell,[7] during the time of the World War, that under normal conditions the mediastinum in man is so mobile that from the standpoint of the intrapleural pressure relationship the two pleural cavities function as one. By so doing these investigators established the rationale for the avoidance of a wide open pneumothorax in an early acute empyema, and for the substitution of the closed method of treatment in such cases. As is well known, the mortality following this introduction of aspiration, and closed drainage of the streptococcus epidemic empyema cases, dropped from a maximum of 84 per cent, and an average of over 30 per cent, to an average of under 5 per cent. While the high mortality was doubtless due in considerable measure to the virulence of the infection and to the effect of a general septicemia, of which the empyema was only a part, and while the fall in mortality was due in part to a decrease in virulence of infection, it is generally recognized that it was due in large measure to the avoidance of open pneumothorax. The application of this principle to the treatment of acute empyema seems obvious. In the presence of an early acute empyema with a mobile mediastinum, an opening into the pleural cavity, of the size usually made for draining an empyema, lowers the respiratory capacity of both lungs. A normal individual has from four to seven times the respiratory capacity required when at rest. He has therefore a large reserve for compensating for the handicap of an open pneumothorax, of which he avails himself automatically by deeper and more rapid breathing. If, however, his vital capacity is greatly lowered by a pneumonia and associated toxemia, or if it is lowered by other serious illness, by operation or by old age, the added load imposed by the open pneumothorax affecting both lungs may be more than his reserve capacity can compensate for. An infant has normally a very low vital capacity, which a synpneumonic pneumonia further reduces. To do a wide open operation, therefore, early in a synpneumonic empyema, in a critically ill patient from any cause, or in an infant, is to contribute to an unnecessarily high operative mortality. Open operation in such circumstances, in my opinion, is chiefly responsible for the excessive mortality in infants under 2 years of age.

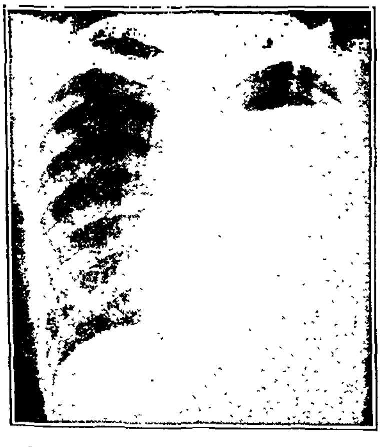

Fig. 3.—Massive tuberculous empyema with secondary infection.

The alternate method in such cases is aspiration or closed drainage. Aspiration of the pus at intervals of one or more days cannot properly be classified as a method of drainage, in that it removes only part of the pus. It is the most conservative and proper method of relieving mechanical embarrassment during the synpneumonic stage preparatory to instituting closed drainage, and it is particularly valuable in infants. A cure may be effected in the case of a small empyema cavity due to mild infection. If pus continues to form, adequate drainage is indicated. However, to continue with aspiration indefinitely is to repeat the experiences of the period before antiseptic surgery, when cases were reported in terms of the number of aspirations performed, and the collective amount of pus obtained. One instance is recorded of 122 aspirations in eleven months (Bouchet[8]), another of 50 gallons of pus aspirated. Simmons[8] recorded forty-eight cases treated by aspiration, of which forty-two were unimproved. Sir Astley Cooper[9] complained that he had never had a cure. Dupuytren[10] had four cures among fifty patients, and when he himself developed an empyema chose to die "by the hand of God rather than by the hand of the surgeon." The complications developing after prolonged aspiration are probably due more often to lack of drainage than to the disease causing the empyema, to which it is usually credited. It seems at least open to serious doubt whether infected effusion, even in the early, seropurulent, stage ever exerts any beneficent action by "resting the lung," or by stimulating antibodies.

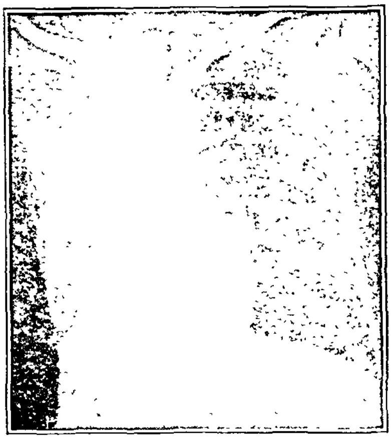

Fig. 4.—Same patient as in figure 3, following posterior thoracoplasy and resection of the anterolateral rib segments for obliteration of the cavity.

Recently Danna[11] has reported favorable results from aspirating all the pus, and substituting equal amounts of air, injected through the aspirating syringe. This method has long been in use in the treatment of tuberculous empyema,[12] particularly that variety of empyema complicating therapeutic pneumothorax treatment for tuberculosis. Elias,[13] in 1925, advised the procedure in nontuberculous empyema, and Davis[14] combined it with irrigation.

One important difference between this method and simple aspiration is that the pus may be practically all removed. What the influences of the air may be seems uncertain. I have used the method in tuberculous empyema but the pus has regularly reaccumulated for many months until thoracoplasty was performed.

Closed drainage can be made to approximate simple aspiration as an operative procedure. It can easily be done in the patient's room. The technic which I have followed with much satisfaction for twelve years is essentially as follows: Under local anesthesia a catheter (number 22 F.) is inserted through an ordinary bladder trocar and cannula, which it just fits, and fastened in place essentially after the method described by Mozingo,[15] and recently by Alexander.[16] Pus is then aspirated by means of a 60 or 120 cc. glass syringe. If the patient is an adult and the cavity is large, from 200 to 300 cc. is drawn off. The tube is then clamped and the piston of the syringe is removed. Saline solution in amount a little less than the amount of pus evacuated is then introduced by gravity, through the barrel of the syringe used as a funnel. The same amount of the mixture of pus and saline solution is now aspirated, a syringeful being first reinjected a few times to bring about a complete mixture. The process is repeated until the solution returns fairly clear. The catheter is now clamped off or attached to a tube after the method of Buelau. The process is repeated every two hours during the day and once or twice at night while the patient is toxic and the cavity is large. The nightly irrigations may then be omitted, but continuing it insures better drainage. Often it can be carried out without awakening the patient from sleep.

If there is no evidence of a bronchial fistula, e. g., no cough and sputum and no irritation during the irrigation with saline solution, surgical solution of chlorinated soda is substituted after the first two or three irrigations. If there is any doubt, the saline solution can be colored with methylene blue (methylthionine chloride U. S. P.). If the patient coughs up colored sputum, the presence of the fistula is proved, in which case only saline or nonirritating, weak, antiseptic solutions are used as long as there is evidence of its persistence.

In infants a smaller catheter is used and only small amounts of pus are withdrawn before saline solution is substituted. In this way there is no appreciable fluctuation in intrathoracic pressure.

Sometimes fibrin plugs the cathether during the first few irrigations. In my experience this has never occurred until some of the pus has been withdrawn. It is then permissible to introduce an equal volume of surgical solution of chlorinated soda for the purpose of softening up the fibrin. After this procedure has been repeated for a few two hour intervals, the fibrin is dissolved. Introduction of acid pepsin for the same purpose is recommended by Hermannsdorfer[17] and

By this simple method the cavity is not only kept emptied of pus but its walls are washed mechanically clean, fibrin and necrotic material are dissolved, and, if surgical solution of chlorinated soda or other bactericidal solutions are used, the surfaces are at least partly sterilized. The lung is kept partly expanded from the others. onset of treatment. The tube remains practically air tight for from one to three weeks or more. If air is excluded from the tube for such a period, which is an easy matter, the degree of expansion of the lung is controlled by the amount of fluid left in the cavity at each irrigation. By filling it to capacity once a day, by a few centimeters of gravity pressure, pocketing of pus is prevented. It is important to observe this precaution, especially during the first week, when dealing with very large primary cavities. Later, the same procedure serves to measure the progressive obliteration of the cavity. After the first few sittings the irrigations can be entrusted to a nurse, with the simple precaution never to inject the solution but always to use gravity in filling the cavity, and to discontinue the irrigation if the patient coughs unusually, or tastes the solution, or if the return becomes blood streaked. By the observance of these simple precautions I have never seen any untoward results from bronchial irritation, "pleural reflex," air embolus or sudden collapse, occasionally mentioned in the literature.

Irrigation is continued until the cavity is obliterated or until there is no further decrease in the size of the cavity. At such a stage the patient is practically always in good condition and the resection of a rib, with or without removal of the parietal pleura for open drainage, is simple and safe. If the cavity is of 50 cc. or more capacity, a complete removal of the roof of the cavity shortens convalescence. It is emphasized that the closed drainage is not done for the purpose of avoiding rib resection but to safeguard the life of critically ill patients, to give the less ill patient the benefit of what may well be termed the "de luxe" treatment, and to prevent the development of a large chronic cavity.

Cellulitis of the chest wall along the catheter sometimes develops, especially in patients who have a virulent infection, such as from mixed anaerobic and pyogenic organisms from the rupture of a lung abscess, and who cough a good deal. Such infection calls for open drainage, and for wide incision of the cellulitis as when occurring elsewhere.

Other varieties of the closed method, based on the procedure of Buelau and of Perthes are on the same principle as that described except that they do not include irrigation. Hart's[18] ingenious method included tidal irrigation, brought about by the respiratory fluctuating intrapleural pressure. Whether or not a rib is resected is of no particular consequence, except that leakage around the tube is perhaps more apt to develop.

In the milder types of acute empyema, in adults in good general condition, the choice between an open or a closed method of treatment depends largely on the size of the empyema cavity. If it is of large capacity, particularly if there is a massive collapse of the lung, the closed method practically assures as much reinflation of the lung as its expansibility will allow, and the antiseptic solution treatment will prevent pocketing and secondary infection, and will hasten recovery.

If the cavity is small and encapsulated, healing will occur by any method that provides and maintains adequate drainage until the cavity is obliterated.

Empyemas with bronchial fistulas are best suited for the closed method. If the fistula is small, irrigation and some degree of negative intrapleural tension can be maintained. If the fistula is large, open drainage is indicated, which also allows for cauterization or other treatment of the fistula.

By such individualization of treatment the mortality in the treatment of acute empyema has been very materially reduced. Muller [19] recently reported eighty-nine cases, 42 of them in infants, with a mortality of only 6.5 per cent.

CHRONIC EMPYEMA

An empyema is usually considered chronic when it shows no further progress toward healing, or when it has been present beyond a certain period of time, usually three months. Chronicity is usually due to inadequate treatment but may develop in spite of the best possible treatment. In 50 per cent of 310 cases under my observation,[20] chronicity was judged to have been due to inadequate drainage in the sense that it was not maintained until the cavity had become obliterated. It may be due to late primary drainage, to too early open drainage, resulting in extensive or complete pneumothorax collapse of the lung, to bronchial fistula, to foreign bodies and to fibrosis of the lung.

The aim of treatment of chronic empyema should be obliteration of the cavity by a method involving the least risk to the patient's life and minimal sacrifice of structure and function. This implies securing the greatest possible degree of reexpansion of the lung and the minimum degree of chest wall collapse.

In my experience it has been possible to secure a partial reexpansion of the lung, varying from 50 to 90 per cent, in more than two thirds of the cases without bronchial fistulas, by irrigation with surgical solution of chlorinated soda. Even if the cavity is not materially reduced there is always a marked improvement in the patient's general condition, as evidenced by gain in weight and strength often to a marked degree. The infection is greatly reduced in amount and virulence even if the cavity is not entirely sterilized. The magnitude of the operation is thus reduced, the patient's condition for operation improved and the operative field prepared.

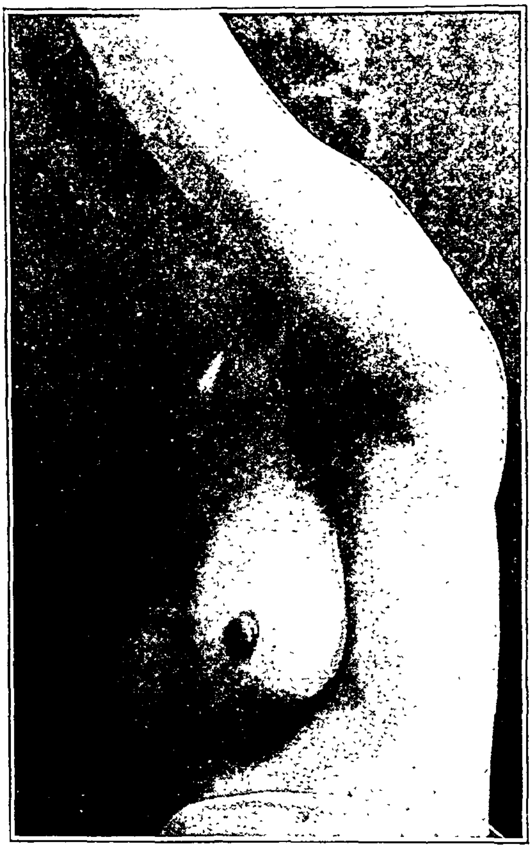

Fig. 5.—The scar of incision through which the anterolateral segments have been removed.

The technic is simple. If the patient presents himself with a sinus, the drainage tube is introduced through it, if possible. If not, it is introduced through a stab wound, as for the acute condition. The pus is aspirated and the cavity irrigated every two hours during the day.

The type of operation for the residual cavity depends on its size and shape. If less than 100 cc. capacity and flat, simple rib resection (Estlander) may be sufficient; but if the parietal pleura is thick and stiff, it should also be removed together with the intercostal bundles.

If the cavity is more or less globular, a decortication (Fowler Delorme) may release the lung, which will then more or less completely obliterate the cavity. However, in my experience decortication usually fails of its object in those cases in which irrigation with surgical solution of chlorinated soda has failed to bring about its reexpansion.

If the cavity has a capacity of several hundred cubic centimeters, it is usually desirable to do an operation in two or more stages, the ribs being resected at the first stage and the soft tissues at later sittings, with a muscle plastic operation after the method of Keller.[21] Skin plastic operations into large cavities overarched by the ribs often leave areas uncovered, which continue to suppurate indefinitely. I have recently done extensive plastic operations in several such cases of years' duration. If the cavity approaches 0.5 liter in capacity, a posterior extrapleural thoracoplasty is the operation of choice. It is performed in a clean field and can be subdivided into stages as made necessary by the condition of the patient. A plastic operation is then done for the residual cavity.

In case of total permanent collapse of the lung of long duration, a decortication usually fails. Extrapleural posterior thoracoplasty followed by anterolateral costectomy with final removal of the roof of the residual pocket, in my experience, will bring about the complete healing of any cavity, regardless of its size, including cavities with complete collapse of the lung.

Chronic empyema with bronchial fistulas are treated as other cases, according to the size of the cavity, but with additional measures directed to bring about healing of the fistula, provided it does not drain a pulmonary cavity, in which case it must be left open till the latter is cleared up. If a fistula is small, a few cauterizations with the electric coagulation current, or with the silver nitrate stick, together with the relaxation of the lung from the plastic procedure, will usually bring about healing. If it is 0.5 cm. or more in diameter, my practice has been to do a decortication of the lung around it, after which it may be closed by suture or a muscle plastic operation. If it is very large and lined with epithelium, this is first destroyed by the cautery, and the plastic operation is done after granulation tissue has developed. Calcium deposits on the pleura will prevent healing. If thin, they can be scraped away. If very thick and buried in the thickened pleura, they are removed piecemeal.

TUBERCULOUS EMPYEMA

An empyema is considered to be tuberculous if it develops primarily without a preceding acute infection. A history of preceding pleurisy with effusion should always suggest the possibility that a later empyema is tuberculous, even if it follows an acute infection.[22] If pyogenic organisms cannot be demonstrated in aspirated pus by smear or culture, it should be treated as of tuberculous origin. Occasionally tubercle bacilli can be demonstrated by smear, and often by culture or guinea-pig inoculation; but the latter procedures require too much time to be of much practical value from the standpoint of immediate treatment.

Differentiation of a sterile tuberculous empyema from one of pyogenic origin is of the first importance to treatment, in that a sterile tuberculous empyema should not be subjected to open drainage. To do so induces a secondary pyogenic infection, which endangers the patient's life and inevitably leads to chronicity. If the pleura is tuberculous it has little resistance to pyogenic infection and little healing power. In such cases only the most radical thoracoplastic procedures will bring about healing.

A sterile tuberculous empyema of idiopathic origin, and without clinical evidence of pulmonary tuberculosis, is treated on diametrically opposite principles to those governing treatment of a sterile tuberculous empyema with active pulmonary tuberculosis on the same side. In the first instance an effort is made to obliterate the cavity by securing reexpansion of the lung. In the latter, treatment is directed to keeping the tuberculous lung collapsed.

The treatment of a sterile tuberculous empyema of the idiopathic type is aspiration of the pus, filtered air being substituted in such an amount that the intrapleural pressure is about atmospheric. The procedure is repeated at intervals as the pus reaccumulates. The pneumothorax usually lessens the purulent secretions. Absorption of the air into the blood stream creates a less than atmospheric intrapleural tension, which tends to reexpand the lung. If pus continues to reaccumulate after from six months to a year of such treatment, and the lung shows no evidence of extensive reexpansion, a graded posterior extrapleural thoracoplasty is indicated. Prolonged absorption of pus usually results sooner or later in irreparable damage of the heart, of the kidneys, or both, and may produce extensive amyloidosis.

Sterile tuberculous empyema with associated active pulmonary tuberculosis is treated similarly to the idiopathic type, except that an attempt is made to prevent expansion of the diseased lung by keeping the pneumothorax pressure atmospheric or positive. If pus reaccumulates indefinitely it constitutes the same indication for thoracoplasty as in the case of the idiopathic type. The age, the condition of the patient, and the presence and the type of the pulmonary or other tuberculous process naturally may constitute contraindications to thoracoplasty.

An undrained tuberculous empyema may be secondarily infected by a bronchial fistula or by the lymph or blood stream. Presumptive evidence of an associated tuberculous pleuritis, in case pyogenic organisms are demonstrated in the smear or on culture, rests on the history of previous idiopathic pleurisy with effusion, or on the presence of an obvious tuberculous process in the lung or elsewhere. If the bacteria are few in number and the clinical symptoms mild, treatment should be the same as for the sterile tuberculous form. If there are large numbers of organisms, particularly streptococci, and if there are marked symptoms of sepsis, drainage must be instituted as in the pyogenic form, except that an erosive solution such as surgical solution of chlorinated soda or that of gentian violet must not be used if there is evidence of a pulmonary tuberculosis. If the pyogenic infection can be cleared up, the case is then treated as the sterile tuberculosis.

A tuberculous empyema secondarily infected by injudicious drainage may present the same presumptive evidence of tuberculosis as the undrained type. Its preliminary treatment is that of the chronic pyogenic type; its final treatment as outlined for the tuberculous. If there is no pulmonary tuberculosis it is desirable to bring about reexpansion of the lung; if there is pulmonary tuberculosis on the same side a thoracoplasty is usually indicated.

SUMMARY

1. Empyema may be of pyogenic or tuberculous origin. Differentiation depends essentially on examination of smear and culture for pyogenic organisms. Treatment differs radically.

2. The mortality rate and the incidence of chronicity in acute empyema depend not only on treatment but also on the type and virulence of infection, on the pathologic anatomy, age and general condition of the patient, and on the nature and gravity of the primary infection, of which it is almost always a complication. Comparative statistics of results of different methods of treatment that do not take these variable factors into account are inconclusive and misleading.

3. The fundamental principle of treatment is drainage, instituted early, by a method that will not embarrass respiration and circulation, and maintained until the cavity is obliterated, plus general supportive measures.

4. In the early stages of an acute empyema, before the lung has become adherent or the mediastinum has stiffened, the two pleural cavities function as one. Open drainage then lowers the respiratory function of the other lung. If the vital respiratory capacity is reduced by a coincident pneumonia and toxemia or other cause, or if the patient is an infant who normally always has a low vital capacity, such open drainage always adds to the respiratory load, often to a degree beyond the patient's compensatory reserve.

5. Closed drainage not only does not interfere with respiratory capacity but improves it. It is therefore the method of choice in all early, acute cases, in severely ill patients and in infants. Irrigation with antiseptic solutions makes possible the removal of all the pus without changing the intrathoracic pressure relationships and is bactericidal.

6. Ordinary rib resection and pus drainage is the alternative method, after the lung has become fixed by adhesions, and is the method of choice in cases with large bronchial fistulas.

7. Closed drainage and irrigation with surgical solution of chlorinated soda in chronic cases usually reduces the size of the cavity to a marked degree, improves the patient's condition and prepares the field for operation.

8. Residual empyema cavities may be obliterated by plastic operations varying according to their size, shape and position. Cavities involving the whole pleural cavity can be obliterated with minimal operative risk [illegible]terior and later extrapleural thora[illegible] by the removal of the thickened pleura over the residual cavity.

---

22. Hedblom, C. A.: Diagnosis and Treatment of Tuberculous Empyema, Surg., Gynec. & Obst. 34: 445-465 (April) 1922.

9. Drainage is contraindicated in sterile tuberculous empyema. If without clinical evidence of associated pulmonary tuberculosis on the same side, air is substituted for the pus, and an attempt is made to bring about reexpansion of the lung. If there is associated active pulmonary tuberculosis, pneumothorax is continued, and, if pus continues to form, a plastic obliteration of the cavity is brought about, as for the nontuberculous type.

10. Undrained tuberculous empyema with a mild grade of pyogenic infection may be treated as though sterile tuberculosis. If there is a draining sinus, or if the pyogenic infection is virulent, treatment at first is by the closed method for the pyogenic infection followed by a complete thoracoplastic collapse and excision of parietal pleura over the residual cavity.

30 North Michigan Avenue.

ABSTRACT OF DISCUSSION

Dr. Ethan F. Butler, Elmira, N. Y.: My discussion, based on 323 cases in my own experience, is limited to the acute and chronic nontuberculous groups. Only by refined diagnosis can the most logical plan of operative attack be formulated. In acute empyema the mortality varies widely, dependent on the causal organism. The rate for the pneumococcus is approximately 10 per cent; for the streptococcus it is twice as high; for the mixed infections secondary to foci in other parts of the body, it is seven times as high. The age of the patient influences mortality figures; they are much higher during infancy and old age than during adolescence and early adult life. The lowered vital capacity of the infant, as Dr. Hedblom has pointed out, and the degenerative changes in the aged or relatively aged, determine this variation in mortality rates. Vital capacity is a good guide in deciding on the type of primary operative attack for acute empyema. If the vital capacity is diminished, closed drainage is indicated. As the vital capacity improves, open drainage may be substituted. I like open drainage, whenever it may be properly employed. Speed of recovery must be a secondary consideration in all cases of thoracic infection—a slow program is safer for the patient than a rapid one. Probably from fifteen to twenty different operations for empyema can be listed, but so far as the acute cases are concerned they can be grouped into closed or open methods. The general surgeon need not know them all, but he should be thoroughly familiar with at least one closed operation and one open operation. These patients require close daily attention and the surgeon must be willing to give this service. A value of 10 may be placed on the operating room procedures and a value of 90 on the day by day bedside care of the patient. In chronic cases this is particularly true.

Dr. John Alexander, Ann Arbor, Mich.: There are only four essential principles in the treatment of empyema: 1. No empyema should be drained until a culture or smear of a sample of aspirated pus shows pyogenic organisms. If none is present the empyema is probably a pure tuberculous one whose drainage, as Dr. Hedblom said, would inevitably lead to grave mixed infection. This rule should be adhered to, no matter how high the temperature and no matter how ugly the appearance of the pus. 2. No acute empyema should be drained by a tube that is not air tight with the thoracic wall, until one has reasonable assurance that the empyema is encapsulated at its periphery by firm adhesions, which take from one to three weeks to form. Until encapsulation has occurred, the pus should be aspirated as often as symptoms of pressure or toxicity may indicate. Drainage by a certainly air tight technic may advantageously be substituted for repeated aspirations. 3. Two tubes should invariably be used in either the open or the closed drainage of empyemas without bronchopleural fistulas. One of the two tubes should be wide enough to carry off any clots that the pus may contain; the second tube may be narrow and is used for the introduction of whatever antiseptic irrigating solution may be chosen. The use of one tube for both drainage and introduction of antiseptic solution has the disadvantage that every drop of solution introduced causes distention of the empyemic cavity, which tears the fine adhesions that pull out the lung and obliterate the cavity. Dr. Hedblom's one-tube system has not this objection because he keeps the tube clamped and periodically instils a lesser amount of solution than he has just evacuated. I myself prefer to maintain constant air tight siphonage drainage of acute cases. 4. The two tubes of proper size and length should be kept in place at the very bottom of the empyemic cavity until there is evidence that it has become obliterated. Their removal just because the temperature has become normal and the secretion scanty too often results in a chronic empyema. Were these four principles applied as the only important ones for the average patient and minor considerations and fancy types of drainage forgotten, the end-results of treatment would be immeasurably improved.

Dr. J. W. Barson, Joplin, Mo.: Here is a case of a boy, aged 17, who, after playing football, developed a pleurisy with effusion. Unhappily he had been treated by an osteopath for about seven or eight weeks before. On each inspiration a point could be seen where the pus was trying to make its way through the chest wall. There was a bronchial fistula. The heart was pushed over to the right side, and when a rib was resected about 3 quarts of extremely foul pus was evacuated. The empyema sac was drained for about three months, and it seemed to be almost obliterated, but not quite. The boy was then allowed to go West in the hope that within a couple of years he would regain his health, but so much lung tissue had been destroyed that the cavity in the pleural sac persisted and he came back with a large bronchiectasis on each side. This is a thing that has not been mentioned. There is danger that, instead of the lung expanding, bronchiectasis may develop and that is a serious matter. This boy then required avulsion of the phrenic nerve and two or three operations on the ribs in order to collapse the lung. The point I wish to make is that too long neglect of a proper resection of ribs when there is a persistent pleural cavity may, by negative pressure, cause the bronchi to dilate and thus produce a bronchiectasis that is more serious than the primary disease.

Dr. J. A. Danna, New Orleans: In a paper in The Journal, May 2, I reviewed thirty-five cases of empyema treated by aspiration and air replacement. Dr. Hedblom dismisses the subject of aspiration rather lightly. I think that a series of some thirty-nine or forty unselected cases in which the causal organism was of every possible variety and in which there were only two deaths, neither of which could be attributed to the method, should not be passed over quite so lightly. The treatment consists of aspirating the pus with a 50 or 100 cc. syringe, and as each syringeful of pus is removed, an equal quantity of air is injected, the object being not to interfere with the architecture of the cavity, as it were, and not to traumatize it. By replacing the fluid with air, one is able to remove every bit of fluid. In cases in which the fibrinous exudate prevents the needle from working, the same effect will be produced by making a small stab wound, placing open forceps in the wound, and having the patient forcibly inspire and expire, with each expiration forcing fluid out, with each inspiration forcing air in. If fibrinous masses block the opening, with the same forceps one should pull them out until the cavity is entirely empty. Some patients have been cured with one aspiration or treatment of this kind. By the way, when these little stab wounds are made they heal right up and have to be reopened in order that the treatment may be renewed. Others have required ten or fifteen or twenty treatments, the difference being as to whether the empyema cavity is still being fed by the focus of infection. If this method is tried before open or closed drainage is begun in patients who are very sick, some of them will recover without other treatment.

Dr. Carl A. Hedblom, Chicago: Dr. Butler has rightly emphasized the importance of the after-care of patients treated for acute empyema by the closed method. Adequate drainage by the closed method in my experience necessitates washing the cavity until the irrigating solution returns clear every two hours during the waking hours; e. g., from about 6 a. m. to about 10 p. m. If the patient is highly toxic, my practice has been to shorten the interval and to irrigate also once or twice during the night. Properly carried out, it does not tire or irritate the patient. Often he will not be aroused from sleep. If, for any reason, this routine cannot be carried out adequately it will be better for the patient to have wide open gravity drainage as soon as the critical stage of his illness is past. I cannot quite agree with Dr. Alexander that two tubes are necessary. In fact, in my experience a secondary tube has never been necessary. If pus is aspirated first, and if the amount of irrigating solution allowed to flow in is always less than the amount of pus removed, and if air is not admitted, there can be no dilating effect on the cavity. The result, in fact, is to the contrary. In my paper I have referred to Dr. Danna's method. Aspirating the pus and replacement with air is, of course, a recognized method of treatment of sterile tuberculous empyema. Just how effective this method will prove to be in dealing with pyogenic empyema, experience will have to determine. Dr. Danna's results certainly have been good. The method may prove of great value in empyema due to infection of low virulence.

ONYCHOLYSIS

AN INDUSTRIAL DERMATOSIS *

H. J. TEMPLETON, M.D.
OAKLAND, CALIF.

Very little has been written in regard to separation of the fingernails from the nailbeds. Practically nothing has been recorded in regard to such a condition, onycholysis, being related to the industries. Since 1928, I have been called on to determine the industrial status of five cases in which patients claimed that their fingernails had separated in whole or part from the nail beds as a result of their particular occupations. An investigation disclosed that their allegations were correct. The cases all became compensable and, hence, of interest to industrial physicians and insurance companies.

A thorough search of all the available literature failed to disclose any similar cases. Any claim to priority of description of such cases was shattered, however, when in a personal interview Oppenheim told me that he had reported several similar cases in 1910. Although there are some dissimilar features in his cases, there would seem to be no question but that they belong in the same category as mine.

REVIEW OF THE LITERATURE

Oppenheim's cases were all presented before the Vienna Dermatologic Society during November, 1909.[1]

Case 1.—A woman, aged 50, a housewife, with no history of dystrophies of the nails in her family, first noted a separation of her fingernail eight or nine years previously. She believed that her trouble was caused by doing laundry work. All her nails, with the exception of that of the left thumb, showed a separation of the nail from the nailbed in various degrees (fig. 1). This separation was limited by a semilunar line with its convexity proximal. The separation was an extension proximally of the normal separation between the nail and the end of the finger. The nail itself was unchanged in color and luster. The nail lunula and the surrounding skin were normal and the skin of the nailbed was smooth. The separation had never reached the lunula. The toenails were normal.

Case 2.—A woman, aged 35, a housewife, noticed a loosening of her fingernails five years previously, following considerable laundry work. This separation occurred without producing any symptoms. The nails of the second, fourth and fifth right fingers and of the third left finger were involved. The changes were exactly the same as seen in case 1.

Case 3.—A woman, aged 23, a housewife, observed an asymptomatic separation of her fingernails one year previously, which she attributed to laundry work. All the nails of her right hand and those of the third and fourth left fingers were involved. The changes in the nails were the same as in the other two patients.

Oppenheim's patients were all women domestically engaged in laundry work. Their afflictions began gradually without subjective symptoms and lasted for years. Their toenails were all normal.

The author felt that the separation was brought about by laundering with hot water and soda, although the question remained open whether the chemical or the mechanical insults were to be given the greater rôle or whether they work in conjunction. He showed that trauma was applied to the free ends of the nails by their part in rubbing the clothes over the washboard and in wringing the clothes dry. Those fingers were most affected which suffered the most trauma. The chemical factor of the water and soda macerating the tissues under the nails would render them more liable to separation by the mechanical factor.

Case 4.[2]—A woman stated that she used a washing powder called "Persil" for laundering. About one week later small vesicles appeared under the nails, which loosened to the extent shown in figure 2. Four years later the nails had regrown, with the exception of the one on the third finger of the right hand.

AUTHOR'S CASES

Case 1.—Mrs. Anna J., aged 34, began washing paste from labeled catsup bottles, May 14, 1928. She had not been engaged in this type of work previously. It necessitated intermittent submerging of her hands in water throughout the day. On the second day she noticed blue black spots appearing under the nails of several of her fingers (fig. 3). These dark areas spread rapidly and in two days had involved nearly the whole of the nailbeds of all her nails. This process was remarkably free from pain. May 18, four days after beginning bottle washing, she was forced to lie off and consult the plant physician. He found all her nails loosened from the nailbeds. There was a slight serosanguineous discharge from under the nails. There was no evidence of paronychia, nor was there any pus under the nails. The nailbeds were not acutely inflamed. Within three weeks the nails had entirely separated from the

[2] An unpublished case, reported by courtesy of Professor Arzt and Docent Fuhs and Matras of Vienna.

nailbeds except at the lunula. Some of the nails came off with the dressings. By June 23, the nails had begun to regrow. June 27, it was felt that the patient could resume light work.

There was no history of familial nail dystrophies. No illness or drug ingestion preceded the onset of her trouble. There was no history of previous dermatoses nor was there any other cutaneous abnormality present. A general examination showed her to be apparently in good health. There was no evidence of thyroid abnormality. Scrapings from the toenails were negative for fungi. A Wassermann test was not obtainable.

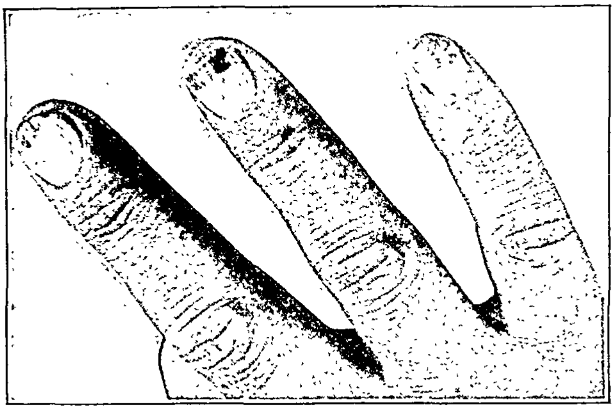

Fig. 2.—Onycholysis in a washerwoman using "Persil," a washing compound. Courtesy of the Klinik Arzt.

The diagnosis was onycholysis, industrial in origin. The insurance company accepted liability and compensated her for thirty-nine days' loss of time.

Case 2.—Miss Eva F., aged 18, began the same type of bottle washing two weeks before consulting me. Her hands were immersed in water the greater part of her eight hour day. She had not done this type of work previously. Two days after beginning work she noticed "black spots" appearing close to the free edge of the nails. These black areas appeared to be under the nails. They rapidly enlarged and spread toward the root of the nail. As they spread, the nails separated from the nailbeds. Within a week the nails were loose except at the proximal portions. All the nails of the right hand and those of the third, fourth and fifth left fingers were involved. The process was free from pain. There was no discharge of pus, serum or blood from beneath the nails (fig. 4).

There was no history of nail dystrophies in her family, nor of recent illness, drug ingestion or previous dermatoses.

Examination disclosed that the patient was perfectly healthy. There was no evidence of thyroid dysfunction or of xeroderma. There was no other cutaneous abnormality. Her toenails were normal. Scrapings from her fingernails were negative microscopically and culturally for fungi.

The girl was removed from bottle washing. When seen four and a half months later the nails had grown again in a normal manner. The diagnosis was onycholysis, industrial in origin. The insurance company accepted liability and compensated her for three months of disability.

Case 3.—Anna B., aged 21, began the same type of bottle washing one month before consulting me. She had not worked at this type of work previously. Two days after beginning work she noticed light brown spots under the nails of her fourth and fifth right fingers (fig. 5). These have gradually increased in size up to about 5 mm. in diameter. No symptoms have been present except slight pain when the fingers have been immersed in water. The other nails have not been involved. There was no separation of the nails from the nailbeds, nor was there paronychia. Her history revealed no familial nail dystrophies. She had had no skin troubles previously. No illness or injury to the nails preceded the onset. She used no nail polish. She had taken occasional doses of a proprietary phenolphthalein laxative.

A complete physical examination was essentially negative. Specifically, there was no evidence of thyroid abnormality, no acrocyanosis, no cutaneous lesions elsewhere and no abnormalities of the toenails. Scrapings from the fingernails were negative for fungi. The diagnosis was impending onycholysis, industrial in origin. The patient was taken off of bottle washing and no disability occurred.

Case 4.—Mrs. Mollie S., aged 22, noticed slight tenderness of her fingertips the first evening after beginning the washing of catsup bottles, which type of work she had not done previously. The next day black areas appeared under the distal portions of all the fingernails except that of the first left finger. Within a few days the nails had separated from the nailbeds wherever the blackening had occurred (fig. 6). On most nails this was limited to their distal halves. The process stopped here and the nails slowly grew and became attached normally to the nailbed. At no time was there any evidence of inflammation such as pain, discharge or paronychia.

The patient was healthy. Her family and personal histories were of no interest. A complete physical examination was negative. Her toenails were normal. There were no other cutaneous abnormalities. Scrapings from her fingernails were negative for fungi. The diagnosis was onycholysis, industrial in origin. The insurance company accepted liability and compensated her for ten weeks' loss of time.

Case 5.—Miss Alice H. was referred to me four months after her nails had become loosened from the nailbeds following the same type of work as in the preceding cases. The old nails had come off of the second, third and fourth right fingers. The first and fifth right fingernails showed about 90 per cent regrowth. The third and fourth left finger nails were only slightly loosened at their free edges.

Like my other patients, she stated that this process had begun acutely within forty-eight hours after she first began to wash catsup bottles. Black areas had appeared under the nails and the nails had rapidly separated from the nailbeds at these locations.

There had been no cutaneous or ungual dystrophies in her family. Her personal history was negative except for nystagmus (due to birth injury?) and symptoms suggestive of hypothyroidism. Her toenails were normal, as was her skin. Scrapings from the involved nails showed no fungi.

When seen two years later all her nails were perfectly normal. She said that about six months' time elapsed from the injury to perfect restitution of her nails.

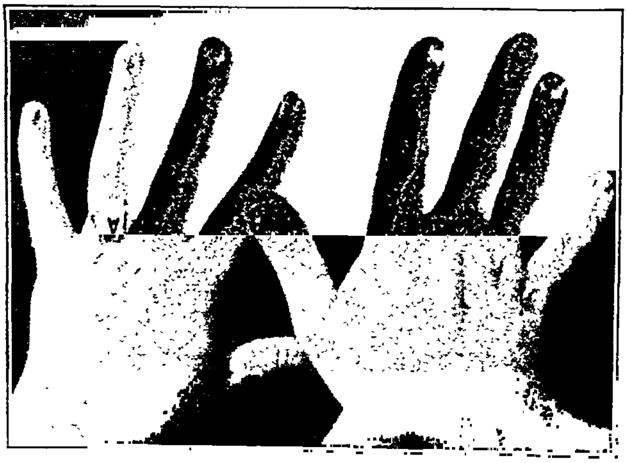

Fig. 3.—Onycholysis in author's first patient.

The diagnosis was oncholysis, industrial in origin. The insurance company accepted liability and compensated her for loss of time.

INVESTIGATIONS

As all these patients incurred their trouble while working at one particular plant, all doing the same type of work, an investigation of working conditions was made in cooperation with the employers and the insurance company.

It was found that the sanitary and working conditions of the plant were of the highest order. All the trouble occurred in healthy young women who were engaged in washing paste off of catsup bottles which had just been labeled. The catsup bottles were first washed, then filled with catsup and capped. The catsup was then washed off and the bottles were dried. Labels were then pasted on. All the work up to this point was done by groups of girls other than the bottle washers. None of these groups suffered from nail disorders. The bottles, covered with paste, were delivered to the bottle washers on a conveyor and were dumped into wooden wash tubs filled with lukewarm city water to which no chemicals had been added. The bottle washers wore no gloves and used no soap. They were provided with sponges with which they removed the paste. Their hands remained submerged in water a large part of the time.

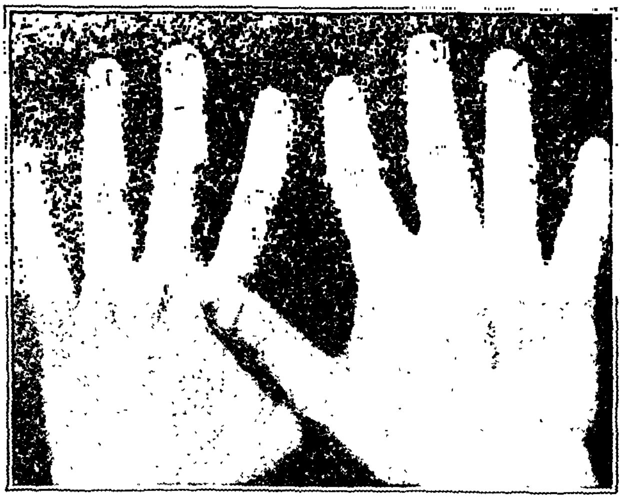

Fig. 4.—Onycholysis in author's second patient.

Possible causative factors which we considered were as follows:

1. Could the catsup have been at fault? This possibility would seem to be eliminated by the freedom of the groups who came in contact with the catsup and by the fact that it was thoroughly washed off the bottles before they were sent to the bottle washers.

2. Could the paste be blamed? The group of girls whose hands were in the paste all day did not suffer from nail disorders.

3. Could the chemicals on the labels be the cause? The label manufacturer informed us that no similar cases had occurred in his plant.

4. Could the chemicals in the water be the cause? No soaps, lyes or chemicals were added to the water. Only 0.06 part per million of chlorine was added to the water supply at its source. As this would have been neutralized in the city mains it could be of no significance.

5. Was there irritation from the sponges? We were unable to secure much information in regard to sponges, but as the ones provided were old and frequently washed we did not believe that they could be at fault.

6. Could maceration of the tissues which bind the nail to the nailbed occur by long continued immersion of the hands in water? This is self explanatory and, I believe, a very important factor.

7. Was mechanical trauma to the free ends of the nail to blame? We observed some of the girls picking at resistant specks of dried paste on the bottles. I think that this factor is one of several, operative in producing the disorder.

8. Is there a personal factor predisposing to ease of separation of the nails? No evidence could be found in our examinations of the afflicted girls to support such an hypothesis. Yet the fact that only a small percentage of new employees were involved speaks in favor of it. If a new employee tolerated the work and did not show loosening of the nails within forty-eight hours, she apparently was capable of washing bottles indefinitely.

SUMMARY

New employees, apparently healthy, developed black spots under their fingernails within forty-eight hours after beginning work washing paste from labeled bottles. Within a few days the nails loosened from the nailbeds at these areas. The process was without symptoms. The nails regrew in from four to six months. Investigations revealed no specific industrial irritants at fault. I believe that the disorder was precipitated by maceration of the tissues by prolonged immersion in water plus, possibly, the mechanical insult to the tips of the fingernails from picking at resistant pieces of paste.

But back of all of this, in my opinion, was some personal factor which made the nails separate from the nailbeds more easily than would those of normal individuals.

COMMENT

Although my cases and those of Oppenheim belong to essentially the same group, it can be seen that there are some differences. My patients presented an acute fulminating separation of the nails, while the process in Oppenheim's patients was essentially a chronic one. This difference might be explained by my patients' immediate removal from the offending work. Oppenheim made no mention of the sudden appearance of blackened areas under the nails, which was so characteristic in my cases.

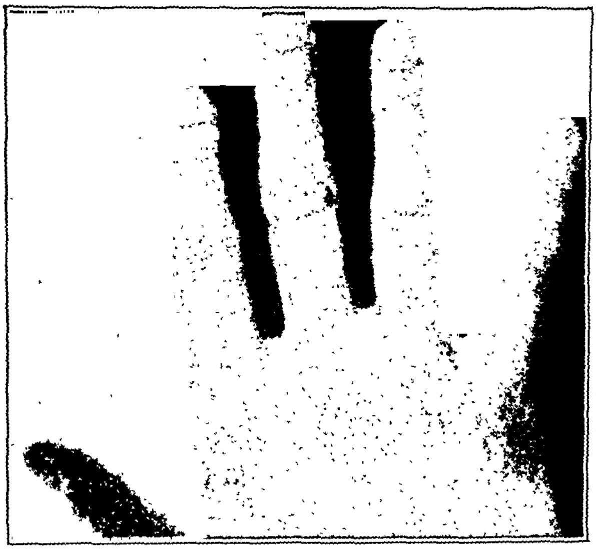

Fig. 5.—Earliest stage of onycholysis, as seen in author's third patient. Only a darkened area can be seen under the fifth nail.

Heller[3] described ten cases of onycholysis in which the etiology was indefinite. He believed that external irritants, such as soda did not play a causative rôle. His cases were unrelated to the industries and differed clinically from mine. He made no mention of sudden onset with darkening of the nailbed.

---

[3] Heller, Julius: Die Krankheiten der Nagel, Berlin, Julius Springer, 1927, p. 113.

A search of the available literature revealed no other records of onycholysis of this type.

R. Prosser White[4] stated that he had not observed any similar cases and that in conversation with his British colleagues he had been unable to find any record of such. One of the leading authorities on industrial medicine, Dr. E. R. Hayhurst,[4] stated that the condition was unknown to him.

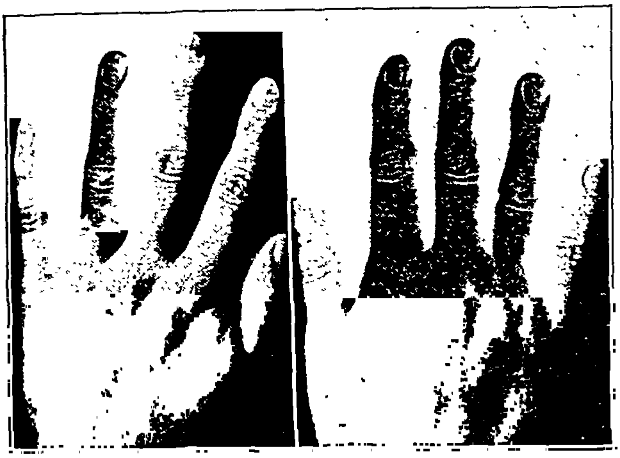

Fig. 6.—Onycholysis in author's fourth patient.

Dr. E. E. Taylor,[4] physician in charge of the eastern plant of the company in which the cases that I have reported occurred, stated that they had had two or three similar cases in a period of twenty-two years. These cases were not reported.

CONCLUSION

1. Five cases of onycholysis are reported.
2. As they were industrial in origin and compensable, they should be of interest to industrial physicians and insurance companies.
3. Investigations as to their etiology are reviewed. Some personal predisposition, maceration of the tissues and mechanical trauma applied to the nails probably act concurrently to produce the disorder.

3115 Webster Street.

ABSTRACT OF DISCUSSION

Dr. Laurence R. Taussig, San Francisco: In my practice I have seen no instances of a separation of the nails such as Templeton has described, nor have I seen it mentioned in the American literature. In looking over the indexes of the *Dermatologische Zeitschrift* for the past four years, I encountered three cases presented at dermatologic societies under the name of onycholysis semilunaris. Falkenstein presented a woman, at the February, 1927, meeting of the Cologne Dermatologic Society, in whom the condition was considered to be due to trauma from manicuring. The same physician presented another woman, at the October, 1928, meeting of the same society, who was a cook's helper, and the discussers considered the condition occupational in origin, although nervous influences were looked on as a possible underlying factor. The third case was presented by Carlson at the Rhine Westphalia Dermatologic Society, in October, 1929, and details of occupation were not given. The condition had persisted for four years in spite of various forms of therapy. I am inclined to believe that the disease is purely mechanical in origin, but it is obvious that some other factor plays a part in determining a hypersensitivity which may possibly be neurogenic in character.

Dr. M. J. Strauss, New Haven: Dr. Lane and I have at present a similar case under observation. I think it was in 1921 that Martin Friedman in reporting some cases reviewed the literature up to that time and the only cases which had been considered as due to industrial hazards were those of Oppenheim, of which we have just seen the pictures. The case we are studying is more marked than those presented today. The patient is a man, aged 20, and the condition began while he was a predental student and earning his living by selling books. There is no history of constant immersion in water or of constant mechanical irritation of the nails and up to the present time we have not been able to find the cause of the condition. The condition is of two years' duration, and in spite of the fact that he has done no work at all for more than six months it has become more marked. This patient's toenails are also affected, which makes it seem improbable that in his case it is an occupational disease. I hesitate to use the term trophic. That really is an admission of ignorance, but it may be significant that the onset was simultaneous with a typical alopecia areata. I wish to call attention to another type of separation of the nails which is slightly different. It is the type in which the entire nail falls out spontaneously. Several etiologic factors have been suggested for this. It has been reported as occurring after scarlet fever, after severe psychic shock, in tabes and after arsenic poisoning.

Dr. Howard J. Parkhurst, Toledo, Ohio: Within the past two weeks I have observed a case of three years' duration in a middle aged woman, who has been employed for that length of time in washing dishes in a cafeteria. For treatment I simply suggested that she wear rubber gloves.

Dr. Marion B. Sulzberger, New York: I think there is no doubt that this condition is more frequent than is supposed. If one looks for it, I am sure quite a number of cases will be reported in the future. The question arises as to how one will divide these cases. Some undoubtedly are trophic; some are due to trauma, some purely to chemical causes, and some to a combination of factors. In Dr. Templeton's case I think the history is suggestive of a combination of trauma and some other cause. In considering Dr. Oppenheim's cases, one is struck by the fact that one was due to Persil, which is known to be an irritant causing many skin eruptions. The interesting point regarding trauma and skin sensitization was brought out well by the work of Naegeli, who found that skin tests were often positive on traumatized skin, whereas they were negative on other not previously traumatized areas.

Dr. C. Guy Lane, Boston: I was reminded by Dr. Templeton's case of a case I saw some years ago in a dentist who had dermatitis of the nails. I do not know whether it was exactly the same type of case, but the slight maceration and separation of the nail was due to procaine hydrochloride sensitization.

Dr. Karl G. Zwick, Cincinnati: During the war I was engaged in a chemical factory where they manufactured quite a number of pharmaceutic preparations, which were put up in ampules, and I noticed that many of the girls who were engaged in cleaning these ampules of the paste would come in contact with some of the chemicals that were used in washing the ampules. The ampules were put through a bath of sodium hydroxide, then water, and finally distilled water to clean them. It seemed that quite a number of the girls would not be affected, whereas quite a number of other girls, doing the same type of work, would. This would bear out the thought that a general predisposition would be a factor in the production of the trouble. We used to term them onychomalacia, although I think the term suggested by Dr. Templeton is better.

Blood Platelets.—The number of blood platelets in healthy animals is fairly constant, though daily and even hourly fluctuations of considerable volume occur. In general, the level is not as constant as that of erythrocytes but is more constant than that of leukocytes. Spontaneous variations, when they occur, can usually be explained on the basis of infections or of alterations of the environment, especially changes in light. In experimental procedures devised to study the problems of the origin and the function of the blood platelets, a great variety of agents have been employed for altering the platelet content of the blood. —Steiner, P. E., and Gunn, F. D.: The Response of Blood Platelets to External Stimuli—Ultraviolet Light, Iodine and Coal Tar, *Arch. Path.* **11**:241 (Feb.) 1931.

THE BLOOD PICTURE IN SIX HUNDRED CASES OF GOITER

ESPECIAL REFERENCE TO THE EFFECT OF IODINE AND THYROIDECTOMY *

ARNOLD S. JACKSON, M.D.
MADISON, WIS.

In 1924 I began a study of the blood in toxic goiter to ascertain, if possible, whether or not the data would be of any value in determining the prognosis of the disease. European authorities, notably Kocher,[1] and his American disciple, Crotti,[2] have laid considerable emphasis on the importance of the blood picture in hyperthyroidism. Little study of this subject has been made in our own country, with the exception of an important contribution by W. A. Plummer [3] in 1918, and general observations by Hertzler [4] and a few others. Plummer's report was made before the metabolic rate had come into general use. Hertzler states, in conclusion, that the observations to date are so variable that a further study is much desired. So far as I have been able to ascertain there has been no report of the coordinated blood picture and metabolic studies, nor any of the effect of iodine on the former.

The purpose of this study is to show:

1. Whether or not the blood picture in hyperthyroidism varies from that in the normal person.
2. Whether the differential blood count is or is not of diagnostic and prognostic significance.
3. Whether there is or is not a definite relationship between the blood picture and the metabolic rate.
4. Whether a secondary anemia is typical or atypical of hyperthyroidism.
5. A change or the absence of one in the blood picture through the use of iodine.
6. Whether or not the blood picture in hyperthyroidism is of any practical clinical importance.

Although Miscowicz and Ciuffini in 1904 found a lymphocytosis in the blood of patients with hyperthyroidism, and Caro in 1907 reported similar observations in one case, it was Kocher who in 1908 gave these observations their true significance and considered them as the result of the disease. Since then a number of authors have reported the results of their investigations, upholding these conclusions.

Crile [5] believes that the most characteristic change in the blood picture in hyperthyroidism is the presence of a moderate degree of lymphocytosis.

Crotti states that the chief characteristics of the blood in patients with hyperthyroidism are leukopenia, hyperlymphocytosis and hypopolynucleosis.

Hertzler remarks that the lymphocytes generally are from 25 to 45 per cent but may reach 50 per cent or more. In many of the most severe cases, however, the lymphocytes are actually reduced.

According to Kocher, the differential blood count should be normal in simple goiter, while exophthalmic goiter should be characterized by a more or less marked lymphocytosis together with a general leukopenia in two thirds of the cases. The ingestion of the thyroid products should produce in man and animals a relative, or more often an absolute, increase of lymphocytes and a decrease in the polymorphonuclears.

De Quervain,[6] on the other hand, from a study of 250 cases found practically no change in the lymphocyte count in simple and toxic goiter. He found that the average percentage of polymorphonuclears is 64 in simple goiter, 61 in hyperthyroidism and 65 in hypothyroidism. The lymphocytes range about 28 per cent in simple goiter, 30 per cent in hyperthyroidism and 29 per cent in hypothyroidism. He adds that his results tally with those of Muller, Bielajew, Bauer, Lampe and others with regard to the nonspecificity of the leukocyte formula for the different conditions of the thyroid gland.

Kocher emphasized the presence of a leukopenia and based his conclusion on 106 cases in which there was an average count of about 5,000 leukocytes.

Plummer's series, based on a study of the blood counts in 578 patients with exophthalmic goiter, showed an average leukocyte count of 6,973.5. Plummer found that there is a relative and an absolute mononucleosis and a decrease in the percentage in the polymorphonuclear neutrophils, thereby confirming Kocher's observations. When a leukopenia is present the decrease is in the number of the neutrophils. He found that in the mortality statistics the relative lymphocyte count is a few points under the average but not sufficiently to be of value in prognosis. He believes that the differential count is of limited value in diagnosis. Except for a polymorphonuclear leukocytosis immediately following operation and during tonsillitis and other acute infections, he was unable to determine any factor which influences the characteristic blood picture.

On the contrary, Crotti believes that the differential blood count is of great help in deciding whether one has to deal with a thyrotoxic condition or not, and the same is true of the prognosis. He believes that a marked leukopenia, a high lymphocytosis and a marked hypopolynucleosis will show that the case is a serious one. A high percentage of lymphocytes without or with only a moderate leukopenia is of good prognostic value, whereas a marked leukopenia with a low percentage of lymphocytes must be regarded as a bad prognosis.

TABLE 1.—*Average Blood Count in Six Hundred Cases of Goiter*

	Colloid Goiter	Nontoxic Adenoma	Toxic Adenoma	Exophthalmic Goiter
Hemoglobin	75	79	78	78
Erythrocytes	4,200,000	4,190,000	4,960,000	4,790,000
Leukocytes	9,543	8,956	8,463	8,412
Polymorphonuclears	64	60	60	59
Lymphocytes	30	33	35	35
Transitionals	4	5	4	4
Eosinophils	2	2	1	2

From these conclusions it is evident that a wide divergence of opinion exists with regard to the differential blood count in goiter and also with regard to its diagnostic and prognostic importance.

In this series of 600 goiter cases, blood studies were made on the following types of goiter: colloid goiter, 100 cases; nontoxic adenoma, 100 cases; toxic adenoma, 200 cases; exophthalmic goiter, 200 cases.

The average blood count for this entire group is shown in table 1.

---

* From the Jackson Clinic.

[1] Kocher, T., quoted by Crotti (footnote 2).

[2] Crotti, André: The Thyroid and Thymus, Philadelphia, Lea & Febiger, 1922.

[3] Plummer, W. A.: The Blood Picture in Exophthalmic Goiter, Collected Papers of the Mayo Clinic **10:** 359-363, 1918.

[4] Hertzler, Arthur: Diseases of the Thyroid Gland, St. Louis, C. V. Mosby Company, 1922.

[5] Cleveland Clinic: The Thyroid Gland: Clinics of George W. Crile and Associates, Philadelphia, W. B. Saunders Company, 1922.

[6] de Quervain, F.: Goitre, New York, William Wood & Co., 1924, pp. 80-81.

It is at once apparent that the differential blood count is of no clinical significance in simple nontoxic goiter. It is likewise evident that in exophthalmic goiter there is only a slight increase in the lymphocytes and a decrease in the polymorphonuclears. Considering the normal average leukocyte count as from 7,000 to 8,000, it is apparent in this study that a leukopenia does not occur in hyperthyroidism. These figures do not corroborate most of the reports in the literature.

Table 2.—*Blood Count in Patients with Highest and with Lowest Metabolic Rates*

Exophthalmic Goiter	Highest	Lowest
Basal metabolic rate	+64	+28
Leukocytes	7,415	9,540
Polymorphonuclears	60	61
Lymphocytes	35	34
Toxic Adenoma		
Basal metabolic rate	+46	+15
Leukocytes	8,919	8,817
Polymorphonuclears	61	59
Lymphocytes	33	37

It might be well to diverge and call attention to the fact that, from this study, anemia is not a characteristic observation in hyperthyroidism. The impression has been made by several writers that anemia is a frequent sequela.

Table 3.—*Loss of Weight in Patients with Exophthalmic Goiter*

Exophthalmic Goiter	Average Weight Loss 10 Pounds (4.5 Kg.)	Average Weight Loss 30 Pounds (13.6 Kg.)
Leukocytes	7,261	8,089
Polymorphonuclears	62	65
Lymphocytes	33	31

Plummer ascertained by a study of the differential blood count of fifty-four patients who died of exophthalmic goiter that neither the leukocyte count nor the degree of mononucleosis is dependent on the severity of the symptoms and that they cannot be used as a guide in prognosis. Since these observations are in marked contrast to those of Crotti, it seems of interest to study this point. If the lymphocytes are increased in proportion to the severity of the disease, one would expect a similar increase in the metabolic rate in the majority of cases.

Table 4.—*Effect of Thyroid Extract on Blood Count in Colloid Goiter*

Colloid Goiter	Before Thyroid Extract	After Thyroid Extract
Leukocytes	10,116	8,971
Polymorphonuclears	65	63
Lymphocytes	28	32

Table 5.—*Effect of Iodine on Blood Count in Toxic Adenoma*

Toxic Adenoma	Before Iodine	After Iodine
Leukocytes	8,084	9,240
Polymorphonuclears	58	60
Lymphocytes	38	34

A group of forty patients having the highest and the lowest metabolic rates were found to have an average blood count, as shown in table 2.

From these studies it is apparent that the blood count does not vary according to the metabolic rate. The lymphocytes are not increased when the rate is elevated, or decreased when it is lowered.

While the degree of hyperthyroidism may not always be accurately gaged by the metabolic rate, particularly in toxic adenoma, yet the amount of weight loss often indicates the severity of the disease. Consequently, those suffering the greatest weight loss might be expected to show the highest lymphocyte count.

From the figures shown in table 3, my conclusions are the same as Plummer's, that neither the leukocyte count nor the degree of mononucleosis is dependent on the severity of the symptoms and that they cannot be used as a guide in prognosis.

Kocher felt that the ingestion of thyroid products should produce a relative or an absolute increase of lymphocytes and a decrease of polymorphonuclears. Consequently, the differential blood count was determined in a group of colloid goiters in children before and after the daily administration of 2 grains (0.13 Gm.) of thyroid extract (table 4).

Table 6.—*Blood Picture in Exophthalmic Goiter under Various Conditions*

Exophthalmic Goiter	Before Iodine	After Iodine	After Operation
Basal metabolic rate	+46	+34	+6
Leukocytes	7,540	8,146	9,071
Polymorphonuclears	61	60	65
Lymphocytes	32	34	20

A unanimous opinion does not exist with regard to the effect of iodine in toxic adenoma. In our experience at the Jackson Clinic, about 40 per cent of patients with toxic adenoma show improvement after administration of iodine. The studies summarized in table 5 show that there is no appreciable change in the blood count.

Table 7.—*Influence of Sex on Blood Picture in Exophthalmic Goiter*

Exophthalmic Goiter	Male	Female
Leukocytes	8,829	8,436
Polymorphonuclears	61	60
Lymphocytes	34	35

It is evident that iodine administration in exophthalmic goiter results in a period of marked temporary remission of the clinical symptoms accompanied by a fall in the metabolic rate. If the conclusions of Kocher and Crotti are correct, one would expect a proportionate decrease in the lymphocyte count. Our observations are to the contrary.

Table 8.—*Influence of Age on Blood Picture in Exophthalmic Goiter*

	15 to 25 Years	50 to 75 Years
Leukocytes	8,953	7,620
Polymorphonuclears	53	62
Lymphocytes	31	35

Finally, if the lymphocyte count falls as the severity of the disease lessens, one would expect the same to occur after thyroidectomy. Table 6 gives a comparison of the blood picture in exophthalmic goiter before operation and before the use of iodine, after iodine and after operation. While iodine is shown to have no effect on the blood picture, thyroidectomy does cause a marked reduction in the lymphocytes and a proportionate increase in the polymorphonuclear count.

The influence of sex also was considered (table 7). The influence of age which was also taken into consideration is shown in table 8.

CONCLUSIONS

In a study of 600 cases of goiter, the following conclusions are drawn:

1. The blood picture in hyperthyroidism does not vary essentially from that in the normal person.
2. The differential blood count in hyperthyroidism is not of diagnostic and prognostic significance.
3. There is not a definite relationship between the blood picture and the basal metabolic rate. The lymphocyte count is not varied by an increase or a decrease in metabolism.
4. The blood count is not influenced by the severity of the disease, considering metabolism and weight loss as paramount factors.
5. A secondary anemia is not typical of hyperthyroidism.
6. A leukopenia is not characteristic of hyperthyroidism.
7. Sex and age do not influence the blood picture in toxic goiter.
8. In spite of clinical improvement, no appreciable change was observed in the blood count following the use of iodine in hyperthyroidism.
9. The only appreciable change in the differential blood count in goiter was observed following thyroidectomy for exophthalmic goiter. An increase in the polymorphonuclear count and a decrease in the lymphocyte count occurred.
10. I do not believe that the blood picture in hyperthyroidism is of any practical clinical importance.

MENINGITIS CAUSED BY FRIEDLÄNDER'S BACILLUS

A CASE WITH RECOVERY *

KARL ROTHSCHILD, M.D.
NEW BRUNSWICK, N. J.

Most bacteria that are capable of causing general septicemia have at one time or another been found responsible for a case of meningitis. A most interesting rôle has been played by bacteria of the mucosus type. Reports have been published of meningitis caused by Streptococcus mucosus, and Bacillus mucosus-capsulatus has been several times found to be the cause of fatal meningitis. And yet, it is rather peculiar, in view of the fairly large number of pneumobacillus septicemias, that not more cases of pneumobacillus meningitis have been reported. I was able to find in the American literature only a single case of Friedländer's meningitis. This case was reported by Malis [1] and had a fatal outcome. The scarcity of reported and the rarity of nonfatal cases give me special impetus to report another case of pneumobacillus meningitis, this time with a favorable outcome:

J. M., a Negro, aged 34, a janitor, admitted to the otolaryngologic service of Dr. B. M. Howley, Oct. 30, 1930, and treated by the neurologic department in conjunction with Dr. Howley, complained of high temperature, pain in back of the right ear, stiffness of the neck, and drowsiness.

The patient's father is living. His mother died from heart disease. The other members of the family, two brothers and one sister, are living and well. There has not been any tuberculosis, diabetes or insanity in the family.

As a child the patient had measles, mumps and chickenpox. At the age of 11 years he had a slight attack of malaria. While in the army in France, he had a slight attack of pleurisy. He has had gonorrhea, but stated that he had not had syphilis. He is married. His wife is healthy. They have no children.

Aug. 6, 1930, the patient was out swimming. A few days later he felt as if he had water in the ear. After a few more days he heard noises in the ear but did not have any pain. At that time a physician considered the condition harmless. September 15, he became ill with fever and called a physician, who treated him for nine days. He improved and went back to work. September 24, he saw Dr. Howley, who did a paracentesis. The patient went home and felt better for a few days but became worse again. October 5, Dr. Howley operated on him for mastoiditis. He stayed in the hospital one week and then went home. He felt fine until October 29, when he was seized with a high temperature, delirium, and stiffness of the neck.

At the time of the physical examination the patient was unconscious and was irrational at times. The right pupil was somewhat larger than the left. The pupils reacted well to light. Accommodation could not be tested. The ears and nose were normal. There was a scar behind the right ear, originating from a mastoid operation done three weeks previously. The head was held slightly backward, and it was impossible to bend it forward to any great extent. The skin of the whole face was very sensitive to the touch. The thyroid gland was not enlarged. The apex beat was heard in the fifth interspace, one fingerbreadth within the nipple line. There were no murmurs. The volume was good. The lungs were normal to percussion and auscultation. No râles were heard. Slight general rigidity was noted in the abdomen. Motor power was good in all the extremities. The tendon reflexes of the right arm and leg were slightly exaggerated. Abdominal and cremasteric reflexes could not be elicited. There was no Babinski sign. Clonus was not present. The head was turned toward the right. A temporary diagnosis of brain abscess with meningitis was made.

October 30, a spinal puncture was done, which showed decreased pressure and a very cloudy fluid of a peculiar viscous consistency. Dr. Howley operated immediately and found a subdural abscess, with pus of yellowish color and mucoid appearance.

Urinalysis showed: specific gravity, 1.026; reaction, acid; albumin, a trace; sugar, 1.43 per cent; acetone, negative. Urates and a few epithelial cells were demonstrated microscopically.

Examination of the blood showed: hemoglobin, 55 per cent; erythrocytes, 3,690,000; leukocytes, 21,150; differential count: polymorphonuclears, 88 per cent; large lymphocytes, 4 per cent; small lymphocytes, 8 per cent.

Examination of the spinal fluid gave the following results: cell count, 1,100; globulin, 4 +; Fehling reaction, not reduced. Smears did not show any organisms. Culture was made.

October 31 the patient was in a slightly better condition. The temperature was up to 103 but dropped late in the morning to 99.4. It rose again in the evening to 102. The pulse was between 80 and 100. Respirations were 20 per minute. The patient showed signs of meningitis: slight stiffness of the neck and a medium Kernig sign.

There were no focal signs present. The reflexes were equal on the two sides, and no pathologic reflexes were noted. There was no disturbance of the cerebral nerves.

Mentally, there was a rather marked stupor. After a long interval following an order, the patient opened his mouth. On being given any other order such as show the tongue or open the eyes, he always opened his mouth and did nothing else. Questioning elicited the same answer:

"What is your name?" "John Mason."
"Where do you live?" "John Mason."
"Are you married?" "John Mason."

---

* From the department of Neuropsychiatry, St. Peter's General Hospital.

* Read before the Section on Nervous and Mental Diseases at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

[1] Malis, Solomon: Pneumobacillus (Friedländer's) Meningitis Secondary to Otitis Media, Arch. Otolaryng. **12:** 162-174 (Aug.) 1930.

It was not found advisable to do another spinal puncture that day.

November 1 the culture of the spinal fluid showed Bacillus mucosus-capsulatus (Friedländer's bacillus). The characteristics are shown in the accompanying tabulation. The culture from the brain abscess also showed Bacillus mucosus-capsulatus in a pure culture. The patient appeared much improved. He answered some questions and understood orders. The temperature had dropped to 100. Spinal puncture was performed. Only a small amount of fluid was obtained. Blood culture was negative. Culture of the fluid showed Bacillus mucosus-capsulatus.

November 3 the temperature was normal. Great improvement was noted. The spinal fluid pressure was 4 mm. of mercury. The fluid was semicloudy. A specimen of the fluid showed: cell count, 271; globulin, 2 +; culture, negative. The Wassermann and the Kahn reactions of the blood were negative.

November 6 the patient was doing well; no neurologic symptoms were noted.

November 8 the patient had an elevation of temperature and complained of a headache. The reflexes were equal on the two sides. The reaction of the pupils was normal. Very slight rigidity had recurred. The following observations were made: Kernig sign, 2 +; spinal puncture: pressure about 2 mm. of mercury; cell count, 122; globulin, 2 +. The fluid was much more cloudy than before. The patient was taken to the operating room again and the wound was explored by Dr. Howley. Some more free pus was found.

Bacteriology of Bacillus Mucosus-Capsulatus Found in the Spinal Fluid

1. Pus of brain abscess is mucoid, semiviscous.
2. Pure cultures of Bacillus mucosus-capsulatus derived from abscess and spinal fluid.
3. Gram-negative, nonmotile bacillus.
4. Bacillus is surrounded by large capsule.
5. When touched with a loop, a filament can be drawn out to a length of 2½ inches.
6. Liquid beef broth: diffuse growth, without pellicle.
7. Solid medium: grayish-white, diffuse colonies.
8. All carbohydrates (dextrose, lactose, mannite, salicin) are fermented with the formation of gas and acid.
9. Continuous incubation for seven days: Gas is absorbed with development of alkaline reaction (*p*H 7.1 to 7.2).
10. Gelatin: not liquefied.
11. Potato: very scanty growth.
12. No indole formation.
13. Milk: good growth, without coagulation.
14. Pathogenic for mice.
15. Patient's serum agglutinates strain in 1: 25 solution.

November 10 there was much improvement. The spinal fluid showed: globulin, 2 +; cell count, 122; sugar, negative. No organisms were demonstrated in the culture. The Wassermann reaction was anticomplementary.

Examination of the blood showed: hemoglobin, 68 per cent; erythrocytes, 4,110,000; leukocytes, 14,400; differential count: polymorphonuclears, 82 per cent; large lymphocytes, 3 per cent; small lymphocytes, 13 per cent, and eosinophils, 2 per cent.

November 12 the patient was doing well. The temperature was normal.

November 14 the patient was out of bed, walking around, and felt well. The wound of the head was closing up. The patient was discharged.

I have seen the patient several times since discharge, the last time, May 15, 1931. He is perfectly normal and has returned to work.

One of the latest studies of pneumobacillus meningitis comes from the pen of Carcelli.[2] He reports one fatal case and also makes a survey of the literature. He finds that, of twelve cases reported, recovery has occurred in three. In analyzing those three cases, however, I have certain doubts about their real classification. Guinon and Simon,[3] in 1910, reported one case of recovery in a child, aged 5 years. This recovery was rather complete, with the exception of a few difficulties in motion of the lower extremities which remained a permanent impediment. Reviewing the bacteriology of the case, one finds, however, that the cultures were very poor ones; pneumobacilli were found as well as pneumococci. Animal inoculations were negative. After inoculation with a bouillon culture, one mouse was sick for several days but did not die. All the other mice, inoculated with the pus from a spinal puncture, did not suffer at all. From the point of view of bacteriologic study, I consider this case a doubtful one. The other instance of recovery was reported by Lacoste and Boidin,[4] with a series of cases of acute meningitis in 1915. In one case, that of a soldier, they found pneumobacillus septicemia with a positive blood culture. The spinal fluid was under pressure but entirely clear, without increase in albumin and without leukocytosis. Yet they report that a pure culture of Friedländer's pneumobacillus was grown from the spinal fluid. They explain this as one of the rare cases of meningitis in which the cytology of the fluid is negative. I cannot agree with that classification and would rather suggest that in withdrawing the spinal fluid a vein was punctured and the culture was actually obtained from the blood. This renders this case doubtful, too.

Perrier's[5] case is that of a soldier in whom meningitis developed following a head trauma. The spinal fluid was under pressure and slightly bloody. Blood culture and spinal fluid cultures showed "une forme cocco-bacillaire," which was gram-negative and which he considered a form of Friedländer's bacillus. This patient had pneumonia also. Billet, in discussing the paper, considers this case a doubtful one because no sugar coagulation tests were performed, and inoculation was not attempted. Besides the cases mentioned by Carcelli, Elias[6] reports in 1924 a case in an infant who suffered a pneumobacillus meningitis following an umbilical infection. The child was apparently on the way to recovery but then died from influenzal pneumonia. This case is also doubtful as far as recovery is concerned.

In his article already mentioned, Malis[1] reports a second case of pneumobacillus infection. In this case, too, there was an increase in the pressure of the spinal fluid and at one time also an increase in cells, but I do not think that he himself wants this case, in which recovery occurred, classified as one of meningitis but rather as general septicemia with meningeal irritation but without invasion of the bacilli into the spinal canal. This leaves the present case as the only one in the literature in which the patient recovered, and the chemical and inoculation tests made the diagnosis of Friedländer's meningitis a definite one.

Papandrea[7] reports two fatal cases. Brunner[8] describes one fatal case of acute metastasizing generalized infection following otitis media and empyema of the mastoid process. Brain and Valentine[9] in an interesting article also report one fatal case following mastoid infection. Comte, Lévy-Bruhl and Dany,[10] in the latest publication on this subject, report a fatal case the bacteriology of which is very similar to that in the case reported here, in that all sugars were fermented with gas formation and later reabsorption, and gelatin was not liquefied. Animal inoculation tests were fatal in mice as well as in rabbits. A case described by Gernez and Razemon[11] has, besides meningitis, signs of osteomyelitis, and they consider this the first case of bone invasion by Friedländer's bacillus. The case of Bocca, Ranque and Sénez[12] was a fatal one in an infant. Rénon and Blamoutier[13] report a case of chronic labyrinthitis with Friedländer's bacillus, which is a rare occurrence and paralleled only by the case of Brain and Valentine.[9] The case of Lion and Minvielle[14] had also a fatal outcome, as had those of Dufourt, Delattre and Bonnet[15] and Lequeux.[16] The fatal case of Ménétrier and Bertrand-Fontaine[17] is mentioned because of the extremely sudden onset with coma (début brutal). The cases of Weichselbaum,[18] Mills[19] and Dmochowski[20] are mentioned here because they were described before the practice of lumbar punctures was known. In their cases the organisms were found in cultures obtained from the meninges on autopsy. Breton and Mahée,[21] in making a survey of Friedländer's pneumobacillus meningitis in 1929, report that of nineteen cases studied twelve were purely meningeal, while in seven the meningitis developed secondarily to other infections. In my case pure cultures of the same organisms were obtained from the spinal fluid and from the brain abscess.

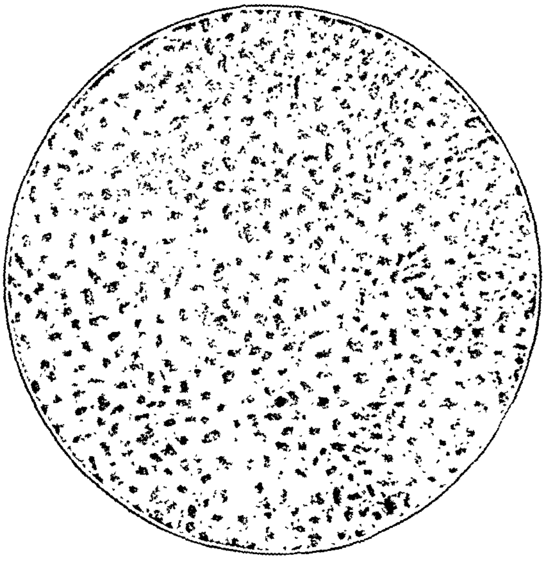
[9] Brain, W. R., and Valentine, F. C. O.: Infection of the Meninges and Blood Stream by Bacillus Mucosus-Capsulatus, Lancet **1**: 855-856 (April 28) 1928.



Bacillus mucosus-capsulatus (Friedländer's). Culture from spinal fluid. Note clearness of capsules.

The bacteriology of these peculiar organisms has been described in several articles, by Friedländer,[22] Malis, Brain and Valentine and others, and I will restrict myself to a few general remarks referring to the table for comparison. It has been asserted that the main characteristic of Friedländer's bacillus, besides the formation of mucoid colonies and the capsules (shown in the illustration), is the ability to ferment all the sugars with or without the formation of gas, and its inability to liquefy gelatin.

Two interesting reports have been made lately by Kraus[23] and by Kliewe,[24] who have found a bacterium in two different cases which Kraus calls Bacterium mucosum-mutabile. He found gram-negative mucus-forming rods which in the beginning were hard to differentiate from Friedländer's bacillus, but soon there developed a yellowish color of the colonies which was never found with Friedländer's, and milk was coagulated. Sugars were fermented. Gelatin was liquefied. The patient's serum was agglutinated in a 1:160 solution. The bacillus did not coagulate cultures of other mucoid bacteria. It was pathogenic for mice. In the course of the disease the color changed, and Kraus believes that all capsule bacteria can change their morphology by adaptability of the germs to the environment. Hence he gave this particular one the name of Bacterium mucosum-mutabile. Yet, according to Kliewe, it seems probable that several types are well characterized.

Malis, in his article referred to, shows several photographs of bacilli which are forming long chains and which rather deserve the name of Streptococcus mucosus-capsulatus. Urbantschitsch[25] in 1926 reported a series of eight cases of streptococcus mucosus meningitis in which only one patient recovered. He considers the infection so severe that he recommends, in doubtful cases, an early lumbar puncture and, in case a mucosus germ is present, immediate bilateral operation without consideration of the conditions of the drums.

What makes infection with mucus-forming bacilli so dangerous? As I have mentioned in the description of my case, the pus contained in the brain abscess had the appearance and consistency of a mucoid semiviscous fluid. The spinal fluid, too, was transformed into a gelatinous liquid. It seems to me that these physical properties may be the cause of the grave prognosis. The mucus will tend to fill in spaces and to clot the foramina, and cerebral blocks may well be responsible for the generally fatal outcome.

CONCLUSIONS

1. Cases of meningitis caused by Bacillus mucosus-capsulatus (Friedländer's bacillus) are usually fatal.

2. Only three cases in which the patient recovered have been reported; in all these the diagnosis is not satisfactorily confirmed.

3. A case is presented in which Friedländer's meningitis was associated with a subdural abscess, following mastoiditis. The same micro-organism was found in cultures of the abscess and of the spinal fluid.

4. By bacteriologic tests the micro-organism was identified as Bacillus mucosus-capsulatus (Friedländer's bacillus), with the characteristics of the most frequent type of this group.

5. The patient recovered completely, representing the first case with recovery reported in the American literature and the first nonfatal case in general in which definite bacteriologic tests were made.

6. A survey of the literature is also presented.

49 Bayard Street.

ABSTRACT OF DISCUSSION

Dr. Bartholomew M. Howley, New Brunswick, N. J.: When I saw this man he had been rather neglected. He stayed away after I had performed a paracentesis and came in with full-fledged mastoiditis. He did not have the regular symptoms—no pain back of the mastoid at all. His most prominent symptom was headache. Roentgen examination showed definitely involvement of the mastoid, and I operated on him that day. I found the mastoid filled with pus, and going down deeper I found a sinus thrombosis. I opened that up, removed the thrombus, and packed with iodoform gauze. The patient recovered and in a week's time was discharged. His temperature did not go up after I operated on him. I saw him at my office and dressed the wound every second or third day. About the third or fourth day before he went to the hospital the second time he began to complain of headaches. I knew I had drained the wound well, so I was a little bit suspicious. I asked him whether he had a syphilitic infection, and he admitted that he did. To my surprise, a few days later I had a telephone call at 2 o'clock in the morning that the man was unconscious and in bad shape. I called the ambulance, and he was admitted to the hospital that morning. At 7 o'clock it looked as if he was going to die. I made a hurried examination and found that he had a cerebrospinal meningitis. Spinal puncture showed the spinal fluid loaded with pus cells. I had him on the operating table by 12 o'clock. I opened up the sinus again and removed some clot; there was no sign of pus, but the internal wall had been necrosed. I passed a probe in the brain tissue for an inch and a half. I opened the dura and drained it, using an iodoform drain. But I had in mind the fact that the man had acknowledged the syphilitic infection of nine years before; so that same day I gave him 0.4 Gm. of arsphenamine. The next day he was better. About six days later he had another injection. That same day his temperature went up to 104 F. I didn't think it was due to the injection, so I brought him again to the operating room. I found some pus in the sinus near the dura, opened the sinus up well and packed it with metaphen. After that the man improved nicely. I don't know why he recovered. Almost all such patients die.

Dr. Karl Rothschild, New Brunswick, N. J.: My general attitude toward the treatment of meningitis, outside of the epidemic type, is extremely conservative. I have found that by injecting serums or chemicals one may often do more harm than good. I recently saw a number of rare cases, among them one of the few cases reported of a nonhemolytic streptococcus meningitis. The patient recovered after having been in a coma for three weeks. I kept the man alive solely by injecting 5 per cent solution of dextrose, 1,000 cc. intravenously two times a day. It was the only food he received for three weeks. Besides, I performed spinal drainage two times a day, taking out as much fluid as I possibly could. The case is going to be reported in an early issue of the *Journal of Nervous and Mental Disease*. It is my opinion that conservative treatment in these cases might lead one further than one usually arrives at by the use of chemical combinations and more or less nonspecific serums.

THE SUBSEQUENT COURSE OF FORTY PATIENTS WITH ACUTE "DRY" PLEURISY *

MARSHALL N. FULTON, M.D.
PROVIDENCE, R. I.
AND
RICHARD G. HAHN, M.D.
BOSTON

There is a tendency, now reasonably well established, to consider acute lesions of the pleura as tuberculous, unless some other cause is evident. Like the criminal in the French courts, a patient with an attack of acute pleurisy is "guilty" of tuberculosis until it can be proved otherwise. Particularly is this true of the serofibrinous type, or pleurisy with effusion. The literature abounds in reports of patients with this type of pleurisy who have been followed for years. The percentage of these in whom tuberculosis of the lung develops varies in the different reports according to the treatment carried out following the acute illness, the length of time the patients are followed, and the ascertainable cause of death in those who have died. Whatever the end-result, pleurisy with effusion occurring as a primary illness without demonstrable cause is looked on as a sign of tuberculous infection just as is an unexplained hemoptysis.

The etiologic factor in acute dry pleurisy is less definitely established. The question is important because the physician must often decide whether a patient, previously well, in whom the symptoms and signs of an acute dry pleurisy suddenly develop, should be treated as a patient with incipient pulmonary tuberculosis. That a dry pleurisy is a frequent precursor of pulmonary tuberculosis is well appreciated. From 20 to 50 per cent of patients with phthisis give a definite history of pleurisy of one form or another,[1] and doubtless many of these have only the transient dry pleurisy with nothing more than a brief period of acute pain in the chest. From the other end of the scale, attempting to answer the question as to the number of cases presenting acute dry pleurisy in which tuberculosis of the lung develops, the facts are meager. In the literature one finds very few statistical studies on the subject. Lord[2] in 1909 reported sixty cases presenting this disease, followed from one to twelve years, in eighteen of which pulmonary tuberculosis "certainly or probably developed." In the series reported by Allard and Köster[3] in 1911, clinical tuberculosis developed sooner or later in 42 per cent of the patients with dry pleurisy (fifty-seven in number). The many statistical studies made are on patients in tuberculosis sanatoriums who give a history of pleurisy, on patients with pleurisy with effusion, or on those with "idiopathic" pleurisy in which no figures are given differentiating the dry form from that with fluid. The question arises as to whether these two forms of pleurisy represent a difference in the severity of the infection, in the extent of involvement of the pleura, in the resistance and reaction of the individual, or in the etiologic incitant. Scheel and Föien[4] believe that the greater effusions are followed more frequently by tuberculosis than are the less abundant exudates and the dry pleurisies. The acute dry form frequently develops into a pleurisy with effusion, a fact which suggests that a dry pleurisy is but a mild or early expression of the pathologic process which results in the outpouring of fluid. If such is the case, one may justifiably look on an acute dry pleurisy as just as good evidence of tuberculous infection as is pleurisy with effusion. Such is certainly the tendency in the modern textbooks on this subject,[5] yet there are very few figures to support this contention.

The reasons for the paucity of definite data on patients with acute dry pleurisy are apparent. In the first place, because patients with this disease are not often severely ill for any length of time, they are not treated as hospital patients, and therefore hospital statistics are not forthcoming. If they become hospital patients, it is not easy to get adequate follow-up studies on them, for reasons which will be cited later. Secondly, the diagnosis of acute dry pleurisy in the absence of a friction rub or fever is often difficult, however definite the symptoms, and any series of cases must contain some in which the diagnosis will be open to question. Lastly, as stressed by Lord[2] and by Capps,[5] the condition is very rarely if ever primary, being related much more commonly to infection in the lung, lymph glands or other sites not detectable at the time of the acute illness.

The present study was undertaken to secure additional information regarding the subsequent course of patients with acute dry pleurisy. The case histories of all patients seen at the Peter Bent Brigham Hospital from 1913 to 1930 in whom the condition was diagnosed as pleurisy were reviewed. Only those cases were accepted for follow-up study in which the pleurisy was acute, without definite evidence of fluid, and in which no primary disorder could be demonstrated. Thus, all cases of pneumonia, of pulmonary tuberculosis or lung abscess, of pleurisy with effusion, of heart disease in which infarction of the lung was either evident or suspected, of pericarditis or mediastinitis, of definite rheumatic infection, of sepsis and of chronic nephritis were excluded. Four cases with symptoms and signs indicating an acute bronchitis were included in which there was evidence as well of a definite pleurisy. A tabulation of the cases reviewed indicates the incidence with which pleurisy is seen at this hospital. The 930 cases reviewed fall into three groups. One hundred and forty-nine were acceptable as instances of acute dry pleurisy. In the second group there were 142 cases in which this diagnosis might have been made but, because of the absence of a rub or râles, of fever or a clear-cut history, they were not accepted and were classified as "questionable." Our review of these case histories has made us willing to subscribe to the aphorism of Sir Thomas Horder,[6] who wrote, "There are probably few diseases more often diagnosed without adequate reasons than pleurisy; there are probably few diseases that exist more often unsuspected." It is commonly very difficult to make a diagnosis of pleurisy. A patient who complains only of chest pain without cough or fever and who has no friction rub or râles may be suffering from nothing more than myositis or neuralgia, yet the diagnosis of pleurisy nearly always comes first to mind. Hence one finds many instances of "questionable" pleurisy. The third group of 639 contains the cases of pleurisy with effusion or pleurisy secondary to some other condition, such as pneumonia or tuberculosis, which was recognizable at the time the cases were under observation.

Follow-up studies were possible on only 40 of the 149 patients with acute dry pleurisy. Information could be obtained on so few, largely because of the peripatetic habits of ward and dispensary patients, and partly because many of them, having no subsequent illness, did not return to the hospital or were apparently unwilling to do so when asked. The 109 cases in which no follow-up records were obtainable have been discarded because little that is new can be learned from them.

The important facts concerning the forty patients followed are these: There were twenty-one males and nineteen females. The average age was 30 years, with 14 and 54 as extremes. To indicate the extent of the illness, the duration of symptoms before the patients were seen averaged nine days, with one and ninety-six as extremes. The patients admitted to the hospital had an average stay of thirteen days. Concerning the symptoms and signs of pleurisy, all forty had pain, eighteen (45 per cent) of them had cough, twenty-eight (70 per cent) had a pleural friction rub, and twelve (30 per cent) had râles. The average maximum mouth temperature was 99.8 F. Twelve had no temperature higher than 99; eleven had temperature between 99 and 100, and fifteen between 100 and 103. The average white blood cell count was 11,800, with 8,000 and 25,000 as extremes. We are chiefly concerned here with the subsequent course of these patients. Our information about them was obtained in twenty-two instances by correspondence and in eighteen by examination in the outpatient department of this clinic. The patients written to were sent a questionnaire inquiring about their interval history and their health at the present time.

Source of the Material Studied

	Number of Cases		
	Acute Dry Pleurisy	Questionable Acute Dry Pleurisy	Pleurisy with Effusion or Secondary to Other Conditions
House patients (among 36,000 admissions)........	74	23	471
Outpatients (among 139,000 patients).................	75	119	168
Total..................	149	142	639

Of particular interest is the fact that in only four of these patients did pulmonary tuberculosis develop. The remaining thirty-six who have reported on their health or have been examined after a period of from one to sixteen years have been found to be essentially in good health. The average length of time they have been followed is seven years, one year being the shortest and sixteen years the longest period. Four patients have had one or more recurrences of pleurisy, and two have had lobar pneumonia. A few have reported respiratory infections without any consequential sequelae, and doubtless many of the others had "colds" or bronchitis which they did not report. One patient has chronic bronchitis at the present time, and another has peptic ulcer.

[6] Horder, Thomas: Medical Notes on Pleurisy, Practitioner **103:** 248 (Oct.) 1919.

The four patients in whom active pulmonary tuberculosis developed are worthy of mention. The first gave a strong family history of tuberculosis. She had had cervical adenitis at the age of 12 years and again at 14, and an acute pleurisy at the age of 21½, at which time roentgen examination of the chest showed enlarged hilus shadows and increased lung markings. On the patient's admission to the hospital six months later, the roentgenogram showed fibrosis of the lung fields, including the apexes, and a hazy costophrenic angle indicating an old pleurisy. It is probable that she had active pulmonary tuberculosis at this time, though it was not definitely diagnosed till a year later. She received treatment in a sanatorium and, at the present time, eight years later, is in good health. A second patient with a negative family history had acute cervical adenitis at the age of 20 years, followed in nine months by acute dry pleurisy, at which time she was seen in the hospital and had two negative roentgen examinations of the chest. One month after her discharge, a pleural effusion developed, and she was treated as a patient with tuberculosis but never was shown to have a parenchymatous lesion of the lung. At present, seven years later, she is in good health. The other two patients gave no family or past history of tuberculosis. In one of them a pleural effusion developed four months after her dry pleurisy, and she died ten years later from pulmonary tuberculosis. The other at present, six years after the acute dry pleurisy, shows roentgen evidence of a small apical lesion which is inactive.

An interesting side-light in this study concerns the family and past history of certain of the patients as obtained at the time they were first seen. That these details of a history sometimes are inaccurately given is well appreciated, yet most patients are aware of the presence of active tuberculosis in the members of their own family. In dealing with a patient with acute pleurisy, one should consider the family history of great importance. From the records there was evidence of a family history of tuberculosis in only five instances. In one of these patients, previously noted, pulmonary tuberculosis developed. The other four are well at the present time. Seven patients gave a history of a previous attack of pleurisy. Two of these were among the four in whom tuberculosis subsequently developed. These cases are too few to treat statistically and are cited merely to indicate the incidence of a "positive" past or family history in patients of this type.

COMMENT

This review was undertaken, as previously stated, to secure additional information on the after-course of individuals with acute dry pleurisy. The current teaching is that, in most if not in all instances in which no primary cause is evident, such pleurisy should be considered tuberculous in nature. Figures given in the literature indicate that from 30 to 40 per cent of patients with dry pleurisy eventually manifest pulmonary tuberculosis. In view of this we were surprised to find that, among forty individuals with acute dry pleurisy in whom no primary cause could be shown and who have been followed from one to sixteen years (average seven years), pulmonary tuberculosis has developed in only four. Two of these had had infections that were probably tuberculous in character before they had pleurisy. In three of them, either pleural effusion or pulmonary tuberculosis developed within a year after their acute pleurisy. The fourth has only roentgen evidence of tuberculosis at the present time and is working. The remaining thirty-six patients, eighteen of whom have since been examined at this hospital (ten by roentgen examination), are in good health, with the two exceptions previously noted.

We are unable to explain the marked difference in the eventual course of these forty patients as compared to the series previously reported. In selection of the patients, care was taken to include none that had pulmonary tuberculosis or pleural effusion at the time. Some of them had mild cases of pleurisy, yet twenty-seven patients were ill enough to necessitate hospital treatment. Whether the after-care they received played any part in this low incidence of subsequent illness is impossible to ascertain accurately. Because of the prevailing opinion that dry pleurisy is probably of tuberculous etiology, most of the patients were doubtless advised to rest for a period of several weeks before resuming activity. It is not an unfair assumption that many of them did have a mild tuberculous infection, which became quiescent with a period of rest. Further follow-up studies should be made on these patients after a longer period of time, particularly on those who have been observed for only one or two years following their pleurisy.

While this group of cases is not large, it points strongly to a favorable prognosis in acute dry pleurisy of unknown cause. Some instances of this disease, by their subsequent course, will prove to be the early manifestations of pulmonary tuberculosis. This study suggests, however, that phthisis does not develop in as many cases of dry pleurisy as has been taught previously. Nevertheless, in any patient with this disorder every care should be taken to rule out the possibility of pulmonary tuberculosis by careful physical and roentgen examination. Following the acute illness, the patient should be kept under close surveillance for several months. From the few instances in this study it would appear that if further tuberculous activity is to occur it is most apt to show itself during the early months following the pleurisy. In those who have fever during the acute illness, a month of bed rest is a safe investment, and all patients should follow an easy-going mode of life for from two to six months' time. They should have repeated roentgen examinations during this interval and a complete check-up at the end. Those whose family or past history makes tuberculosis seem a possible etiologic factor should be kept in bed at rest for a longer period of time, until the likelihood of the development of pulmonary tuberculosis has passed.

SUMMARY

1. The records of 639 patients with pleurisy seen at the Peter Bent Brigham Hospital were reviewed. One hundred and forty-nine of these were acceptable as instances of acute dry pleurisy. The subsequent history of forty of the latter during a period averaging seven years has been obtained by correspondence or examination.

2. In four of the patients pulmonary tuberculosis developed, in three of them *within one* year after the acute pleurisy. The remaining thirty-six are in good health.

3. While one should appreciate the likelihood that an acute dry pleurisy may be an early manifestation of tuberculous infection, this study suggests that pulmonary tuberculosis is apt to develop in fewer of the cases than has been taught previously.

ADVANTAGES OF CECOSTOMY PRELIMINARY TO RESECTIONS OF COLON AND RECTUM *

ALLEN O. WHIPPLE, M.D.
NEW YORK

Cecostomy has been advocated especially in acute obstruction of the colon but has not been sufficiently emphasized as a measure preliminary to interval operations on the large intestine. Wound repair differs markedly according to the tissues injured, the single, repeated or continued factor of injury preceding or associated with repair, the factor of rest, but especially the factors of blood supply and of presence or absence of infection. An uncomplicated, sutured, sterile incised wound of the skin presents the simplest form of repair, for the injury is mechanical and single, and the reparative process goes on without the interference of further injury. Repair in a sutured incised wound of the colon is quite the opposite. It is complicated from the start by factors which not only delay but which may prevent wound healing: infection with bacteria of the most virulent forms, tension on suture points and lines due to peristalsis or distention, and compromised blood supply due to edema of the infected tissue or to vascular compression, the result of a distended intestine.

Unfortunately, the proof of the foregoing premise is the very high percentage of morbidity and mortality associated with the surgery of the large intestine, and unfortunately too many surgeons accept this high risk or evade it by not attempting surgery of the colon. Ought we not rather to analyze the reasons for this risk and seek means of reducing it?

In studying the subject of wound repair in various tissues, one is immediately struck with the similarity in the graphs of the rate and rhythm of healing, as determined by different investigators. Carrel and Lecomte du Noüy,[1] and Spain and Loeb[2] obtained similar curves in cicatrization of skin wounds; and Harvey, Howes and Sooy[3] found remarkably consistent curves in the repair of wounds of the skin, fascia, muscle and stomach. These mathematically measured rates of healing agree consistently with many of everyday clinical observations, but they show definite critical periods. In all these curves there is a "lag" period of from four to six days during which repair is quiescent; then a period of from six to nine days of fibroblast proliferation and organization, when healing rapidly rises to its maximum point of tensile strength. Following this is a long period, varying in different tissues of maturation of the cicatrix.

It is to the "lag" period and the first days of fibroplasia in the colon that I would call attention. During the first two to four days of repair following anastomosis of the colon, the cut ends, or stoma edges, are held together by suture material or by pressure of apposing buttons, if such a mechanical means is used. Leakage is prevented, to a certain extent, by accurate suture, but far more important and effective is the sealing off of the peritoneal lines of contact, which are usually apposed by the seroserous stitch, by the rapidly forming fibrinous exudate. Provided there is no gross leakage and provided the sutured part can be kept at rest for a few hours, the wonderful reparative peritoneal exudate builds up a sufficient barrier to infection until the process of fibroplasia has united the wound edges and the epithelium has bridged the defect.

But it is during this critical first four to six days, when only peritoneal exudate and sutures are holding the barriers, that tension on the suture line either by atonic distention or by overactive peristalsis can accelerate the factor of infection in destroying the peritoneal line of defense and establishing a peritonitis, localized or diffuse, or a fecal fistula.

Distention of the colon both stretches the tenuous line of suture and diminishes the much needed blood supply to the area of wound repair. This in turn favors pressure necrosis of the suture line and leakage.

Whether one uses the suture or button method of anastomosis in a contaminated field, or attempts one of the 200 or more described methods of aseptic anastomosis, the factors of distention and peristalsis will continue to be damaging and even fatal factors during the first two to six days of repair. It is in an effort to reduce these factors and to place the colon at rest during the critical period of healing that I am advocating the use of cecostomy, preferably two to four days before the major procedure on the colon.

The advantages of a cecostomy carried out two to four days before a resection of the colon or rectum are:

1. It makes possible a proper cleansing of the colon before the major procedure.

2. It permits the part anastomosed to be at rest until the period of fibroplasia is complete.

3. It increases the comfort of the patient by reducing distention and pains of ineffectual peristalsis.

4. It obviates the temptation and the necessity in some cases of giving enemas or irrigations in the critical period of repair.

5. In cases of partial or complete obstruction of the colon or rectum it has long been recognized as essential. If it works so well in the patients who are desperately sick, it is even more efficacious in the nonobstructed case.

I advocate cecostomy rather than appendicostomy for the following reasons:

1. The appendix either is missing or is so atrophic in adults as to be of little use as a sheath for a rubber tube.

2. A cecostomy properly done by the Kader or the Witzel method closes more promptly than an appendicostomy.

3. A tube sufficiently large to act as a real safety valve can be placed in the cecum more easily than in the appendix.

There are certain dangers to be avoided in the use of preliminary cecostomy:

1. The overenthusiastic use of the cecostomy tube as a means of administering fluids or enemas or irrigations before and after major procedures on the colon and rectum should be discouraged. This carries risk of leakage around the cecostomy opening and, after resections, of distending the intestine proximal to the suture line.

2. The tube should be kept in one position. If it comes out, it should be left out.

---

* From the Surgical Department, Columbia University College of Physicians and Surgeons and Presbyterian Hospital.

* Read before the Section on Surgery, General and Abdominal, at the Eighty-Second Annual Session of the American Medical Association, Philadelphia, June 10, 1931.

1. Carrel, Alexis; and Lecomte du Noüy, P.: Cicatrization of Wounds: Latent Period, J. Exper. Med. **34:** 339 (Oct.) 1921.

2. Spain, K. C., and Loeb, Leo: Wound Healing, J. Exper. Med. **23:** 107 (Jan.) 1916.

3. Howes, E. L.; Sooy, J. W., and Harvey, S. C.: The Healing of Wounds as Determined by Their Tensile Strength, J. A. M. A. **92:** 42-45 (Jan. 5) 1929.

3. Only the most gentle syringing of the tube to dislodge fecal particles in the several terminal perforations should be used.

4. We have found that a number 24-28 French colon tube of good rubber, with from four to six openings in the terminal 8 cm., gives the best results as a safety valve. The Witzel method is the one of choice in introducing the tube into the cecum. The cecostomy is usually done under local anesthesia from two to three days before the major procedure.

In the Presbyterian Clinic in New York, we have used cecostomy preliminary to resection of the colon or rectum in twenty-nine patients during the past ten years. But in the majority of these patients, especially during the first five years, the cecostomy was done only in cases of acute obstruction with the patients in poor condition. In the majority of these patients the growth was advanced and the Mikulicz procedure was done. For these reasons the mortality rate was high in this series; that is, ten of the twenty-nine patients died from one to thirty days after the major procedure was done. In only four cases was there a peritonitis or fistula resulting in fatal complications. Death in the other six was due to such factors as uremia, pneumonia, heat stroke, pulmonary embolism and cachexia.

In the nineteen patients recovering from resection of the colon or rectum, the postoperative course was characterized by lack of distention and of gas pains. It was possible in the cases with the Mikulicz procedure or with abdominoperineal resection of the rectum to leave the colostomy closed until from the fifth to the eighth day, allowing for good wound healing and subsidence of edema in the colostomy.

I have been impressed by the fact that in only one of these cases in which colocolostomy was preceded by cecostomy did a fecal fistula develop.

CONCLUSIONS

1. Cecostomy preliminary to colocolostomy favors uncomplicated healing of the suture line by preventing distention and peristalsis of the proximal colon.

2. Cecostomy preliminary to a Mikulicz procedure in the colon or to an abdominoperineal resection of the rectum permits delay in opening the colostomy, until wound healing has occurred and edema in the colostomy has subsided.

622 West One Hundred Sixty-Eighth Street.

ABSTRACT OF DISCUSSION

Dr. Irvin Abell, Louisville, Ky.: I am sure that there will be no dissent from the statement of the author that the safety of resection of the colon in the presence of obstruction is tremendously enhanced by the two-stage operation. With obstruction, the absorbed toxins lower the resistance of the patient; the thickening and edema of the obstructed intestine interfere with its vitality and lower its reparative ability, which is at best none too good; the accumulation of septic fluids renders asepsis difficult to maintain and prevents satisfactory technic, while the abdominal distention hampers both technic and manipulation. The primary decompression permits of a proper preparation of the colon and certainly obviates in large degree the dangers just mentioned. When the obstruction is in the left half of the colon, cecostomy is an ideal procedure. When the obstruction is in the cecum, such an enterostomy brings the drainage point directly in the field to be utilized later for resection. In such instances, when the local and general conditions permit, I prefer an ileocolostomy as the primary or first stage and later the removal of the cecum and ascending colon as the second stage. When this has not been advisable I have done an ileostomy proximal to the obstruction, bringing the tube out through a stab wound in the midline, leaving the right half of the abdomen free from drainage, so that a clean field is afforded for the second operation. In the obstructions due to rectal growths I have not used the cecostomy but have been content with the left abdominal colostomy, the type and character of the colostomy depending entirely on the choice for or against subsequent extirpation of the rectum. It is necessary to make an incision in order to acquire the knowledge on which such a choice is based; this will also permit one in the event of choice of the radical operation to do the first step in it and, if not, to do a palliative colostomy. A large rubber tube anchored in the proximal segment by superimposed purse-string sutures has been satisfactory in giving drainage as needed and is helpful in protecting the wound from fecal contamination, until sufficiently firm healing has occurred to prevent infection of the wound itself. In the instances in which there has not been associated obstruction, I have employed the two-stage operation as a routine measure in the left half of the colon, whereas in the right half of the colon I have done the right hemicolectomy with the union of the terminal ileum to the transverse colon as a one-stage procedure. The differences in the anatomy and function of the two halves of the colon furnish the reasons that have led me to this practice.

Dr. Alexius McGlannan, Baltimore: I am glad to corroborate Dr. Whipple's observations and his conclusions. It has been said that in cases of anastomosis of the colon an enterostomy, proximal to the suture line, is a life-saving method of procedure. This, I believe, is literally true, and Dr. Whipple has given us grounds on which to base this belief. There could be no question that the preliminary colostomy, the preliminary enterostomy for the resection and removal of the tumor, adds tremendously to the patient's chance for recovery, both as to freedom from the toxemia and as to later development of peritonitis.

Dr. J. Shelton Horsley, Richmond, Va.: Physiologic rest is our chief therapeutic resource. Instead of making a tube enterostomy, it would be better to do a complete enterostomy and so give not partial but complete rest to the affected bowel. Through a muscle splitting incision, preferably on the right side, the ascending colon is brought up onto the wound, and a glass rod is placed under it. A rubber tube is inserted for two or three days. The bowel is packed around with gauze and opened after two days, a complete artificial anus thus being made. If by any chance the fecal matter tends to pass over the glass rod, gentle pressure with the dressing will prevent it. The distal part of the colon can be irrigated by manipulation of the glass rod, and ten days later the diseased bowel is resected. For a while I was carried away with the so-called aseptic technic, but I have abandoned it, because by giving the bowel rest and by cleaning it of fecal matter one can reduce the bacterial flora to such an extent that the colon can be sutured from within with the same impunity that the upper small intestine is sutured. It is important to approximate the mucosa accurately so as to leave no raw or peritoneal pockets for accumulated feces, and that can be done only by suturing from within, but a second row of interrupted mattress sutures is applied externally. After ten days, when the bowel is clean, the resection is done, and ten days later, when the united bowel has healed, the artificial anus is closed quite readily by suturing it with two or three layers of interrupted mattress catgut sutures, leaving the ends of the last layer long, sinking the sutured bowel into the abdominal cavity, passing the long ends of the sutures through the inner portion of the abdominal wall and so approximating the bowel to the anterior peritoneum. This makes a three-stage operation: ten days after the complete enterostomy, the resection, and ten days after resection, the closing of the enterostomy.

Dr. G. A. Hendon, Louisville, Ky.: I want to present a method of performing enterostomy that has the advantage of simplicity combined with efficiency and that will answer the purpose in the majority of cases. I take a mushroom catheter and thread it over a stilet; it can be introduced into the bowel through an extremely small opening; when the stilet is withdrawn, the end of the catheter expands, and it remains in situ. The objection to the Witzel method is that it violates one of the fundamental mechanical laws; namely when one binds together substances of unequal density and subjects them to any stress or strain, the substance of less density will yield and thereby produce a leak. In the method that I am proposing, one does not pass any sutures through the catheter. If the bowel is not too much damaged, one may make a layer or two of purse-string sutures. The catheter can be brought through the omentum, as described by Dr. Mayo, which adds security to its position, and brought out through the operative incision. When its usefulness has expired, the shank of the catheter is drawn up as closely as possible and cut off, and the remainder is passed out through the alimentary canal by the natural processes of evacuation. It will be found that the method serves many useful purposes and can be rapidly done.

DR. ALLEN O. WHIPPLE, New York: I meant to state in the paper that the method of cecostomy was limited to the cases in which the cecum was not involved. Dr. Abell is quite right in stating that it is not a method suitable for cases in which the cecum is to be resected. In regard to the subsequent dealings with the cecostomy, in none of the cases in which this method was carried out was it necessary to close the cecostomy. In some ways, undoubtedly, a cecostomy such as Dr. Horsley mentioned is a more effective method, but it certainly requires a subsequent closure. I am interested in the suggestion of Dr. Hendon in regard to the use of a mushroom catheter. The only objection that I could see, possibly, to that method is that it might be a little more difficult to irrigate in case the openings of the catheter became obstructed, but I should be greatly interested in trying it for that purpose.

Clinical Notes, Suggestions and New Instruments

TRANSITORY HYPERTENSION DURING SPINAL ANESTHESIA: REPORT OF A CASE

EDWARD P. HELLER, M.D., AND CARROLL P. HUNGATE, M.D.
KANSAS CITY, MO.

During the past few years the literature has contained numerous articles intended to encourage the use of spinal anesthesia and pointing out the safety of this procedure. Excluding the conditions in which this type of anesthesia is contraindicated, e. g., intestinal perforation, shock and conditions contraindicating the Trendelenburg position, it has been amply shown that the morbidity and mortality are increased through rapid fall in vascular tension not properly controlled by the use of epinephrine or ephedrine.

The literature stresses the complete relaxation that usually occurs in surgery below the diaphragm following the administration of spinal anesthesia. With this type of anesthesia there is usually an absence of intestinal distention during the operation and during the postoperative period. The latter is usually marked by normal peristalsis, a soft abdomen and the absence of pain associated with distention, which is so common following ether anesthesia. In our work we have found that, in surgery below the diaphragm, spinal anesthesia almost invariably gives complete relaxation and diminishes postoperative discomfort.

In a review of the literature we fail to find any reports of hypertension following the use of spinal anesthesia. McKittrick, McClure and Sweet[1] and practically all others in their reports on this type of anesthesia fail to note any cases in which hypertension developed but rather stress the fall in vascular tension. Twenty-five per cent of the series had a fall of 50 per cent or more in blood pressure. Although the exact physiologic action of ephedrine is not agreed on, Burch and Harrison,[2] in their experiments on dogs anesthetized by spinal anesthesia, found that when ephedrine was given intravenously in no instance did the "mean blood pressure rise above the control value before anesthesia." When ephedrine was given intraspinally the blood pressure was equal to or above normal. They do not record a marked hypertension following the use of ephedrine either intravenously or intraspinally.

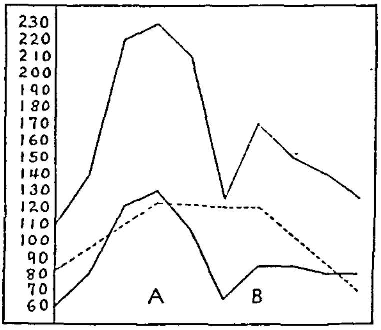
REPORT OF CASE

A man, aged 39, seen by one of us, Jan. 1, 1930, complained of abdominal discomfort with localized tenderness in the right lower quadrant. Periodic attacks of a similar nature had occurred over a period of eight months. He was again seen, July 16, 1931, at which time an operation was advised for chronic appendicitis. On the first date the blood pressure read 125 systolic and 70 diastolic. He was admitted to the Research Hospital, July 17, at which time the blood pressure read 110 systolic and 60 diastolic. He was given a preliminary narcotic consisting of one-sixth grain (11 mg.) of morphine and 1/150 grain (0.4 mg.) of atropine an hour before operation, July 18. He was given 0.025 mg. of ephedrine subcutaneously immediately before the spinal puncture; 3 cc. of a proprietary preparation containing procaine hydrochloride and strychnine sulphate (spinocaine-Metz) was given intraspinally. The blood pressure, pulse and respiration were recorded every five minutes during the operation, as shown in the accompanying chart. The administration and the control of the anesthesia were in the hands of one who is well versed in spinal anesthesia, Dr. Frank Hurwitt.

A right rectus incision was made. Coincidental with the rise in vascular tension there was a marked rigidity of the abdominal musculature. Fifteen minutes elapsed before the patient was moderately relaxed and anesthesia present. During the entire operation, complete relaxation was absent. The appendix was long and tortuous and decidedly bound down by many adhesions. The incision was closed with difficulty. During the closing of the incision, another rise in blood pressure was noted.

The postoperative convalescence was marked by gas pains and distention, insomnia and some febrile reaction. The day following the operation the patient complained of abdominal pain, which was due presumably to distention. This continued for four days. The patient sat up in a chair on the sixth day and was dismissed from the hospital on the ninth day.

During the convalescence the blood pressure was 118 systolic and 80 diastolic. The temperature ranged from 99.6 to 101.2 F., the pulse from 80 to 100. Since returning home he has eaten well, slept well and had normal bowel movements and a good appetite. The wound healed primarily. He began some work at his office, August 1 and has continued at work without difficulty.



Blood pressure (solid lines), and pulse (broken line): *A*, incision; *B*, closure.

After having written to several authorities on spinal anesthesia, we have come to the conclusion that the mechanism of this reaction is perhaps most clearly explained by Dr. L. F. Sise[3] of Lahey's Clinic. He believes that the anesthetic did not get entirely within the dura. A light anesthesia resulted. Therefore, motor paralysis and muscular relaxation were not sufficient. The full dose of ephedrine not being counterbalanced by the full action of the spinal anesthesia would produce the marked rise in blood pressure.

Even though we believe that the spinal anesthesia was given correctly, e. g., the lumbar puncture was done without difficulty and a free flow of spinal fluid obtained at once, Dr. Sise's explanation would seem plausible.

1010 Professional Building.

Council on Physical Therapy

The Council on Physical Therapy of the American Medical Association has authorized publication of the following article.
H. A. Carter, Secretary.

SOURCES OF RADIATION AND THEIR PHYSICAL CHARACTERISTICS

COLD RED RAY AND COLD ULTRAVIOLET RAY LAMPS

W. W. COBLENTZ, Ph.D., D.Sc.
WASHINGTON, D. C.

In two previous communications I[1] described the physical characteristics of sources of ultraviolet (also infra-red) radiation from carbon and from metal arcs; also from incandescent solids, gas flames, and so on.

Recent additions to the physical therapist's armamentarium are the so-called cold red ray and cold quartz ultraviolet ray lamps. The former is a foreign product. The term "cold ray" is a misnomer. Thermal radiation of all wavelengths (whether ultraviolet, visible or infra-red rays), when absorbed, produces heat. The reason that these two sources of so-called cold rays do not have a sensible heating effect and that the burners do not become highly heated is that but little electric power is put into the lamps, and, in turn, but little radiant power is emitted. The germicidal action obtained by ultraviolet rays is a physiologic phenomenon that does not depend primarily on the intensity (energy value) but on the wavelength of the rays to which the organism is sensitive.

DESCRIPTION OF THE COLD RED LIGHT

As pointed out in the preceding papers, but few sources of radiation remain unexploited for therapeutic purposes.

A device that has recently come to my attention is the so-called cold red light emitted by the neon glow discharge tube, familiar to all in the form of the sign-lighting tubes in show windows and street signs.

The intensity of the total radiation emitted by the neon glow lamp is low. It consists of a narrow band of wavelengths in the orange-red part of the spectrum, with a maximum in the region of 650 millimicrons (6,500 angstrom units). Neon emits practically no radiation of wavelengths longer than about 1,000 millimicrons.[2]

If the deep-penetrating rays, in the red and near infra-red, have a specific action on the human skin, it would be more efficient to use a more intense source of these rays. For example, a powerful source of red and near infra-red rays is a 500 watt gas-filled tungsten lamp in front of which is placed a combination filter, consisting of a sheet of red glass to shut out the shorter wavelengths, and a cell of water or a sheet of Corning heat-absorbing glass to intercept the infra-red rays of wavelengths longer than about 1,000 millimicrons. The maximum of the filtered radiation will be in the spectral region of about 700 to 800 millimicrons, with an intensity that far exceeds the ordinary neon glow lamp.

From the clinical tests made by Cramer and Fechner[3] with a neon glow lamp, made for therapeutic purposes, it appears that the cold red ray lamp has but little, if any, specific stimulating effect on the human body.

DESCRIPTION OF THE COLD QUARTZ ULTRAVIOLET LAMP

The quartz mercury arc, described in my previous communications, was of the low voltage type (from 110 to 220 volts), in which the incandescent column of mercury vapor carries a relatively high current, amounting to 4 or more amperes, or from 400 to 600 watts in the burner. As a consequence, the temperature and hence the vapor pressure is relatively high, and the ultraviolet radiation is contained principally in the intense emission lines at 254, 280, 297, 302, 313, 334 and 365 millimicrons.

The intensities of the wavelengths of from 254 to 280 millimicrons are relatively weak as compared with the emission lines at 297 and 302 millimicrons, which have a high therapeutic action (there is practically no action by wavelengths longer than 313 millimicrons), at least in activating ergosterol and in preventing rickets.[4]

In contrast with the previously described quartz mercury arc lamp, which has a relatively high vapor pressure, a low potential and a high amperage, the so-called cold quartz mercury vapor lamp has essentially a low vapor pressure, a low amperage (0.015 ampere) and a high potential (5,000 volts, open circuit) glow discharge, similar to the well known Geissler tubes of glass, to be found in physical laboratories.

The power consumed in the so-called cold quartz mercury vapor lamp is small (about 75 watts in the primary of the transformer, and only about 8 to 10 watts in the lamp) and hence there is no great rise in temperature of the burner.

The Cooper Hewitt vapor lamp (a commercial illuminant in a long tube of flint glass) and the "Uli-Lampe" (in a uviol glass tube, used abroad for therapeutic purposes) are essentially low vapor pressure glow discharge tubes.

It is interesting to note that, by providing suitable ionization, by means of electrons emitted from a hot cathode, only a relatively low voltage is required to excite resonance radiation in the glow discharge through mercury vapor. A typical example of this type of radiation is the new ultraviolet glow lamp, G-1,[5] in a bulb of special glass.

As will be shown presently, practically all the activating radiation from the low vapor pressure glow lamp is contained in the resonance emission line of mercury vapor of wavelength 254 millimicrons (2,537 angstrom units). However, in view of the highly active property of this emission line in producing conjunctivitis the enclosure of the new, G-1, glow lamp is made of Corex-D glass, which intercepts practically all radiation of wavelengths less than 270 millimicrons. In this connection it is relevant to add that when one is working near the cold quartz mercury vapor lamp it is important to wear glasses (clear white crown glasses will answer the purpose) in order to absorb the ultraviolet radiation of wavelength 254 millimicrons, which is so active that conjunctivitis was produced by radiation accidentally shining back of the spectacle lens when the face was exposed sidewise to the lamp.

PHYSICAL CHARACTERISTICS OF THE ULTRAVIOLET RADIATION EMITTED BY COLD QUARTZ LAMPS

Radiation measurements were made on two types of cold quartz ultraviolet generators (mercury glow lamps): (1) a long slender quartz tube type of orificial applicator and (2) a grid type in an aluminum reflector.

The radiometric measurements were made with the vacuum thermopile and a quartz fluorite achromatic spectroradiometer, regularly employed in such work. No attempt was made to obtain spectrum photographs, because they cannot give quantitative measurements, though if intelligently employed they may show something of the spectral quality of the radiation emitted. For example, spectrum photographs of new, clean applicators usually show emission lines of wavelengths shorter than about 190 millimicrons. However, one applicator type of lamp was brought to my attention that, according to the spectrograms submitted, did not emit (transmit) ultraviolet rays shorter than about 226 millimicrons. Assuming that the ultraviolet spectrograph was functioning properly, it appeared that the absence of ultraviolet rays shorter than 226 millimicrons probably resulted from the fact that, since the walls of the quartz tube forming the applicator were no longer perfectly clear, the short wavelengths were absorbed in their passage through the tube; for it requires but little contamination of the surface of the quartz tube to effect great absorption of the very short wavelength ultraviolet rays.

Cold Quartz Orificial Applicator.—The following data were obtained on a cold quartz orificial applicator operated on 0.013 ampere, and 640 volts, or about 8 to 10 watts in the burner. This particular lamp was operable on two voltages. The intensity of the ultraviolet radiation emitted when the lamp was operated on the higher voltage was 1.6 times that obtained on the lower voltage.

By placing the luminous tube of the cold quartz ultraviolet generator lengthwise, close to the slit of the spectroradiometer, it was found that the intrinsic intensity of the 2,537 angstrom unit line is relatively high, being about 215 microwatts per square centimeter at the surface of the applicator. It was observed also that 96 per cent of the total erythemogenic rays (of wavelengths less than and including 313 millimicrons) was emitted by the resonance line at 254 millimicrons. By means of a thermopile and filter method,[6] it was found that 97.8 per cent of the erythemogenic rays was emitted by the line at 254 millimicrons, which is in good agreement with the preceding test.

Cold Quartz Grid Type Ultraviolet Generator.—Measurements of the ultraviolet radiation emitted by this lamp were made with an achromatic spectroradiometer and a vacuum thermopile; also by a balanced thermopile and filter method.[7]

The lamp was operated on 115 volts, alternating current, and 60 cycles on the primary of the transformer, with 30 milliamperes through the lamp as specified.

Under these conditions it was found that the relative intensities (corrected for absorption in the spectroradiometer [7]) of the short wavelength ultraviolet lines that were measurable at 313, 297 and 254 millimicrons were 45, 14 and 865. From this it follows that about 94 per cent of the total radiation of wavelengths less than and including 313 millimicrons is contained in the resonance emission line at 254 millimicrons. This is a trifle lower than the value obtained for the cold quartz applicator. But in the grid lamp examined, the quartz tubes were not quite so clear as in the applicator, which would reduce the intensity at 254 millimicrons relative to the intensity at longer wavelengths.

The total radiation of wavelengths less than and including the line at 313 millimicrons, at a distance of 25 cm. from the center of the lamp, measured by a new balanced thermocouple and filter method [7] was 186 microwatts per square centimeter.

Physiologic tests [7] were made of the erythemogenic efficiency of this lamp, and a close agreement was found between the observed and the calculated time of exposure to produce a minimal perceptible erythema.

Since the publication [8] of experiments on irradiation of cod liver oil, ergosterol and cholesterol, showing that wavelengths shorter than 280 millimicrons are destructive to vitamin D, the feeling is abroad that it is undesirable to use ultraviolet rays of wavelengths shorter than about 280 millimicrons for therapeutic purposes, and hence, in recent years, therapeutic lamps are generally covered with a glass that eliminates these rays.

The radiation from the quartz mercury vapor glow lamp is predominatingly of wavelengths that have a high germicidal action.[9]

In fairness to the purveyor of the particular make of lamp examined, it is relevant to add that the accompanying literature indicated that the device was being promoted as a germicidal agent. Credit is to be given also for the caution sign on the instrument to "protect the eyes at all times by wearing glasses."

Even after this warning is heeded, accidents are possible, as witness the aforementioned case of conjunctivitis in the outer corner of the eye, caused by radiation passing back of the spectacle lens when the subject was standing with the face exposed sidewise to the lamp.

CONCLUSION

It seems relevant to comment on the great difference in the physiologic action of the ultraviolet rays of wavelengths less than 265 millimicrons in artificial sources (absent in sunlight) as compared with the wavelengths from 310 to 315 millimicrons, which are very intense in sunlight. The ultraviolet rays of wavelengths in the region of 254 millimicrons do not penetrate deeply into the skin, the erythema produced is superficial, and an overexposure of several times the dosage required to produce a minimal perceptible erythema does not produce a blister.

In contrast, if the untanned skin is exposed to the more deeply penetrating rays of wavelengths 310 millimicrons and longer, for an interval that is only slightly longer than the dosage time required to produce a minimal perceptible erythema, a painful blister is produced. This phenomenon was noted by Hausser and Vahle,[10] and more recently by us.[11]

During the past summer, further physiologic tests were made,[12] measured amounts of ultraviolet radiation from artificial sources and from the sun being used. The observed time of exposure to the clear noonday sun (which was in good agreement with the calculated time of exposure based on measurements with a newly designed intensity "dosage" meter) to produce a minimal perceptible erythema was twenty minutes, whereas an exposure of thirty minutes produced a painful burn.

While these facts are known to a few, it will require a long time to inform the public of the importance of properly timing the sunbath in order to avoid severe burns. In the meantime, office workers, store clerks, and the like will suddenly emerge from their daily routine for two weeks' vacation, and, without any preliminary systematic timing of the exposure of the untanned parts of the body, will bask in the summer sun for hours (instead of from fifteen to twenty minutes) and, as a result, will suffer painful burns that could have been avoided if a warning had been given.

2737 Macomb Street, N.W.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

The Council has authorized publication of the following report. W. A. Puckner, Secretary.

McKESSON'S COPPER-IRON COMPOUND NOT ACCEPTABLE FOR N. N. R.

McKesson's Copper-Iron Compound was presented for consideration by the Council as being of value in the treatment of anemia. The firm gives the following statement of composition: "Copper Caseinate, McK&R (4.87% Cu.), 2.565 grams; Iron Peptonate Merck (17.5% Fe.), 5.700 grams; Sodium Citrate Merck U. S. P. 9.000 grams; Alcohol (grain) 150.000 cc.; Glycerin, 100.000 cc.; Oil of Orange (sweet), 0.160 cc.; Acetic Ether, 0.160 cc.; Vanillin, 0.020 grams; Distilled Water to make 1000.000 cc. Alcoholic strength about 14.25%."

The Council considered the evidence presented by the firm for the value of the product in anemia and found it insufficient to justify the recognition of a copper-iron preparation for widespread clinical use. The paper of M. E. Lewis (The Journal, April 4, 1931, p. 1135) to which the firm referred is favorable as far as the few cases reported are concerned; but further confirmatory clinical evidence is needed. The firm was informed that this confirmatory evidence should come from two or more clinics of recognized standing and that the individual cases should be presented in some detail at least as comprehensively as the cases reported in Lewis's article. The firm has not submitted this further evidence. On the other hand, it has informed the Council that the product is being marketed and has submitted the advertising which is now being used and which makes claims that clinical evidence has shown the efficacy of the product. The submitted circular states, "Clinical evidence submitted in confidence by prominent physicians has supported our experiments in vivo." Such confidential reports do not constitute acceptable evidence. In the advertising circular "A Presentation of McKesson's Copper-Iron Compound for the treatment of Anemias," by W. J. Horn, the referee questions the following statement: "Clinical evidence, likewise, shows that this product is quite efficacious in the treatment of several forms of secondary and primary anemias. In most cases there was an increase in red blood cells comparable to the increase in hemoglobin. In nearly all cases the patients noted remarkable improvement in vitality, appetite and general well-being."

Since the firm has not submitted acceptable evidence to show that the iron-copper preparation offered as McKesson's Copper-Iron Compound is superior to the iron preparations in current use, the Council declared the product unacceptable for N. N. R. because of unwarranted therapeutic claims.

Committee on Foods

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public. They will be included in the Book of Accepted Foods to be published by the American Medical Association.

Raymond Hertwig, Secretary.

DIAMOND BREAD

Manufacturer.—Mason City Baking Company, Mason City, Iowa.

Description.—A white bread made by the sponge dough method.

Manufacture.—The sponge dough ingredients, 70 per cent short patent flour of Northwest wheat, water, malt syrup, yeast, and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, are mixed in a high speed mixer. The sponge dough is fermented for from four to five hours, after which are added flour, water, sucrose, salt, lard and sweetened condensed skimmed milk to make the completed dough, which is cut into pieces of desired weight. The pieces are fermented for a short time, molded into loaf form, panned, further fermented, baked for from thirty to thirty-five minutes, cooled, and wrapped in wax-paper.

The factory, equipment and storage rooms for the materials used are kept in strictly sanitary condition.

Chemical Composition (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	37.3
Ash	1.3
Fat (direct ether extraction method)	0.7
Protein (N × 6.25)	8.9
Crude fiber	0.2
Carbohydrates (by difference) other than crude fiber	51.6

Calorics.—2.48 per gram; 70.4 per ounce.

Claims of Manufacturer.—A bread of good quality.

PIXIE STRAINED VEGETABLE SOUP

(Mildly seasoned with salt)

Manufacturer.—Fruit Belt Preserving Company, East Williamson, N. Y.

Description.—Canned vegetable soup of sieved carrots, peas, celery, tomatoes, spinach, potatoes and onions, containing in large measure the mineral and vitamin content of the raw materials used; contains a small amount of added salt.

Manufacture.—Canned carrots, spinach, peas, tomatoes and celery (specially prepared for maximum retention of the natural vitamin content), potatoes and onions are the ingredients used. Fresh potatoes are washed and skinned in a potato peeling machine; are trimmed, inspected and boiled until soft; the potato water is used in the soup. The onions are hand peeled, trimmed and cooked in a closed kettle. The water with its strong onion flavor is discarded. The partially cooked onions are further cooked in fresh water, which is also discarded. The different vegetables in definite proportions are mixed in a closed kettle, cooked, sieved, canned and processed by essentially the same procedure as that described for Sieved Carrots (The Journal, Nov. 14, 1931, p. 1467). A small amount of salt is added.

Chemical Composition (submitted by manufacturer).—

Specific gravity 20 C./20 C	1.03
	per cent
Moisture	91.1
Total solids	8.9
Ash	0.6
Fat (ether extract)	0.03
Protein (N × 6.25)	1.8
Crude fiber	0.4
Carbohydrates other than crude fiber (by difference)	6.1

Calorics.—0.32 per gram; 9.1 per ounce.

Vitamins; Micro-Organisms; Claims of Manufacturer.—See these sections for Pixie Strained Carrots.

THE JOURNAL OF THE
AMERICAN MEDICAL ASSOCIATION

535 North Dearborn Street - - - Chicago, Ill.

Subscription price - - - - - Seven dollars per annum in advance

Please send in promptly notice of change of address, giving both old and new; always state whether the change is temporary or permanent. Such notice should mention all journals received from this office. Important information regarding contributions will be found on second advertising page following reading matter.

SATURDAY, DECEMBER 26, 1931

MALIGNANT CONDITIONS IN RADIOACTIVE PERSONS

Martland,[1] in 1925, reported cases of anemia and of necrosis of the jaw in persons who had been employed in painting watch dials with paint made luminous by the addition of radium, mesothorium and radiothorium. During several years previous to 1924, 800 girls did such work in a New Jersey factory. The girls swallowed small amounts of radioactive paint day after day as a result of pointing the brushes with the lips. Some who had worked for one or more years developed necrosis of the jaw and anemia, from which, up to 1928, thirteen died. Martland, who had followed these carefully, believed toward the end of 1928 that the worst period was over and that, with few exceptions, no more workers would develop radium poisoning. Dial painting was stopped there several years ago. Now, however, another pathologic condition seems to have arisen among the employees who swallowed radioactive paint. Since 1928, rapidly growing osteogenic sarcomas have appeared in at least eight cases. One girl died of sarcoma of the pelvis and of the orbital cavity; another, described as healthy in 1925 although her expired air was radioactive, developed osteogenic sarcoma at the site of a spontaneous fracture of the femur; another dial painter has twice sustained a pathologic fracture of the femur at the same site and sarcoma is suspected, and another former dial painter has recently developed osteogenic sarcoma of the pelvis. Four additional possible cases of sarcoma in former dial painters have come to Martland's[2] attention. These delayed cases of illness passed through the period when necroses of the jaw and anemias were developing in these workers and the present attack on their health is of a different nature. The difference is explained thus: In the early cases, mesothorium, which is physiologically more active than radium, predominated, but enough time has elapsed since their exposure to radioactive substances to allow the mesothorium to diminish in quantity by its own natural decay to below half its former strength. In the late cases which have resulted fatally, only radium, which is less active physiologically than the mesothorium, has been detected, and this has accumulated in the bony skeleton. Gettler, who examined the bones of a dial painter exhumed five years after death, found 0.05 mg. of radium distributed in the skeleton. He estimated that one-fourth ounce of bone from this painter contained $1/50,000$ mg. of radium and that the number of atoms of radium in this amount of bone was fifty billion. One thousand alpha particles per second were ejected from this one-fourth ounce of bone. Alpha particles, which, Martland says, are probably the most destructive agent known to science, consist of nuclei of helium atoms containing two positive charges ejected from the nuclei of the parent radioactive atoms at an initial velocity of from 12,000 to 18,000 miles per second. This destructive bombardment in the bones produces pathologic changes that give rise to anemia and to radiation osteitis and it is these areas of bone in which later sarcomas arise.

Flinn[3] recently suggested a method of treatment that will eliminate radium salts from the organism as well as improve the condition of the bone if continued for sufficient time. His next report of the treatment of radioactive patients is awaited with interest.

The study by Martland and his associates will aid in understanding the effects of other radioactive substances. The high incidence of primary carcinoma of the lungs in the cobalt miners of Schneeberg and in the pitchblende mines of Joachimstahl, and the various lesions produced by external exposure to radium and x-rays, demand investigation. Many of the radioactive substances sold to the public for the cure of various ailments may be dangerous to health. Martland was called to testify against the interstate sale of vials of mesothorium and radium which were to be ingested after being dissolved in water for the cure of disease. If taken as directed, the amount of radioactive substances in them would equal that taken by some of the dial painters. He examined two patients who had taken such water from one to two years; both showed radioactivity when tested by electrometers, and both had extensive necrosis of the upper jaw. Should these waters which are sold to the public contain only emanations in the form of radon or thoron it would be impossible to drink enough to furnish emanation that would be beneficial. Waters containing only emanation, Martland says, are frauds, and he doubts whether they are harmless. In 1926, more than 150,000 emanators were sold on the Pacific Coast. The human body in its normal environment is radioactive, but the normal radioactivity of the body should not be increased if it is presumed that increased amounts of radioactivity may in years produce a malignant condition. The drinking over long periods of time of radioactive waters containing radon, and the drinking of natural radioactive waters, should be discouraged. Martland likewise cautions against the intravenous injection of long lived radioactive elements. Some questions concerning the pathogenesis of cancer are suggested by this study of radioactive persons. May not other forms of malignancy depend on the presence in the body of increased amounts of radioactivity too small perhaps to be detected by present methods?

SYNOVIAL FLUID

Most textbooks of physiology and biochemistry are singularly silent about the synovial fluid and its origin. Yet this substance is of unquestionable moment to the body in providing assurance of comfort in the movement of joints. It often presents pathologic considerations that are quite tantalizing to the physician who is compelled to deal with them therapeutically. The synovial fluid is sometimes grouped with transudates and exudates that occur in various parts of the body, notably with such fluids as peritoneal or pleural effusions. The composition of the synovia is not constant but differs in rest and motion of the joints that it bathes. There is a notable distinction between the fluid and blood plasma or ordinary lymph, presumably due to a mucin-like substance in the synovia. This serves to explain the wide difference in fluidity and stickiness of fluids within joints which is not commonly encountered in plasma. The exact nature of the mucinous constituent remains unknown. Its existence, however, contributes to the view that synovial fluid is something more than a mere transudate.

In 1926, Fremont-Smith and Dailey[1] of the Harvard Medical School made a comparison of the distribution of chloride and protein in plasma with that in noninfected peritoneal, pleural and synovial effusions. As a consequence they concluded that the equilibrium between plasma and synovial fluid is of the same nature as that between plasma and peritoneal or pleural effusions. Investigations by Kling[2] in New York, however, lead him to the conclusion that the synovial fluid is something more than a mere transudate. The viscosity of normal, and the majority of pathologic, synovial fluids is higher and the range of variation is greater than that found in plasma and exudates. The mucinous substance is recognized to be a physiologic product. Inflammation and irritation tend to increase its output. Normal synovial fluid contains few cells, and they are chiefly synovial lining cells. Different types of leukocytes in various amounts, according to the stage and the degree of the process, are found in inflammatory effusions; trauma brings red blood corpuscles into the fluid. Kling accordingly believes that the structure and the function of the synovial membrane are twofold. One part is built for mechanical binding of the epiphyses constituting the joint; it is the connective tissue capsule, inward and outward. The other part is interposed at the intratesticular surfaces, for the maintenance of smooth motion and lubrication. This is the function of the intra-articular fat depots, synovial folds and villi and their lining containing actively secreting cells.

Kling points out that the development of the membrane and of the fluid is different in various joints. The secretory element is best developed in the knee joint and less well developed in the wrist and tarsal joints. The primary response to inflammation and irritation of the knee is therefore effusion; that of the wrist, infiltration and pannus formation. This explains, he adds, why the same etiologic factor, for instance, gonorrhea, produces in the same patient a chronic exudative arthritis of the knee joint and an infiltrative and ankylosing process of the wrist. Motion is the natural stimulus for the secretion of synovia, as is food for the secretion of gastric juices. The detrimental effect of immobilization, especially in knee joints, is therefore explained by the interference with this secretion in a joint highly adapted to it.

PHYSICAL EXAMINATION AS AN INSTRUMENT OF RESEARCH

The classification of knowledge is second in importance only to the original collection of data; without the orderly arrangement of facts the interplay of cause and effect in the natural sciences, notably the portrayal of function in biology, would be determined with difficulty. The evaluation of data is greatly facilitated by application of statistical methods. This device, long used by the investigator in public health, is now being effectively applied to other fields of scientific endeavor. However, it is axiomatic that a statistical analysis of a mass of data is only as significant as are the individual observations themselves. Whereas data consisting of objective measurements expressed in standard denominations lend themselves admirably to treatment by the statistician, there are certain types of observations that often form the basis of rather extensive studies and are difficult to bring to the common basis required if comparisons are to be made. Data obtained by numbers of thoroughly reliable and capable individuals but dependent on the interpretation of the person making the observation fall into the latter category.

An equitable evaluation of the limitations of the physical examination as an instrument of research has recently been made by Britten.[1] Ordinarily a physician

[1] Britten, R. H.: Pub. Health Rep. **46**: 1671 (July 17) 1931.

makes a physical examination for the specific purpose of helping an individual patient; he is on the watch for definitely pathologic conditions which obviously affect the health of the patient. Doubtless minor degrees of structural or functional impairment are noted and may or may not be mentioned. After the probable major difficulty has been located, the abnormalities on the borderline of significance often receive little attention. However, statistical results are influenced largely by the apparently insignificant deviations from the normal since they constitute the majority. It thus happens that certain types of research of considerable importance in matters of public health depend finally on the uniformity of interpretation by examining physicians. When, for instance, the investigation deals with the influence on health of the temperature and humidity of the air in certain industrial plants, not only the mortality and incidence of sickness but also the physical examination becomes of great significance. Almost no two physicians of equal training, ability and experience will proceed in the same way or attach the same interpretation to their observations. Conditions which one examiner reports within the normal range may be reported as mild or severe by another. Quantitative determinations may be reported in standard denominations, yet the differences in interpretation of what values fall within and what without the normal variation may alter the final conclusions to be drawn from the data. When these cases in point are multiplied many times, as in a nation-wide study of problems of public health, it is obvious that there is a likelihood of differences due largely to the standards of the examiners being incorrectly attributed to factors peculiar to the industry under investigation.

In an effort to obtain greater uniformity of procedure and to enhance the significance of the results of the physical examination, Britten has suggested some principles along which progress might be made. The examiner should, if possible, proceed without knowledge of whether the subject is normal or not; evidence should appear in the report that the condition in question has at least been looked for; some standard scheme for evaluation of degrees of variation from the normal should be established, though it finally devolves on the examiner himself to decide whether or not a condition is pathologic. Since it is necessary that these degrees of abnormality be uniformly understood by all examiners, a definite set of instructions and a short but intensive training in the details of the examination should be given. Not only should a thorough history be obtained but allowance should be made for the presence of an acute condition during the examination and, if possible, the examination repeated after the acute condition has subsided. In an effort to stimulate thoroughness, a minimum time required for the examination should be established.

The foregoing discussion emphasizes one of the problems that have grown out of the expansion in the work of the public health service. It seems reasonable to expect that, in order to obtain results of significance in those investigations depending on the results of physical examinations, this procedure must be standardized to a greater degree than it has been heretofore. This general thesis should, however, be applied with care. While group investigation will doubtless require more or less standardization of procedure on the part of the members of the group, the art and science of medicine will probably be furthered in the future, as it has been in the past, largely by efforts made in the way peculiar to the individual.

Current Comment

OYSTERS—A PLEASANT TYPE OF THERAPY

The announcement by Hart[1] and his collaborators at the University of Wisconsin three years ago that copper is effective in supplementing iron in the cure of anemia produced by an exclusive milk diet in the rat promptly aroused the interest of the medical profession. Despite the importance of this discovery it must be admitted that the inferences hastily drawn by others than the investigators themselves have led to not a little confusion and mistaken advice. The work of Hart referred specifically to a unique type of nutritional anemia in a laboratory animal. There has been no warrant whatever in applying the observations without reservation to some of the unusual conditions of the blood, such as pernicious anemia in man, that have until recently been so baffling to the physician. At the moment there is some debate as to whether copper stands alone in the capacity to promote the function of the indispensable iron in hemoglobin and blood cell formation. Other elements, such as manganese and germanium, are clamoring for equal recognition. Meanwhile all sorts of new products containing both iron and copper are being commercially exploited and foisted not only on an ignorant public but also on an uncertain medical profession, although the Council has reported that the use of copper and iron mixtures lacks sufficient clinical supporting evidence (see page 1967, this issue). The chief objection to such unproved therapy is that a sense of security in the use of some drug leads to the neglect of other modes of therapy that may be far more effective. Many persons assume that copper is a scarce element in our foods, just as iron was formerly assumed to be. The facts are that both elements are more ubiquitous than might be anticipated. Illustrations of this are coming to light in rapid succession. The question Have you had your iron today? no longer conjures up the picture of raisins, which have distressed more than one person through overindulgence. Oysters, for example, have just been shown by Levine, Remington and Culp[2] to be capable of curing the nutritional anemia of milk-fed rats. The presence of copper in the oyster is not new knowledge. The studies indicate that the inorganic elements present in the oyster are responsible for its hemoglobin regenerating capacity and that the antianemic potency of the oyster can be accounted for on the basis of its content of the three elements iron, copper and manganese. Other comparable discoveries are likely to follow, making the administration of copper a gustatory delight rather than the mere ingestion of "a dose of medicine."

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts from 2:25 p. m. to 2:30 p. m. on Monday, Wednesday and Friday over Station WBBM (770 kilocycles, or 389.4 meters), of the Columbia Broadcasting System.

The program for the week is as follows:

December 28. Common Sense and the Open Window.
December 30. New Hazards for Old.
January 1. No broadcast.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Lectures on Medical History.—Prof. Henry E. Sigerist, Institute of the History of Medicine, University of Leipzig, Germany, will give two lectures on medical history, January 12-13, in Lane Hall, San Francisco. The first lecture will be on "Problems and Methods of Historical Pathology," and the second, "The Social Aspects of Medicine." The historical section of the Lane Medical Library, Stanford University School of Medicine, will be dedicated, January 11. Dr. William Ophuls, dean of the school of medicine, will give the introductory remarks; Dr. Emmet Rixford, emeritus professor of surgery, will speak on "Development of the Historical Section of the Lane Medical Library," and Dr. Sigerist, "Relation of History of Medicine to Practice."

Food Poisoning Reported.—One hundred and eighty-one cases of food poisoning were reported during the last month, according to the state department of health, December 5, of which 175 occurred following a high school banquet held in Willows, attended by about 200 mothers and daughters. Those who were affected had eaten creamed chicken, which had been prepared earlier in the day and heated just before serving. About sixty pupils in the domestic science class had handled the chicken in the preparation of the dish. The bulletin of the health department stated that it is probable that arsenic caused the poisoning in the remaining six cases in Santa Monica. These victims had eaten fresh mustard greens, in samples of which laboratory examination revealed the presence of a considerable amount of arsenic. The poison had probably been used in a spray for the destruction of insects.

Society News.—Dr. Anton J. Carlson, Chicago, addressed the Los Angeles County Medical Association, December 22, on "Rôle of the Nervous System in Gastro-Intestinal Functions and Disorders." Dr. Carlson also addressed the Los Angeles Clinical and Pathological Society, December 21, on "Present Status of the Problem of the Endocrines."——Dr. Clinton H. Thienes, Los Angeles, addressed the Los Angeles County Heart Association, December 21, on "Practical Use of Digitalis and Quinoidine in Heart Disorders."——At the meeting of the Society of Neurology and Psychiatry, December 16, the speakers were Drs. Martin G. Carter and Leo J. Adelstein, Los Angeles, on "Psychosis: Its Importance as a Presenting Symptom of Brain Tumor"; Dr. Cyril B. Courville, Los Angeles, exhibited specimens of bone tumors.——Dr. Emmet Rixford, San Francisco, addressed the San Diego County Medical Society, December 8, on "Chinese Native Medicine."——The Alameda County Medical Association was addressed, December 21, by Dr. Nathaniel A. Cary, Oakland, on "Compression Fracture of the Spine with New Method of Treatment"; Mr. Hartley F. Peart also spoke on "Some Legal Aspects of the Practice of Medicine."

COLORADO

Portrait of Dr. Sewall Unveiled.—At a testimonial dinner given by the Medical Society of the City and County of Denver, December 3, a portrait of Dr. Henry Sewall was unveiled and formally presented to the society by Dr. Harry J. Corper. Dr. Frank W. Kenney, secretary of the board of trustees of the society, made the speech of acceptance. Dr. James R. Arneill was toastmaster. Other speakers included Drs. John W. Amesse, president of the society; Gerald B. Webb, Colorado Springs, and Donald C. Balfour and Harold E. Robertson, both of Rochester, Minn. Dr. Sewall, who is 76 years of age, is professor emeritus of medicine, University of Colorado School of Medicine. Among former positions held by Dr. Sewall were those of assistant fellow and associate in biology at Johns Hopkins University, professor of physiology at the University of Michigan, and secretary of the Colorado State Board of Health. In 1926 he was president of the National Tuberculosis Association; in 1930 the association awarded him the Trudeau Medal in recognition of his work on tuberculosis. He also received in 1931 the Kober Medal, awarded by the Kober Foundation.

DELAWARE

Health at Wilmington.—Telegraphic reports to the U. S. Department of Commerce from eighty-two cities with a total population of 36 million, for the week ended December 12, indicate that the highest mortality rate (19.1) appears for Wilmington, and the rate for the group of cities, 11.3 The mortality rate for Wilmington for the corresponding period last year was 14.7, and the group of cities, 11.7. The annual rate for eighty-two cities for the fifty weeks of 1931 was 11.8, as against a rate of 11.9 for the corresponding weeks of 1930. Caution should be used in the interpretation of these weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits, or that they have a large Negro population, may tend to increase the death rate.

DISTRICT OF COLUMBIA

Tumor Clinic Established.—A tumor clinic was formally opened at Providence Hospital, Washington, November 5. Its purpose is the prevention, diagnosis and treatment of cancer and allied conditions among the poor of the city and the dissemination of information on the subject to the public. The clinic is under the direction of Dr. Casimir F. X. Leibell. It is planned to have frequent consultations by members of the staff, thus bringing to bear on every cancer patient the advantages of group diagnosis.

Plans for Antituberculosis Work.—At a meeting of the Washington Tuberculosis Association, November 24, ways of meeting the increasing necessity for antituberculosis work were discussed. The $50,000 approved for the 1932 budget is the largest ever appropriated for this work. A program of health lectures for adults will be extended to every field of industry, and a survey of existing conditions will be made to pave the way for more clinical examinations, more hospital facilities, and the discovery and correction of tuberculous tendencies. Work will be centered around the new Children's Tuberculosis Sanatorium. Speakers at the meeting included George A. Hastings, administrative secretary to President Hoover; Thomas A. Kidner, consulting architect, New York; Dr. Joseph A. Murphy, chief medical inspector of District public schools, and Dr. Kendall Emerson, managing director, National Tuberculosis Association, New York.

ILLINOIS

Society News.—Dr. Leo M. Czaja, Chicago, addressed the Adams County Medical Society, Quincy, December 14, on "Maggot Treatment of Osteomyelitis."——At a joint meeting of the physicians from Randolph, Perry, Monroe and Jackson counties, December 9, Dr. Robert F. Lischer, Mascoutah, spoke on "The Country Doctor," and Dr. William T. Coughlin, St. Louis, "Cancer of the Breast."——Dr. Plinn F. Morse, Detroit, addressed the Winnebago County Medical Society, Rockford, December 7, on bone diseases.——A recent meeting of the Ogle County Medical Society was addressed, among others, by Dr. Roswell T. Pettit, Ottawa, on present treatment of carcinoma.

Chicago

Fellowship in Neurology.—Dr. and Mrs. William H. Wilder, Sr., have established the William H. Wilder, Jr., fellowship in neurology at the University of Chicago, in memory of their son, a student in neurology at the university, who was drowned last summer. The fellowship is to be awarded to a student of neurology nominated by the department of anatomy on recommendation of the professors in charge of neuroanatomy and clinical neurology. Mr. Paul G. Roofe has been appointed the first recipient of this fellowship.

Surgeon General Guest of Honor.—Dr. Robert U. Patterson, surgeon general, U. S. Army, Washington, D. C., will be guest of honor and principal speaker at the annual meeting and dinner of the Medical Department Sub-Chapter, Cook County Chapter, Reserve Officers' Association of the United States in the Drake Hotel, January 6. Other guests of honor will include Major Gen. Frank Parker; Col. Paul C. Hutton, surgeon, sixth corps area; Dr. Arthur D. Black, dean, Northwestern University Dental College; Dr. William H. G. Logan, dean, Chicago College of Dental Surgery, and Dr. Morris Fishbein, editor of The Journal. All medical reserve officers of the sixth corps area, which includes Michigan, Wisconsin and Illinois, are invited to the dinner.

Society News.—At the middle section meeting of the American Laryngological, Rhinological and Otological Society, January 5, the speakers will include Drs. Edward H. Cary, Dallas, Texas, on "The Future of Private Otolaryngological Practice"; Chevalier Jackson, Philadelphia, "Pins at the Periphery of the Lung"; John W. Carmack, Indianapolis, "Maxillary Sinusitis with Blood Stream Infection"; William V. Mullin, Cleveland, "Allergy"; Edmund Prince Fowler, New York, "Prevention of Deafness"; William E. Grove, Milwaukee, "Brain Abscess with Peculiar Bacteriologic Findings"; Edward D. King, Cincinnati, "Nasal Plastic Surgery"; Louis E. Brown, Akron, presentation of new instruments. At a joint meeting of the Chicago Laryngological and Otological Society, Chicago Tuberculosis Society and the Chicago Medical Society, January 4, Dr. Chevalier Jackson will speak on "Suppurative Disease of the Lung Following Operations Involving the Upper Air Passages." Dr. Austin A. Hayden is chairman of arrangements for the meeting.——Dr. Hugh McCulloch, St. Louis, will address the annual meeting of Sunset Camp Service League, January 19, on "Convalescent Homes from the Medical Viewpoint."

INDIANA

Personal.—Dr. Max A. Bahr has been reappointed superintendent of the Central State Hospital, Indianapolis, for the ninth consecutive time, it is reported; Dr. Bahr has been connected with the institution for thirty-two years in various capacities.——Dr. John J. Rife, Boston, recently celebrated his ninetieth birthday; Dr. Rife is still in the active practice of medicine.

Society News.—Dr. Frank C. Walker, Indianapolis, addressed the Hendricks County Medical Society at Danville, November 20, on "Pelvic Cellulitis."——The Montgomery County Medical Society was addressed at Crawfordsville, November 19, by Dr. Mark H. Mothersill, Indianapolis, on "Recent Research in Anemias."——Dr. George Elmo Moses, Worthington, addressed the Greene County Medical Society, Linton, November 12, on constipation.——Dr. Carl A. Hedblom, Chicago, addressed the La Porte County Medical Society at Michigan City, November 19, on "Abscess of the Lung."——The fifteenth annual meeting of the Indiana Academy of Ophthalmology and Otolaryngology was held in Terre Haute, December 9; the guest speaker was Dr. Bernard J. McMahon, St. Louis, on "Progress in Histopathology and Treatment in Otolaryngology."——At a joint meeting of the Fifth District and Vigo County medical societies, November 10, in Terre Haute, Drs. Joseph H. Weinstein and James F. Spigler talked on the "Shoulders resolution," concerning hospitalization of war veterans, and "Abnormal Intestinal Rotation," respectively.——Dr. Herman M. Baker, Evansville, addressed the Gibson County Medical Society, Princeton, November 9, on "Diagnosis and Treatment of Coronary Disease."——The Floyd County Medical Society was addressed in New Albany, November 13, by Dr. Louis Wallace Frank, Louisville, Ky., on cancer.——At the November 12 meeting of the Tippecanoe County Medical Society, in Lafayette, Dr. Charles A. Elliott, Chicago, spoke on "Circulatory Failure in Acute Infectious Disease."——Dr. Cecil L. Rudesill, Indianapolis, addressed the Lawrence County Medical Society, Bedford, November 4, on "Diet in Gastro-Enterology."——At a meeting of the Indianapolis Medical Society, December 15, Dr. Palmer Findley, Omaha, spoke on "Better Obstetrics." Dr. Max A. Bahr addressed the society, December 8, on "Psychiatry in Relation to Crime." The program at the December 1 meeting consisted of case reports.——The St. Joseph County Medical Society was addressed at South Bend, November 18, among others, by Dr. Norman F. Miller, Ann Arbor, on "Bleeding During Third Trimester of Pregnancy."

MARYLAND

Portrait Presented to Faculty.—A portrait of the late Dr. Hiram Woods, Baltimore, was presented to the Medical and Chirurgical Faculty of Maryland, November 17, at a meeting of the Osler Historical Society in the faculty's building. Dr. Lewellys F. Barker made the presentation, and Dr. James M. H. Rowland, president, accepted the portrait on behalf of the medical faculty. Dr. Henry E. Sigerist, professor of the history of medicine, University of Leipzig, gave an address. Dr. Woods died in January. He was a former member of the House of Delegates of the American Medical Association and chairman of the Section on Ophthalmology.

Society News.—Dr. Russell L. Cecil, New York, addressed the annual meeting of the Baltimore City Medical Society, December 4, on "Diagnosis and Treatment of Lobar Pneumonia." Dr. Lay Martin, Baltimore, among others, addressed the society, December 17, on "Early and Late Effects of Nonspecific Protein on Duodenal and Gastric Ulcer."——The Baltimore County Medical Association was addressed at Towson, November 18, by Drs. A. Harry Finkelstein on "Childhood Type of Tuberculosis," and William A. Bridges and John E. Murphy, "Adjuncts to the Routine Treatment of Tuberculosis."——A symposium on the toxemias of pregnancy, the experimental studies in the diagnosis of pregnancy and analgesia in the practice of obstetrics formed the program at the meeting of the West Baltimore Medical Association, November 17; the speakers were Drs. Louis H. Douglass, Alan F. Guttmacher and Francis L. Badagliacca.

The De Lamar Lectures.—Following is the list of the De Lamar lectures given at Johns Hopkins University, together with the names of the speakers:

November 10: Dr. Rolla E. Dyer, acting director, National Institute of Health, Washington, D. C., "Typhus-Rocky Mountain Spotted Fever Group of Diseases."

December 1: Dr. Victor G. Heiser, associate director, International Health Division of the Rockefeller Foundation, "Disease Control and the League of Nations."

December 15: Edgar Sydenstricker, director, division of research, Milbank Memorial Fund, "Statistics of Morbidity."

January 12: Arthur I. Kendall, Dr.P.H., professor of research bacteriology, Northwestern University Medical School, "Filtrability of Bacteria."

February 15: Dr. Charles Armstrong, surgeon, U. S. Public Health Service, "Complications of Smallpox Vaccination."

March 1: William H. Taliaferro, Ph.D., professor of parasitology, University of Chicago, "Experimental Studies on Monkey Malaria."

March 8: Dr. Albert G. Love, medical corps, U. S. Army, "Some Aspects of the Vital Statistics of the United States Army and Their Value in Public Health."

MICHIGAN

Dr. Hickey's Memory Honored.—A bronze plaque in bas-relief of the late Dr. Preston M. Hickey, for many years professor of roentgenology, University of Michigan School of Medicine, Ann Arbor, was presented to the university recently. The plaque, the work of Heinz Peter, was given by the American Roentgen-Ray Society, it is reported, and the presentation was made by Dr. Leopold Jaches, New York, president of the society.

Dr. Bruce Appointed Vice President at Michigan.—The board of regents of the University of Michigan has appointed Dr. James D. Bruce vice president in charge of university relations. This is a newly created position, in which Dr. Bruce's duties will be to centralize all requests made to the university for outside aid and help in meeting them so far as the university's resources allow. Dr. Bruce for the last three years has been director of the department of postgraduate medicine.

Medical Society to Have New Home.—The Wayne County Medical Society recently leased the David Whitney house at Woodward and Canfield avenues, Detroit, and plans to occupy it as new headquarters before January 1, it is reported. The society has been in its present quarters in the Maccabees Building for five years. For the present, only the first two floors and the basement in the new headquarters will be used, but plans for later expansion call for the occupancy of the entire building, it was stated.

Society News.—Dr. Sherman Gregg gave the presidential address, December 15, before the forty-eighth annual meeting of the Kalamazoo Academy of Medicine on "Recent Developments in the Diagnosis and Treatment of Poliomyelitis."——Members of the medical societies of Bay, Saginaw and Genesee counties were addressed, November 4, by Drs. Bernard Fantus, Chicago, and Carl F. Moll, Flint, on therapy of colon stasis, and present-day practice of medicine, respectively.——The Sanilac County Medical Society was recently reorganized; Drs. George Evans and Sanford Martin Tweedie, Sandusky, entertained the society at a banquet, November 5, when Dr. Clarence I. Owen, Detroit, spoke on pathology in medicine.——At the meeting of the Montcalm-Ionia Medical Society, November 10, Dr. George L. Leslie, Howell, and Vernor H. Eman, D.D.S., Grand Rapids, spoke on "Diagnosis and Treatment of Tuberculosis" and "Relationship of Dental Infections to Systemic Diseases," respectively.

MISSISSIPPI

Society News. — The Issaquena-Sharkey-Warren Counties Medical Society was addressed, November 10, by Drs. Doctor A. Pettit, Vicksburg, on "Diagnosis and Treatment of Gonorrheal Urethritis, Anterior and Posterior"; Robert H. Foster, "Neurosyphilis"; Walter E. Johnston, Vicksburg, "Edema," and Guy C. Jarratt, Vicksburg, "Mesenteric Lymphadenitis Simulating Appendicitis in Children."——The Delta Medical Society was addressed at Moorhead, October 14, among others, by Dr. Seale Harris, Birmingham, Ala., on "Hyperinsulism and Dysinsulism."——At a joint meeting of the Fifth District Medical Society of Louisiana and the Issaquena-Sharkey-Warren Counties Medical Society in Vicksburg, December 8, Drs. Stanford Chaille Jamison, New Orleans, gave a discussion of certain phases of chronic congestive heart failure; Henry W. Meyerding, Rochester, Minn., spoke on "Treatment of Arthritis with Special Reference to Prevention and Correction of Deformity," and William H. Olmsted, St. Louis, "Secondary Anemia: Present Status of Dietary and Inorganic Therapy."——The Pike County Medical Society was addressed in McComb, November 5, by Dr. Elise M. Rutledge on "The Menace of Psychiatry," and Dr. Robert H. Brumfield gave a report on hypnosis by barbital derivatives.——At a joint meeting of the North Mississippi Medical Society and the Northeast Mississippi Thirteen County Medical Society recently, Drs. George R. Livermore, Memphis, Tenn., and Oscar W. Bethea, New Orleans, among others, spoke on "Significance of Pus and Blood in the Urine" and "Recent Advances in the Diagnosis of Diseases of the Chest," respectively.——Dr. W. D. Beacham, Hattiesburg, has resigned as health officer of Forrest County after nine years' service.

MISSOURI

Dr. Ravold Honored.—A special meeting was held at the St. Louis Medical Society, December 12, by friends of Dr. Amand N. Ravold in recognition of his completion of fifty years in the practice of medicine. A plaque of Dr. Ravold was presented by Mr. Victor Holm. Dr. Augustus C. Pohlman, Washington University School of Medicine, extended greetings; Arthur I. Kendall, Dr.P.H., department of research bacteriology, Northwestern University Medical School, Chicago, gave an address on "Fifty Golden Years"; Dr. William W. Graves, "Amand Ravold the Builder," and Dr. Joseph Grindon, "Amand Ravold the Man."

Dental Society Celebrates Anniversary.—The St. Louis Dental Society observed its seventy-fifth anniversary at a meeting, December 7-9, in the Hotel Jefferson. According to the *Bulletin of the St. Louis Medical Society*, this is the oldest local dental society in the United States. Included on the scientific program were Dr. Charles H. Mayo, Rochester, Minn., "Organized Effort and Dentistry's Place in the Sun"; Weston A. Price, D.D.S., Cleveland, "A New View of Health and Disease, Including Dental Disease, Based on a Rise and Fall in the Levels of Life with Cycles in Vitamin Tides"; Ura G. Rickert, D.D.S., Ann Arbor, "Dental Diagnosis, with Special Reference to Certain Difficult Aspects Associated with the Focal Infection Problem"; Dr. Theodor Blum, New York, "Mixed Tumors of the Palate"; Paul R. Stillman, D.D.S., New York, "Discussion of the Problems of Periodontal Disease"; George E. Morgan, D.D.S., Milwaukee, "Care of Children's Teeth," and Larkin E. Stark, D.D.S., El Paso, Texas, "Evolution of Human Dentition."

Society News.—At the meeting of the St. Louis Medical Society, December 15, Drs. Harvey S. McKay and Ralph M. S. Barrett spoke on "One Year's Experience with Some of the Newer Methods of Producing Surgical Anesthesia," and Dr. Drew W. Luten, "Points of Special Interest in Coronary Occlusion—Analysis of Cases."——Dr. Frank C. Mann, Rochester, Minn., addressed the Kansas City Academy of Medicine, December 18, on "Physiologic Aspects of Hepatic Insufficiency."——A symposium on endocrine disturbances and allergy in relation to disease of the eye, ear, nose and throat featured the December 17 meeting of the Kansas City Society of Ophthalmology and Oto-Laryngology; the speakers were Drs. Albert D. Ruedemann, Cleveland; Arthur W. Proetz, St. Louis; William W. Duke and William Merritt Ketcham.——Methods of thrift, savings and investments featured the meeting of the Jackson County Medical Society, Kansas City, December 15; the program was furnished by representatives of the Kansas City Real Estate Board, Kansas City Life Underwriters Association, Kansas City League of Building and Loan Companies, and the Kansas City Board of Trade and the Stock and Bond Exchange.

NEW YORK

Personal.—Dr. Don M. Griswold, formerly associate professor of hygiene, State University of Iowa College of Medicine, Iowa City, and commissioner of health in Iowa, has been provisionally appointed consulting epidemiologist in the division of communicable diseases of the state department of health.

Society News.—The Suffolk County Medical Society held its one hundred and twenty-fifth annual meeting, October 29. Dr. Walter Truslow, Brooklyn, spoke on "Treatment and After-Care of Poliomyelitis."——Dr. George W. McCoy, director, National Institute of Health, Washington, D. C., addressed the Buffalo Academy of Medicine at its annual banquet, November 18, on tularemia, psittacosis and pellagra.——Dr. Donald Guthrie, Sayre, Pa., addressed the Seneca County Medical Society, Willard, October 8, on "Early Diagnosis and Treatment of Intestinal Obstruction."——Dr. Emily Dunning Barringer, New York, addressed the Tompkins County Medical Society, Ithaca, November 17, on "Complement Fixation Test for Gonorrhea in Women."

New York City

Uncommon Reportable Diseases. — The bulletin of the department of health recently listed by years the cases of rare reportable diseases that have occurred in New York City since 1920. For 1930 the table shows 14 cases of typhus fever; 8 of undulant fever; 82 of malaria; 2 of smallpox; 2 of yellow fever (laboratory infections); 9 of leprosy; 2 of anthrax; 1 of rabies; 2 of pellagra; 2 of hookworm; 21 of trichinosis; 1 of tularemia, and 19 of psittacosis. Only three deaths occurred among these, all as a result of psittacosis.

Hospital News.—A weekly clinic for the treatment of diseases of the thyroid gland has been opened in the outpatient department of the Fifth Avenue Hospital by the medical and surgical departments, with Drs. Charles W. Lester and Joseph Lintz in charge.——The new six-story building of the Lutheran Hospital was opened with cornerstone ceremonies, October 25; the total capacity of the hospital is now 160 beds.——The board of estimate has appropriated $2,750,000 for the enlargement of the Cumberland Street Hospital, Brooklyn.——Dr. Walter E. Dandy, associate professor of clinical surgery, Johns Hopkins University School of Medicine, Baltimore, delivered a lecture at the Hospital for Joint Diseases, December 16, on "Sciatica and Backache from a Neurological Standpoint."

Gifts to Columbia.—Gifts amounting to more than $20,000 have recently been presented to Columbia University for research and other medical purposes, as follows: $10,000 for research in biologic chemistry and $950 for research in bacteriology from the Chemical Foundation; $5,000 for the special tuberculosis fund, presented anonymously; $1,250 to the department of bacteriology, from Mr. and Mrs. Willis D. Wood; $1,250 for research in acute anterior poliomyelitis under Dr. Frederick P. Gay, from the International Committee for the Study of Infantile Paralysis; $1,000 for research in otology, from Dr. Cornelius G. Coakley; $820 for medical research, from the National Tuberculosis Association; $500 to the Nutritional Research Fund in the department of pathology, from Dr. Alfred F. Hess, and $500 to the department of neurology, from Dr. Moses Allen Starr.

Society News.—Drs. Lloyd H. Ziegler, Albany, and Lewellys F. Barker, Baltimore, addressed the Medical Society of the County of Kings, December 15, on "Neuropsychiatric Problems in Medicine" and "Medical and Other Conditions in Soviet Russia," respectively.——At the meeting of the Medical Society of the County of New York, December 21, addresses were made by Drs. Ward J. MacNeal, on "Use of Bacteriophage in Wound Infections and in Bacteremias"; Fred H. Albee, "Bacteriophage Treatment for Osteomyelitis"; James I.

Farrell, "Mechanism of Prostatic Obstruction," and Joseph F. McCarthy, "Newer Conceptions in the Management of Prostatic Bars and Hypertrophies."——A symposium on surgery was presented before the International and Spanish-Speaking Association of Physicians, Dentists and Pharmacists, December 18, by Drs. William S. Bainbridge, on surgery of the uterus; Eugene H. Pool, the spleen; Howard Lilienthal, the lungs, and Leo Winter, D.D.S., the jaw.——Dr. Hugh H. Young, Baltimore, addressed the Ocean Medical Society, Brooklyn, December 21, on "Problems in Diagnosis and Treatment of Prostatic Diseases."——Drs. Leo M. Davidoff and Maximilian A. Goldzieher addressed the Bronx County Medical Society, December 16, on "Disease of the Pituitary with Special Reference to Tumors" and "Rôle of the Adrenals in Health and Disease," respectively.

OHIO

Hospital News.—A. O. Fonkalsrud, Ph.D., formerly superintendent of the Sioux Valley Hospital, Sioux Falls, S. D., has assumed the superintendency of the Mansfield General Hospital.

Annual Public Health Lectures.—The Cleveland Academy of Medicine has begun its second annual series of public health lectures under the Health Education Foundation initiated last April (THE JOURNAL, April 11, p. 1240). Dr. Elliott C. Cutler, professor of surgery, Western Reserve University School of Medicine, Cleveland, delivered the first lecture, December 6, on "What Science Knows About Cancer." The second will be given, January 17, by Dr. Henry J. Gerstenberger, professor of pediatrics at Western Reserve, on "Why Think About Eating?" and the third, March 20, by Dr. Roy W. Scott, professor of clinical medicine at Western Reserve, on "Fighting Death After Forty." In addition to these, a secondary group of lectures will be presented before smaller audiences in outlying sections of the city. Dr. Harry L. Rockwood gave the first of these, December 10, on "Stemming the Tide with Preventive Medicine." A second will be given, January 15, by Dr. Harry V. Paryzek, on "Keeping Well."

Society News.—A symposium on nephritis was presented by Drs. Clinton D. Fife and Michael R. Haley before the Montgomery County Medical Society, Dayton, December 4.——Dr. A. Graeme Mitchell, Cincinnati, addressed the Mahoning County Medical Society, Youngstown, November 17, on "Practical Application of Principles of Nutrition."——Drs. Norris W. Gillette and August H. Schade, Toledo, addressed the Allen County Medical Society, Lima, November 17, on treatment and pathology of goiter, respectively.——Speakers before the Wood County Medical Society, Bowling Green, November 19, were Toledo physicians: Drs. Elmer C. Unckrich on "Infections of the Upper Air Passages"; Alfred P. Hancuff, "Pneumonia Empyema," and Frank B. McNierney, "Infections of the Urinary Tract."——Dr. John Alexander, Ann Arbor, Mich., addressed the Academy of Medicine of Cincinnati, December 7, on "Changing Status of the Surgical Treatment of Pulmonary Tuberculosis." Dr. Austin A. Hayden, Chicago, addressed the academy jointly with the Cincinnati Oto-Laryngological Society and the Cincinnati League for the Hard of Hearing, December 1, as a feature of "Conservation of Hearing Week."——Dr. Charles E. Hauser addressed the Cincinnati Obstetrical Society, December 10, on roentgen-ray diagnosis in gynecology.——Nathan Sinai, Dr.P.H., Ann Arbor, Mich., addressed the annual joint meeting of the Toledo Dental Society and the Toledo Academy of Medicine, December 4, on "The Way of Health Insurance."——Henry F. Vaughan, Dr.P.H., Detroit, addressed the annual meeting of the Academy of Medicine of Cleveland, December 18, on "The Doctor's Practice in the Future."

RHODE ISLAND

Society News.—Speakers at the monthly meeting of the Providence Medical Association, December 7, were Drs. Anthony Corvese, on "Acute Perforation of Peptic Ulcer"; Howard K. Turner, "Seminal Vesicles as Foci of Infection" and William A. Horan, "Treatment of Fractures at the Hip Joint."

Dr. Chapin Retires.—Dr. Charles Value Chapin, superintendent of health of Providence since 1884, will retire from active service, January 4. Dr. Chapin was born in Providence nearly seventy-six years ago and received his academic degree from Brown University in 1876 and his medical degree from Bellevue Hospital Medical College, New York, in 1879. He has held teaching positions at Brown, Harvard University Medical School and Massachusetts Institute of Technology. He was awarded the Marcellus Hartley Gold Medal by the National Academy of Sciences in 1928 and was the first recipient of the Sedgwick Memorial Medal of the American Public Health Association. In 1927 he was president of the American Public Health Association. Dr. Chapin has served also as president of the Rhode Island Medical Society and the Providence Medical Association, and was the first president of the American Epidemiological Association. He is the author of numerous works on public health and sanitation and has been a frequent contributor to the literature of public health. The Providence Medical Association at its meeting, December 3, adopted a resolution in which tribute was paid to Dr. Chapin's long and distinguished service. The resolution declares that his greatest achievements lie in his own city, "first, in lifting Providence from a condition of well nigh medieval squalor in 1884 to the hygienic and sanitary perfection of today, and, second, in the founding of our city hospital and its later organization, in which he played so important a part." The resolution continues, "In the world his outstanding contribution to mankind is the revolutionary development of medical asepsis with its application to the control of contagious diseases."

WISCONSIN

Society News.—Members of the Green County Medical Society were addressed, November 10, at Monroe, by Drs. Erwin R. Schmidt on "Surgery of the Breasts"; Ira R. Sisk, "Surgical Injuries of the Ureter," and John W. Harris, "Cancer of the Uterus." All speakers are members of the faculty of the University of Wisconsin Medical School, Madison.——The Wisconsin Urological Society met, December 4-5, in Milwaukee. The program included a symposium on injuries of the urinary tract, with the following speakers: Drs. Robert S. Irwin, Wauwatosa; George H. Ewell, Madison; Walter G. Sexton, Marshfield, and Ira R. Sisk, Madison. Other addresses were made by Drs. Russell D. Herrold, Chicago, on "Debatable Questions in the Management of Gonorrhea in the Male"; Maurice J. Reuter, Milwaukee, "Additions to the Treatment of Syphilis in the Last Decade"; Edward L. Miloslavich, Milwaukee, "Pathology of Bladder Tumors," and Herman L. Kretschmer, Chicago, on "Treatment of Bladder Tumors."——Dr. Irving S. Cutter, Chicago, addressed the Medical Society of Milwaukee County, Milwaukee, December 10, on "The Future of the Practice of Medicine."——Dr. Henry K. Pancoast, Philadelphia, addressed the Roentgen Ray Society of Milwaukee, November 20, on pneumoconiosis.

GENERAL

Simmons an Octogenarian.—Dr. George H. Simmons, Editor and General Manager Emeritus of the American Medical Association, who is wintering at his home in Hollywood, Fla., celebrates his eightieth birthday, Saturday, January 2, 1932. The felicitations of organized medicine are tendered him on this occasion.

Bequests and Donations.—The following bequests and donations have recently been announced:

Neurological Institute of the City of New York, $5,000 by the will of the late Mrs. Minnie E. Young.

Brooklyn Hospital, $50,000 under the newly filed will of the late Warren S. M. Mead.

Burlington County Hospital, Mount Holly, N. J., $10,000 by the will of Mrs. Laura Gaskill Crowell, to found the R. Herbert Crowell Memorial Fund; $25,000 more will revert to this fund after the death of heirs who are to receive the interest from it during their lives; 60 per cent of the estate remaining after deduction of numerous bequests is also to be added to the hospital fund.

Temple University Hospital, Philadelphia, $5,000 by the will of the late Mrs. Flora Mae Albright

St. Luke's and Children's Homeopathic and Babies' hospitals, Philadelphia, $50,000 by the will of John Abbot Maguire.

Memorial Hospital, Roxborough, Philadelphia, $2,000 by the will of Mrs. Augusta B. Krook.

Control of Milk Supplies.—During the eight years' existence of the U. S. Public Health Service's milk program, 444 cities, located in 25 states, have adopted it in a coordinated attempt to improve and unify milk control methods in the country. "Before and after" surveys were recently made of the milk sanitation conditions of 152 of the 444 cities. These surveys disclosed that the raw milk supplies of the 152 cities showed a rating of compliance with the grade A raw milk requirements of the public health service milk ordinance of 64 per cent before the adoption of the ordinance, and 91 per cent after periods of enforcement ranging from several months to six years. The pasteurized milk supplies of the same group showed a rating of compliance with the grade A pasteurized milk requirements of 62 per cent before the adoption of the ordinance and 87 per cent after its adoption. The proportion of milk protected by pasteurization increased from 33 per cent to 45 per cent, and milk consumption increased about 21 per cent. Only 1 of the 444 cities which have adopted the milk ordinance has repealed it, and that city has since reenacted it.

Medical Bills in Congress.—S. 572, introduced by Senator Jones, Washington, proposes to provide that the United States shall cooperate with the states in promoting the general health of the rural population of the United States and the welfare and hygiene of mothers and children. This bill has been referred to the Senate Committee on Commerce. H. R. 4739, introduced by Representative Bankhead, Alabama, proposes to provide for the promotion of the health and welfare of mothers and infants. This bill has been referred to the House Committee on Interstate and Foreign Commerce. H. J. Res. 9, introduced by Representative La Guardia, New York, proposes to create a Board of Medical Survey to examine all medical employees of the United States Veterans' Bureau now receiving retirement pay under the Emergency Officers Retirement Act or drawing compensation for 50 per cent or more disability for the purpose of determining whether the recipients of such compensation are actually entitled thereto. H. J. Res. 23, introduced by Representative Celler, New York, and H. J. Res. 28, introduced by Representative Clancy, Michigan, propose to remove the restrictions now imposed on physicians with respect to the prescribing of medicinal liquor. H. Res. 39, introduced by Representative Arentz, Nevada, proposes to direct the Veterans' Administration to proceed at once with the construction of the veterans' hospital heretofore authorized to be erected in Nevada. S. J. Res. 19, introduced by Senator Smoot, Utah, proposes to provide that the first United States narcotic farm, to be established near Lexington, Ky., shall be named the Stephen G. Porter Institute. S. 136, introduced by Senator Hatfield, West Virginia, proposes that the federal government shall cooperate with the several states in the care, treatment, education, vocational guidance and placement, and physical rehabilitation of persons under the age of 21 years who have some physical defect that may be corrected or improved by surgical and medical care. S. 203, introduced by Senator Howell, Nebraska, proposes to supplement the National Prohibition Act for the District of Columbia and provides, among other things, that any physician or pharmacist in the District who shall be convicted of a second violation of any provision of the National Prohibition Act requiring him to do or to abstain from doing any act in his capacity as a physician or pharmacist shall forfeit his license to practice for one year. S. 310, introduced by Senator Hawes, Missouri, proposes to remove the restrictions now imposed on physicians with respect to the prescribing of medicinal liquor. S. 422, introduced by Senator Bingham, Connecticut, proposes to regulate the use and sale of wood alcohol. S. 423, introduced by Senator Bingham, Connecticut, proposes to amend the National Prohibition Act, as supplemented, to permit physicians to prescribe malt liquors for medicinal purposes. S. 425, introduced by Senator Bingham, Connecticut, proposes to authorize the enlargement of the veterans' hospital in Connecticut. S. 588, introduced by Senator McKellar, Tennessee, proposes to provide that an ex-service man who is shown to have or if deceased, to have had, prior to Jan. 1, 1930, a neuropsychiatric disease, spinal meningitis, an active tuberculous disease, paralysis agitans, encephalitis lethargica, a chronic constitutional disease or analogous disease, or amebic dysentery, developing a 10 per cent degree of disability or more shall be presumed to have acquired his disability in service. S. 624, introduced by Senator McKellar, Tennessee, proposes to safeguard the use of wood alcohol in antifreeze mixtures. S. 695, introduced by Senator Smoot, Utah, proposes to authorize $20,877,000 for additional hospital and domiciliary facilities for veterans of all wars. S. 1201, introduced by Senator Copeland, New York, proposes to amend the federal Food and Drugs Act to provide that a drug is misbranded if it or the ingredients or substances contained in it or the curative and therapeutic effect of such drug or its ingredients or substances are falsely or deceptively advertised, represented or described. S. 1229, introduced by Senator Hull, Tennessee, proposes to require the discoloration of poisons which resemble commonly used foodstuffs. S. 1234, introduced by Senator Robinson, Arkansas, proposes to authorize an emergency appropriation of $3,000,000 for special studies and demonstration work in rural sanitation.

CORRECTION

"Insulin a Protein."—In the editorial on this subject (The Journal, December 12, p. 1803), the footnote cites as publisher of the book "Treatment of Diabetes Mellitus," by E. P. Joslin, the W. B. Saunders Company. This citation is in error. The credit should have been to Lea & Febiger, Philadelphia.

The Wellcome Research Institution: A Founder of Many Museums

Lord Moynihan laid the corner-stone of the new buildings for the Wellcome Research Institution. It is intended to maintain the Wellcome Museum of Medical Science, with its special exhibits covering tropical medicine and hygiene, on the ground floor of the new building. University classes and many physicians have made constant use of the old museum. The object is to enable the teaching facilities of the museum and the Wellcome Bureau of Scientific Research, which it serves, to be extended. It is expected that the accommodation heretofore offered by twelve laboratories to students of medical zoology, parasitology, bacteriology and chemotherapy will be doubled. Physiologic and entomologic laboratories will be established. The three floors immediately above the ground floor will be given over to the Wellcome Historical Medical Museum. This museum has the greatest collection of its kind in the world. Special study rooms will now be provided outside the galleries for research workers, who have heretofore been crowded out by the exhibition cases. Lord Moynihan paid a tribute to the forty years' work of Dr. Wellcome in promoting medical research: In 1894 he founded a laboratory for physiologic research in this country, followed two years later by a laboratory for chemical research. On the recapture of Khartoum by Kitchener, he founded a research institute for tropical diseases there, of which the first director was Andrew Balfour, who worked there for twelve years. In 1913 he founded in London the Bureau of Scientific Research and the Historical Medical Museum, in 1914 the Museum of Medical Science, and in 1920 the Entomological Field Laboratory. All these were separate from one another, and the workers lacked opportunities for hour to hour and minute to minute consultation, which would now be possible under one roof. As the result of experiment, medicine was gradually replacing anatomy by physiology. For its advance it depended on the methods of the ancillary sciences, which would be developed in this and similar institutions, in which there might be created "a religion of research." He hoped that in time the discipline of research would be undergone by all who served the hospitals. To advance the science and art of medicine, Dr. Wellcome had done as much as any man in this country.

Sir David Bruce: One of the Founders of Tropical Medicine

At the age of 74, four days after the death of his gifted wife, who greatly assisted him in his scientific work, Sir David Bruce, one of the small band who laid the foundations of tropical medicine, has passed away. Like Ross, he owed much to the teaching and inspiration of Manson, but his ideas and methods were his own. His first great discovery was made in the following manner: A prolonged investigation had failed to disclose the cause of Malta fever until one day he was shown a series of charts relating to possible sources of infection. Goat's milk was among these, and he intuitively seized on this possibility and began to test it. Within a few years he had discovered Micrococcus melitensis and showed that the fever was transmitted by goat's milk, thus enabling a troublesome disease to be stamped out. He next engaged in researches on cholera and methods of immunization. In 1894 the Natal government asked him to investigate nagana and tsetse fly disease, which were supposed to be different conditions. He discovered in two months that they were one disease and due to a trypanosome. Six months later he proved that the tsetse fly was the carrier of the trypanosome. He was the first to show that an insect may carry a protozoan parasite and thus be a source of disease. He studied nagana in a large number of domestic animals and in its latent form in wild animals, leaving little to be added by subsequent observers. In 1903 he was sent by the Royal Society to Uganda to make further investigations into trypanosomiasis, which at the time was being investigated by Castellani. This observer had found a trypanosome in a small number of cases. Bruce at once grasped the situation and stimulated a rapid extension of the observations until evidence was obtained that the organism was the cause of the disease. Later he showed that the tsetse fly, Glossina palpalis, is the carrier of the trypanosome and that the distribution of the former corresponded to that of the disease. During the war he was chairman of the committee on tetanus, which showed the importance of prophylactic injection of antitoxin. He was later chairman of the trench fever committee, when Colonel Byam made the important discovery that the disease is transmitted through the skin by the excreta of the louse. An Australian by birth, Sir David was educated at Edinburgh University and joined the army medical service in 1883. He was assistant professor of pathology at the Army Medical School from 1889 to 1894. He edited the *Journal of the Royal Army Medical Corps* from 1904 to 1908. Many honors were conferred on him, including honorary degrees from the Universities of Glasgow, Dublin, Liverpool and Toronto, and, greatest of all, the fellowship of the Royal Society, which also awarded him a Royal and a Buchanan medal.

Rabies Conveyed by Bats

A mysterious disease which resulted in the deaths of human beings and animals has been reported from southern Trinidad. In his official report to the legislative council, the medical inspector of health, Dr. C. F. Lassale, states that twenty persons died between 1929 and 1931 from an unusual type of ascending transverse myelitis. Dr. Hurst, bacteriologist of the Lister Institute, considers that the disease is due to the virus of rabies of a hitherto unknown type. All the recognized cases were fatal. The report also states that man probably acquired the disease from some biting animal which itself suffers from rabies, but that the animal is not the dog, since the last case of canine rabies occurred in 1914. It was suggested that bats might be concerned in producing the disease in man and in animals. Since this report was issued, Dr. Pawan, the government bacteriologist, has declared that he has found typical rabies lesions in the brain of a Sangre Grande daylight bat.

The Attempt to Alter the Constitution of the Royal College of Surgeons

At the annual meeting of fellows and members of the Royal College of Surgeons the resolution asking for representation of members on the council was brought forward for the forty-third time. The nature of this agitation has been described in a previous letter (THE JOURNAL, February 14, p. 541). This year the resolution was moved by Sir Ernest Graham Little, dermatologist and member of parliament for London University. He pointed out that the college contained 2,000 fellows and 18,000 members; that the governing body, the council, was elected entirely by the fellows, and that no fellow in general practice had been elected. The motion was carried by 32 votes to 3. The president, Lord Moynihan, admitted that the resolution had been supported by very fair speaking, but as the council was doing its duty sincerely in the interests of the whole college he could not offer any hope of the representation desired. By permission of the president a member, Dr. T. Wilson Parry, made a long statement which had received the support of the Society of Members. He thought that some members of the council not unnaturally felt that the proposed representation might involve some disaster to the college. To reassure them he suggested that the members should be permitted to elect one fellow who was a general practitioner and one member also in general practice to represent them on the council, thus safeguarding the traditions of the college at the initial step. Dr. Parry referred to Robert Waring Darwin, the father of Charles Darwin and the great-grandfather of more fellows of the Royal Society than exist in any other family; Jenner, the discoverer of vaccination, and James Mackenzie, the founder of modern cardiology, who were all general practitioners. But these interesting facts are as irrelevant as the usual ground of "justice," on which the members' demand is usually based. The college is a scientific and educational body governed by the eminent men of British surgery elected by all its constituents who are surgeons in the full sense of the term. Its government is beyond criticism. The agitation is not inspired by any desire or capacity to improve the functions now so well discharged but rather to drag the college into medical politics.

New Heart Department at the London Hospital

The Heart Department at the London Hospital was originally created for Sir James Mackenzie. It has now been given a new building at a cost of $31,000. There is a tablet recording the fact that it is a memorial to the work of Sir James Mackenzie. At the opening ceremony, Dr. John Parkinson, physician in charge of the department, said that Mackenzie was universally recognized as the founder of modern cardiology. As long ago as 1913 the department had its beds, clinic and laboratory. The London Hospital was the first of the general hospitals in the world to arrange such a special department for the advancement of this great branch of medicine. Other hospitals had followed, and advance in knowledge and practice had been accelerated.

Recurrent Fever Substituted for Malaria in Treatment of Dementia Paralytica

Mr. Auguste Marie, who was one of the first in France to treat dementia paralytica by inoculation with malaria, is endeavoring to substitute for the plasmodium of malaria the spirillum of recurrent fever, which provokes the same manifestations of hyperthermia, and he has recently communicated to the Academy of Medicine the results of his observations. He presents this method rather as supplementary to the malaria method. The results obtained were less sure; but recurrent fever therapy appears to him indicated in some instances when malariotherapy is not applicable; for example, in persons who had malaria in childhood, or in dementia paralytica in which malaria has been employed but which shows a recrudescence. In such cases, attempts to reinoculate malaria often fail. To get around immunity that might be a contraindication to reinoculations of recurrent fever, it is sufficient to alternate the different varieties (induced by various organisms: Spirochaeta duttoni, Spirochaeta berbera, and others), including the Spanish type. Recurrent fever has the advantage over malaria that the incubation is shorter, being only from three to five days in place of about twelve days. Recurrentotherapy should be supplemented by treatment combining arsenic, bismuth or mercury compounds. Of a total of 51 patients treated with recurrent fever, 18 were dismissed with a remission more or less complete and permanent; 16 were physically restored but had to be retained in the hospital. Seventeen patients died, ten of them during the first months that followed the inoculation, and the others after a partial remission. The average age of the patients who were dismissed following more or less complete remissions was 35;

the average age of the decedents was 45, while the average age of the patients retained in the hospital after partial remission was 40. At the close of the address, Professor Claude expressed wide reservations as regards this treatment, which, in his opinion, is much less effective than malariotherapy and demands extreme care in applying.

A New Conception of Color Blindness

Dr. Polak presented recently before the Academy of Sciences an account of his research on color blindness. It has been frequently assumed that the dyschromatopsia of persons who are color-blind is confined to the confusion of the colors red and green, and the eye examination to which railway engineers are subjected is planned on that basis. In reality, according to Dr. Polak, the colors that persons who are color-blind confuse are blue, violet, purple and greenish blue, all of which produce the same optic sensation. The confusion of orange and yellowish green is extremely frequent, whereas a confusion of red and green is much less frequent, contrary to the current opinion.

Trachoma in Tunisia

Trachoma is one of the scourges of the French possessions of northern Africa. Last year, the minister of the interior sent a mission to Tunisia to organize a campaign against trachoma. Dr. Talbot, head of the mission, has recently issued a report on the results accomplished over a period of nearly two years. The systematic examination of the school children has shown that the proportion affected at Tozeur is 97 per cent; at Gafsa, 76 per cent, and at Gabes, 53 per cent. The infection occurs chiefly in children under 3 years of age, and the child contracts the disease nearly always through the infected mother. The infection is confined to the preschool age, not a single recent case having been discovered in school children. There has been, therefore, no need of organizing special schools for trachomatous children. It was found, however, advantageous to give the children in the schools daily treatment under medical supervision. The co-worker with the physician is the native or the French teacher. The treatments are given after the last class in the evening, the time required being taken out of the regular school hours. Outside of the school, prophylactic aid is accomplished by means of free dispensaries installed at Gabes, Gafsa and Tozeur. Six woman nurses supplied by the Comité central de l'oeuvre de protection de l'enfance in Tunisia are attached to these dispensaries, and during the forenoon they care for the sick in the dispensaries and during the afternoon they are visiting nurses. They carry on a constant publicity campaign with a view to inducing the female element of the population, the chief source of familial contagion, to present themselves for treatment. The important feature of this social movement—in the schools and in the dispensaries—is the absolutely gratuitous character of the drugs, the treatments and the interventions.

Dr. Guéniot, a Centenarian

Dr. Guéniot, member of the Academy of Medicine, is now in his one hundredth year. Surgeon to the hôpitaux de Paris, he spent nearly his whole life at the Hôpital de la maternité, of which he was the chief obstetrician, at a time when specialists in obstetrics were not yet generally known. It was the time when puerperal fever caused such a high mortality that it became necessary, from time to time, to close the institution for a month by reason of the large number of victims. Guéniot knew nothing of antisepsis in those days and believed in the transmission of the infection by miasmas, or noxious effluvia. For fifty-one years he has been a member of the Academy of Medicine and has served also as president. His health is excellent except for some deafness. His mind is perfectly clear, and he attends regularly all the meetings of the academy, sometimes participating in the discussion if the voice of reason appears to be losing in the debate. He published last year a booklet on how to live to be a hundred years old, in which he set forth that the secret of longevity lies in temperance in all things: eating moderately, drinking moderately, taking some wine every day but only a small quantity, avoidance of overwork, getting a full allowance of sleep, and never ceasing to be occupied with something. At the last session of the academy, the president offered his congratulations. He arose and thanked the president, with still sparkling eye and easy speech. Special ceremonies in his honor will be held next year when his hundredth year has been completed.

Emergency Aid in Cases of Asphyxia

The prefect of police in Paris has created in his administrative area a new emergency service destined to place at the disposal of the population prompt aid in cases of asphyxia by illuminating gas, cesspool gas, submersion or electrical shock. A division of the firemen of Paris has been specially trained to give first aid in these conditions and has been supplied with all the necessary equipment, including masks for the rescuers. At any hour of the day or night the public may appeal, in case of accident, to the prefecture of police by telephone, through a call box on the street, or by applying at the nearest police station.

The Amplification of Heart Sounds

With the development of physics and improvements in technic in recent years there has been a desire for better methods of analyzing the heart sounds than is possible by ordinary auscultation. In 1923, Dr. Leo Jakobsohn demonstrated before the Berliner Medizinische Gesellschaft some of the early attempts, and experiments undertaken in the meantime were recently reported before the same society. The physicist Dr. F. Trendelenburg discussed "Physiologic Principles and Physiologic Questions Involved in the Examination and Interpretation of Heart Sound Phenomena." On account of the low intensity of heart sound phenomena, not until recently did it become possible, through the use of high-powered electrical receiving apparatus and static-free amplifiers, to examine sound phenomena in a manner wholly satisfactory to the physicist. The experiments carried out in the research laboratory of the Siemenswerke, and also in a number of institutes and clinics, particularly the IV. Med. Universitätsklinik in Berlin, showed that the most essential components of the heart sounds lie in low tone areas (up to 80 Hertz), whereas the essential components of the diagnostically important heart murmurs lie in higher tone areas (at 300 Hertz and above). The human ear possesses in the high tone ranges great sensitiveness; in the lower ranges its sensitiveness is much less. On comparing the heart sound images recorded by means of the apparatus that functions uniformly in accordance with the laws of physics, with the observations of subjective auscultation, considerable divergences were discovered, which had their basis in the difference between the sensitiveness of the apparatus employed and that of the human ear. To make more easy the comparison of objective results obtained with the scientific apparatus and the results of auscultation, an amplifier was created that possesses to a great extent the qualities of the human ear. This amplifier is affected in its sensitiveness by the pitch, the same as the human ear. The observations of the subjective auscultation can thus be compared at once with the objective records. There is therefore now a possibility of interpreting the origin of the various sound phenomena.

The next speaker, the chief physician of the IV. Med. Universitätsklinik (in the Krankenhaus Moabit), discussed "The Clinical and Didactic Importance of the Objective Examination of

Heart Sounds," and demonstrated sound images of various typical heart sound manifestations and explained their diagnostic importance for bedside practice. Harmonious course of vibrations in a heart tone is characteristic of indurative processes in the vicinity of the site of auscultation, since only tissues with a certain hardness are capable of vibration and can produce a periodic frequency course. For mitral stenosis the wavelike character of the first heart tone is typical. The diastolic murmur in mitral stenosis is registered throughout the whole diastole, although it is usually perceptible in auscultation only during the presystole. All endocardiac murmurs have their chief components in the narrow range between 200 and 400 Hertz units. The Weber theory of the origin of murmurs receives new support from this fact. By reason of the similarity of the sound curves of endocardiac murmurs, one cannot draw from the sound picture any important differential diagnostic conclusions as to their origin. Paracardiac murmurs may, however, be distinctly differentiated from endocardiac murmurs by the greater frequency of interruption of the current as revealed by the course of the curve. The reproduction through loud speakers of heart sounds encounters difficulties, since through marked amplification of sounds subliminal components rise above the auditory threshold and change the nature of the sound. A reproducing apparatus that will overcome this disadvantage will be of inestimable value for clinical instruction.

Finally, the physicist Dr. Sell, who has devoted himself to acoustic problems, explained that a diaphragm which is highly sensitive to body sounds but less sensitive to air sounds, and which possesses a high degree of flexibility, is best adapted to this purpose. If attention is paid to this, no great amplification is necessary. A special loud speaker sensitive to low ranges was constructed. Normal heart tones and heart murmurs become audible, with the new apparatus, for a good-sized audience.

Medical Service on Sunday

For a number of years, the city of Berlin has had not only a special Sunday service as regards the pharmacies but also a special service for urgent medical cases on Sunday. For this purpose, the city is divided into fifty districts, each of which submits, with the opening of each three-month period, a list of physicians who have agreed to perform Sunday duty during the quarter in question. At first, this list lay open for inspection only at the pharmacies, but, later, copies were posted also at the police stations. Now, however, the matter has been further simplified for the public. At the suggestion of the medical league of Greater Berlin, the government telephone service has consented, in response to telephone calls on Sunday, to give the applicant the name of the nearest physician.

Gymnastic Exercise for Women

Gymnastic exercise for women was recently discussed by Professor Sellheim, director of the Leipzig Universitäts-Frauenklinik. In dealing with men, aside from considerations of age, we have to do with only one kind of physical makeup and one mode of functioning of the organism all through life, and can arrange for the strengthening of the physique and for the preservation of robustness by gymnastic exercises by applying what is essentially the same prescription. In dealing with women, one must, in prescribing physical exercises, differentiate precisely between the various types of women with reference to build and the mode of functioning of the organism at the time in question, and only by taking careful account of these differences can one hope to reap the advantages of gymnastic exercise. From the standpoint of gymnastics, eight classes of women must be recognized: (1) the girl approaching puberty and during the years immediately following; (2) the woman during the period of menstruation; (3) the woman during pregnancy; (4) the woman during the puerperium; (5) the woman after cessation of the special functions of the matron and of old age; (6) the woman who is deprived of the privilege of propagation; (7) the woman whose constitution has been undermined by giving birth to too many children, possibly in association with occupational work (these two classes being especially characteristic of the times in which we live), and, finally, (8) the woman with abdominal disease. Specially prescribed gymnastics are more important for women than for men. The more the value of gymnastics comes to be recognized by physicians and the general public, the greater becomes the responsibility of the physician for the sins of omission and commission in this field. There is danger that here the physician may be charged with neglect, and that in case damage results an attempt may be made to hold him responsible.

Hospital Finance in New South Wales

The problem of hospital finance in Australia is becoming more acute daily, and in New South Wales the situation is growing serious. The leading hospitals in Sydney, especially the Royal Prince Alfred Hospital, have been on the verge of bankruptcy for the past twelve months. In the Royal Prince Alfred Hospital it has been necessary to close 200 beds and to place many of the paid medical staff on an honorary basis. At best, the hospitals are living a hand to mouth existence in the face of greatly increased demands on their services. Nearly all the New South Wales institutions depend on large annual government subsidies, which in the past have been granted on the basis of £1 for each £1 contributed by the public. Voluntary contributions have fallen away considerably, and the government, moreover, has found it impossible to continue the subsidy, even on a reduced basis. Since the appointment of the Hospitals Commission in New South Wales, the distribution of subsidies has been under its control.

It has always been strange that hospital service should be financed in connection with gambling, but this relationship is apparently the sole remaining exploitable avenue for hospital finance in Australia, and it is being used more and more, as the economic situation becomes more difficult. For many years now in New South Wales, a percentage of the gross proceeds of the totalizers, which are found on all large race courses, has been reserved for hospitals. When funds from this source showed a falling off, the deficiency was made up by heavy taxation on all wagers made with bookmakers. In view of the fact that considerable support was given from New South Wales to a private Tasmanian lottery and to a government lottery in Queensland, the state premier this year passed an act for establishing a New South Wales state lottery in aid of hospitals. This was strenuously opposed by the council of churches, an organization composed of representatives from most of the protestant churches in New South Wales. This council recommended an appeal to church and state. The premier withheld the operation of the state lottery pending the result of this appeal. The appeal was a hopeless failure, and the state lottery has now commenced operations. Today in Sydney will be seen a queue of people a quarter of a mile long, lined up to buy their tickets at 5s. 3d. each, in the hope that they will win the first prize of £5,000. What the actual proceeds from this lottery will be can only be a matter of conjecture. Experience in Queensland, where the "Golden Casket" lottery has been run for some years, is not encouraging. As the result of the holding of twenty-six art unions, the total sum raised for hospital work has amounted to only £190,059. Of every £1 received by the "Casket," 13s. 4d. is absorbed by prizes, taxes, postage and heavy general expenses. It has been the experience in Queensland that the application of gambling methods to hospital finance definitely dries up the springs of charity. As the tickets in the Queensland Golden Casket were largely taken up in New South Wales prior to the establishing of the latter's own lottery, one result will be that the Queensland lottery will receive much less income, and already a marked falling off is apparent. There is little prospect of the total sum raised by the New South Wales lottery being sufficient to meet hospital working expenses and to leave something over for other forms of charities, which are continually approaching the government for contributions to meet their working expenses, their indebtedness, or their needs for new buildings or extended accommodation.

Of late years, the gifts to hospitals in the form of legacies have considerably diminished. This is said to be due to the heavy death duties. Many prefer to give while they are alive whatever amount they intend to spend on charities. They see something for their money before they go hence. One is often surprised, on reading the wills of rich men who leave behind them tens of hundreds of thousands, to note how comparatively seldom are large sums left either for education or for benevolent purposes.

Meeting the Cost of Highway Accidents

As an attempt to solve the problem of the cost of hospital treatment of patients injured by motor vehicles in New South Wales, the Hospitals Commission has recommended that an extra tax of 5s. each on motor cars and 2s. 6d. each on motorcycles be applied. By this means it is expected to raise £55,000 annually. It is proposed that public hospitals be paid 7s. a bed daily for each motor accident case and 5s. a day for motor accident outpatients, and that 6d. a mile be paid to ambulance services for every mile traveled in attending motor accidents. Motoring circles consider that this tax is iniquitous, as it is based on the fallacy that motorists are solely to blame for traffic accidents in which they happen to be involved and as a result of which persons are injured. Statistics collected in Queensland show that, for the year 1930, of the total number of so-called motor accidents, 52.73 per cent were unavoidable by the car drivers, being attributable to carelessness or the infirmity of pedestrians, or to cyclists, road faults or other causes. The experience of the Brisbane General Hospital for the year 1929-1930 was that only 3.8 per cent of the total cases handled were due to vehicular traffic accidents.

Australian Vital Statistics for 1930

A record low death rate and a low infant mortality rate are the two main features of the annual demography bulletin for 1930, which deals with the population and vital statistics of Australia. The infant mortality rate was 47 per thousand; with the exception of the New Zealand rate, this is the lowest in the world. The rate for New Zealand is 34.5. The death rate was 8.59 per thousand of the population. This rate was the lowest ever recorded in Australia and compares most favorably with that of other countries. The principle causes of death were heart diseases, 15.6 per cent; cancer, 11.1 per cent; tuberculosis, 5.9 per cent; acute and chronic nephritis, 5.7 per cent, and pneumonia, 3.5 per cent. The maternal mortality rate was 5.29 per thousand children born. At the end of 1930 the population of Australia reached the total of 6,476,032, which represents a growth of 1,064,735 during the last ten years. To this total gain, natural increase contributed 73 per cent and net migration 27 per cent. The rate of growth during 1930 was 1.81 per cent and is among the highest rates of increase in the world. The birth rate was 19.93 per thousand of population, the lowest ever recorded. Compared with that of many other countries, the Australian rate is low, but fortunately it is accompanied by a low death rate giving a rate of natural increase which is equaled in few countries. Exnuptial births were 4.62 per cent of all births registered. The average family per mother in 1930 was 2.92 as against 2.96 in 1929. The density of population, that is, the number of persons to the square mile, in Australia is only 2.18 and varies from 1 person in 100 square miles in the Northern Territory to 20.38 to the square mile in Victoria.

BELGIUM

(From Our Regular Correspondent)

Oct. 30, 1931.

The Prince Leopold Institute of Tropical Medicine

The Prince Leopold Institute of Tropical Medicine, recently established, has for its purpose the creation and maintenance of a school of hygiene and of tropical medicine, for the training of colonial physicians and sanitary agents; for the study of all problems pertaining to the etiology and the therapeutics of tropical diseases, and to establish laboratories and clinics as annexes of the school. One of the clinics will bear the name "Clinique Léopold II." The courses given in the new institution will be organized in such a manner as to meet the requirements of the curriculum established by the minister of the colonies for physicians in the government service. For the time being, the courses will be given, in keeping with the needs and the possibilities of the situation, in one or the other or in both the national languages. Later on, the institute will adopt whatever arrangements parliament shall decree for the colonial university. The Prince Leopold Institute of Tropical Medicine has been located in Antwerp.

The Public Health Service in the Belgian Congo

Since 1929, the public health service in the Belgian Congo has been an independent department. It is interesting to note the steady increase, during the past twelve years, of the annual budget of the public health service of the Congo region, as shown in table 1.

TABLE 1.—*Increases in the Annual Budget of the Public Health Service of the Congo Region, Expressed in Millions of Belgian Francs*

Year	Budget	Year	Budget	Year	Budget
1919	2.8	1923	11.5	1927	47.5
1920	3.7	1924	15.5	1928	79.5
1921	4.4	1925	22.5	1929	86.5
1922	8.8	1926	32.0	1930	95.0

Trachoma in Belgium and Foreign Labor

At a recent meeting of the Société belge d'ophtalmologie, R. Hubin and J. Hubert stated that in 1930 and during the first quarter of 1931 there had been at Liége recrudescence trachoma. The majority of the trachomatous patients were foreign workmen who had recently settled in the province. The authors have observed among these workmen instances of contagious transmission of the disease. Belgian workmen have likewise been contaminated by trachomatous foreigners. The trachoma cases consisted of two distinct types, depending on which country the laborers had come from. There was the Mediterranean type, which follows a grave course and leaves significant sequels, although it is only slightly contagious, and trachoma of the Orient, of an acute type, with less grave manifestations but contagious. If this recrudescence of trachoma is general throughout Belgium, it would seem to necessitate the adoption of stricter prophylactic measures at the borders. Mr. H. Coppez, who examined the foreign workmen in a coal mine at Limburg, found 25 per cent of them trachomatous. He did not find any instances of contagion among the Belgian workmen. The school children in these localities should be examined; for trachoma is transmitted chiefly during youth.

Proposed Reforms in Ophthalmologic Studies

Mr. Weekers has published a report on the result of the referendum among the members of the Société belge d'ophtalmologie concerning the proposed reforms in ophthalmologic studies. Of the seventy-one replies received, two indicated no preference, seven were opposed and sixty-two were in favor. The Société belge d'ophtalmologie passed a resolution that proper action should be taken to protect patients against grave harm resulting from the practice of ophthalmology by specialists who are insufficiently prepared. In connection with the referendum, Mr. Weekers proposed the following resolutions: (1) that a course of instruction for specialists be officially organized in the universities, and (2) that the various universities come to some understanding in regard to the organization of such a course of instruction. *All physicians who desire to do so and* who possess the necessary qualifications should have an opportunity to specialize. The physician should be free to choose between the schools that offer such courses as he needs. Eminent specialists who are not members of any university faculty should be afforded an opportunity to collaborate in the training of candidates for specialties, should they have a taste for instruction. In accordance with rules to be agreed on with respect to titles, a specialist should, without an examination, receive a certificate to be issued by a commission composed chiefly of university specialists, and based, as the only precondition, on a short course taken at a university clinic.

In further exemplification of his ideas, the author drew up the following statement: The specialist's certificate should be provided for by law. It will give satisfaction to all. It does not affect in any manner the diploma of the doctor of medicine. There is no constraint about it. It would bring about the elimination of incompetent specialists and would prevent patients from suffering grave injuries at the hands of physicians who are inadequately prepared for the practice of a specialty.

Marriages

Dudley H. Morris to Miss Margaret Donaldson, both of New York, in Greenwich, Conn., October 17.

Vincent W. Koch, Janesville, Wis., to Miss Ardelia R. Olden of Norwood, Pa., October 30.

Eduard Falk Poser, Chicago, to Miss Marcia Louise Bruch of Evanston, Ill., November 7.

Henry Lowey, New York, to Miss Rebecca May of Wilmington, N. C., November 8.

Joseph D. Hayden, Akron, Ohio, to Miss Constance Delaney of Cleveland, September 23.

Dwight L. Jennings to Miss Isabelle Boedeker, both of St. Louis, November 16.

Deaths

Edward Tyler Edgerly ⊕ Ottumwa, Iowa; Chicago Medical College, 1889; formerly instructor of physical diagnosis, Northwestern University Medical School, Chicago; member of the American College of Physicians; served during the World War; medical director of the Sunnyslope Sanatorium; on the staffs of St. Joseph and Ottumwa hospitals; aged 67; died, November 13, in Rochester, Minn., of cholelithiasis.

Edward Milton Pemberton, Little Rock, Ark.; Maryland Medical College, Baltimore, 1902; College of Physicians and Surgeons, Baltimore, 1903; member of the Arkansas Medical Society; formerly professor of physiology and pharmacology, University of Arkansas School of Medicine; aged 50; died suddenly, November 20.

G. Wilfrid Derome, Montreal, Que., Canada; School of Medicine and Surgery of Montreal, 1902; professor of legal medicine, University of Montreal Faculty of Medicine; for many years head of the provincial laboratories of Quebec; aged 54; died, November 24, in L'Hospital Notre-Dame.

Hall Whiteaker ⊕ Anna, Ill.; Barnes Medical College, St. Louis, 1893; served during the World War; formerly member of the state legislature; aged 62; since 1925 on the staff of the Anna State Hospital, where he died, November 24, of acute myocarditis and carcinoma of the prostate.

R. T. Jennings, Columbia, S. C.; University of the South Medical Department, Sewanee, Tenn., 1898; member of the South Carolina Medical Association; formerly city health officer; aged 55; died, November 20, in a local hospital, of injuries received in an automobile accident.

George Graham Hart ⊕ P.A.S., Lieut., U. S. Navy, retired, Beaver Falls, Pa.; Columbia University College of Physicians and Surgeons, New York, 1902; entered the Navy in 1921 and retired in 1928 for incapacity resulting from an incident of service; aged 53; died, September 20.

Ermy Corser Noble, Mayview, Pa.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1907; member of the American Psychiatric Association and the New England Society of Psychiatry; aged 58; died, October 24, in the Randolph (Vt.) Sanatorium.

Edwin Henry Newbold, Oroville, Calif.; State University of Iowa College of Homeopathic Medicine, Iowa City, 1893; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1900; aged 60; died, September 13.

Levi N. Hicks, Burlington, Wis.; Rush Medical College, Chicago, 1878; Medical Department of the University of the City of New York, 1881; member of the State Medical Society of Wisconsin; aged 80; died, November 29, of cerebral hemorrhage.

Austin N. Lakin, State Line, Ind.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1905; Illinois Medical College, Chicago, 1906; aged 64; died, November 22, in the Lakeview Hospital, Danville, Ill., of gunshot wounds.

George S. Watkins, Oxford, N. C.; University College of Medicine, Richmond, Va., 1900; member of the Medical Society of the State of North Carolina; past president of the Granville County Medical Society; aged 53; died, November 18.

George Steely, Danville, Ill.; College of Physicians and Surgeons, Boston, 1905; member of the Illinois State Medical Society and the American College of Surgeons; served during the World War; aged 52; died, November 14, in St. Elizabeth's Hospital, of hypostatic pneumonia and shock following an operation for appendicitis and gallstones.

Edward John Fucik ⊕ Williams Bay, Wis.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903; president of the Walworth County Medical Society; aged 50; died, December 1.

Odeen Luke, Tremonton, Utah; University of Pennsylvania School of Medicine, Philadelphia, 1921; member of the Utah State Medical Society; aged 42; died, October 9, of a skull fracture received in an automobile accident.

John Alphonso Burnett, Hamilton, Ohio; Eclectic Medical Institute, Cincinnati, 1902; member of the Ohio State Medical Association; formerly county coroner and member of the board of education; aged 52; died, November 28.

Jesse Obed Parker ⊕ Owosso, Mich.; University of Michigan Medical School, Ann Arbor, 1899; member of the Radiological Society of North America; aged 55; died, November 30, of a self inflicted bullet wound.

William H. Muelchi, Tell City, Ind.; Rush Medical College, Chicago, 1891; member of the Indiana State Medical Association; aged 73; died suddenly, November 20, of acute dilatation of the heart.

Edward Francis Donnelly, Imola, Calif.; Cooper Medical College, San Francisco, 1894; member of the California Medical Association; aged 69; died, September 20, in the Napa (Calif.) State Hospital.

William W. Smith, Clyo, Ga.; University of Georgia Medical Department, Augusta, 1885; member of the Medical Association of Georgia; aged 68; was killed, November 29, in an automobile accident.

William Henri De Clark ⊕ McGehee, Ark.; University of Arkansas School of Medicine, Little Rock, 1914; served during the World War; aged 45; died, October 30, in Little Rock, of tuberculosis.

Edward Griswold Bray ⊕ East Mauch Chunk, Pa.; Baltimore Medical College, 1904; formerly county coroner and member of the state legislature; aged 55; died, November 15, of pneumonia.

Thomas Duncan, Jr., Pageland, S. C.; University of Maryland School of Medicine, Baltimore, 1906; member of the South Carolina Medical Association; aged 47; died, November 18, of heart disease.

Edwin Augustus Kratz, Champaign, Ill.; University of Pennsylvania School of Medicine, Philadelphia, 1869; Civil War veteran; aged 87; died, November 6, of cerebral hemorrhage.

Ernest S. Wright, Conneaut, Ohio; Cleveland University of Medicine and Surgery, 1895; aged 64; died, November 11, of bronchopneumonia, cerebral hemorrhage and chronic gastritis.

John William Schafer, South Berwick, Maine; Medical School of Maine, Portland, 1897; member of the Maine Medical Association; aged 70; died, November 12, of uremia.

Elizabeth M. Cushier, Montclair, N. J.; Woman's Medical College of the New York Infirmary for Women and Children, 1872; aged 94; died, November 25, of heart disease.

James Albert Currie, Sydney, N. S., Canada; Dalhousie University Faculty of Medicine, Halifax, 1916; served during the World War; aged 42; died, September 6.

William Henry Miller, Macon, Mo.; University of Missouri School of Medicine, Columbia, 1885; St. Louis Medical College, 1889; aged 71; died, October 30.

William Roberts, Chenoa, Ill.; College of Physicians and Surgeons of Chicago, 1886; aged 87; died, November 9, in San Antonio, Texas, of mitral stenosis.

Leon William Shannon ⊕ Hiawatha, Kan.; Rush Medical College, Chicago, 1899; president of the Brown County Medical Society; aged 61; died, December 4.

Samuel Jennings Guy, Winfield, Kan.; Rush Medical College, Chicago, 1881; member of the Kansas Medical Society; aged 76; died, October 31.

Sara A. Pangburn Kime, Fort Dodge, Iowa; State University of Iowa College of Medicine, Iowa City, 1882; aged 73; died, October 30.

William Vannah Taylor, Olla, La.; Memphis (Tenn.) Medical College, 1872; health officer of La Salle Parish; aged 81; died, October 31, of sublingual carcinoma.

Benjamin L. Bryant ⊕ Detroit; Western University Faculty of Medicine, London, Ont., Canada, 1899; aged 64; was drowned, October 6.

Ezra E. Dickerman, West Burke, Vt.; University of Vermont College of Medicine, Burlington, 1892; aged 72; died, November 7.

Leslie Montgomery Kauffman ⊕ Kauffman, Pa.; Bellevue Hospital Medical College, New York, 1893; aged 62; died, in October.

Hyman Morgenbesser, New York; University and Bellevue Hospital Medical College, New York, 1905; aged 49; died, October 7.

John Comber Doolittle ⊕ Des Moines, Iowa; Rush Medical College, Chicago, 1888; aged 71; died, October 2, of pneumonia.

Emilie Brinkerhoff, San Francisco; College of Physicians and Surgeons of San Francisco, 1904; aged 53; died, September 22.

Robert E. Stone, Atlanta, Ga.; Atlanta Medical College, 1891; aged 63; died, October 17, of cardiovascular renal disease.

Abel J. Mathews, Philadelphia; Jefferson Medical College of Philadelphia, 1873; aged 79; died, September 20.

Correspondence

MEMORIAL TO BUCHHEIM

To the Editor:—Dr. G. Barkan, professor of pharmacology at the University of Dorpat, Tartu-Dorpat, Esthonia, has informed me that he is raising funds for a memorial tablet to Rudolf Buchheim, to be unveiled on the occasion of the three hundredth anniversary of the founding of the University of Dorpat. Dorpat has truly been called the cradle of modern pharmacology because there, in 1850, Buchheim founded the first university institute for the prosecution of pharmacology as an experimental science. Buchheim merits remembrance not only in his own right but because he discovered Schmiedeberg, who more than any other man turned the age-old materia medica and therapeutics of our medical schools into the modern and fundamental science of pharmacology. Those who feel disposed to make a contribution to the fund may send their check to me before the close of the year for transmission to Professor Barkan.

John J. Abel, M.D., Baltimore.
Professor of Pharmacology, Johns Hopkins
University School of Medicine.

"LES POISONS DU BACILLE TUBERCULEUX"

To the Editor:—I was surprised in reading the review given in The Journal (October 17, p. 1174) on my book "Les poisons du bacille tuberculeux et les réactions cellulaires et humorales dans la tuberculose: Esquisse d'une conception nouvelle des processus pathogéniques de la tuberculose." The reviewer wrote: "Unfortunately the author has overlooked much of the American literature since 1928 and has thereby missed an immense amount of material germane to his subject. . . . The book will be useful in France in supplementing Calmette's comprehensive work on tuberculosis but will be superfluous to the American physician who has access to numerous reviews of this subject in American publications."

If the reviewer had read my book more attentively he could have seen that a large number of references concerning American, French and foreign researches are later than 1928, and that some are even as recent as December, 1930, and January, 1931; for example, reference is made to the work of C. A. Doan, F. R. Sabin and their associates. Moreover, there is my work and that of the more recent French and foreign investigators, which often is not given due recognition in American publications.

In a subject so extended and complicated as the study of Koch bacilli and of cellular and humoral reactions in tuberculosis, it was evidently impossible for me to quote all the articles published in America and elsewhere without falling into the most complete confusion. I have deliberately chosen my references from this immense amount of material, much of which does not present any important interest for the study and progress of the work. It was my object to make, as much by my own studies as by the composition and presentation of my work, a personal contribution. There does not exist in recent literature any complete work treating of the poisons of Koch bacilli and, at the same time, cellular and humoral reactions in tuberculosis, reactions considered not only with regard to the introduction into the organism of Koch bacillus fractions, artificially separated and prepared, but also in a more general manner with bacillary infection itself; there does not exist any work giving synthetically a general study on the pathogenic processes in tuberculosis, in applying the modern theories concerning the antigens, and giving a modern definition of tuberculous allergy. All the interesting reports that have appeared on these questions are scattered in innumerable publications.

I must then believe that my book is not superfluous for American physicians, since many learned foreign and American authorities on tuberculosis, particularly Dr. W. Charles White, chairman of the Committee on Medical Research of the National Tuberculosis Association, have written to me to send a copy of my book. That will be my greatest reward.

Jean Albert-Weil, M.D., Béziers, Hérault, France.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DOSAGE OF HISTAMINE SALTS FOR TESTS OF GASTRIC ACIDITY

To the Editor:—In the *Archives of Internal Medicine* for August, in an article by Moschowitz, the gastric analysis was commented on as including "the neutral red reaction and histamine." Then in the *Archives of Internal Medicine* for September, an article by Bloomfield and Polland states that dimethyl-amino-azobenzene was used as the indicator in their work. In the pamphlet that was written by Victor C. Myers, revised in June, 1930, and sent out by the American Medical Association, the statement is made, "Although the information obtainable with the Topfer method is fairly accurate, it does not give a modern point of view." Is a difference of indicators important, and if so I should like to know the indicator that is most generally used or accepted, and the method that is considered to give the most modern point of view. I should like to know the status of the alcohol test meal at present. Is it preferable to the other test meals as a routine procedure, to be followed by an injection of histamine if at the end of thirty minutes after the alcohol meal there is no free hydrochloric acid? Is the dose of histamine standard for each person or is it still given by weight? Some assert that 0.25 mg. will provoke as much stimulation as 1 mg. Please give the accepted dosage of histamine for this use, and also the most satisfactory preparations. Please omit name.

M.D., Florida.

Answer.—The type of indicator used in gastric analysis is extremely important because the various indicators have very different ranges of acidity in which they can be used. True neutrality in water is expressed by the p_H value 7; any p_H higher than that is more alkaline than water and any p_H lower than 7 is more acid than water. Di-methyl aminobenzene solution (Töpfer's reagent) is red at p_H values of 2.9 or lower and yellow at p_H 4.0 or higher. Obviously this indicator is of value for detecting mainly relatively high acidities in the p_H range of 2.9 to 4.0. Neutral red, however, is of value only in the truly neutral range, that is, at p_H 6.8 to 8.0. In other words, very faint acidity will change the color of the neutral red solution to yellow, and will also increase the acidity. It does not distinguish between the two kinds of acidities. Di-methyl aminobenzene solution is generally applied and is useful when the acidity is measured by titration. The "modern point of view" is to determine the actual hydrogen ion concentration or p_H of the juice rather than the amount of titratable (total and free) acid. For most purposes, however, the titration method is still the more useful. There does not appear to be a distinct advantage in alcohol over the other test meals when it is used as a routine, but it appears to be fairly well established that histamine hydrochloride or phosphate injected subcutaneously frequently stimulates the secretion of hydrochloric acid when the test meal methods resulted in a diagnosis of achlorhydria. However, in true achlorhydria, the histamine does not cause the secretion of hydrochloric acid. It is of no value in cases of hyperacidity. In any case the tests should be repeated a number of times before a diagnosis is made. The greater the dose of histamine, the higher the secretion of juice and acid in normal individuals. A reasonable dosage to employ as a routine is 0.1 mg. of histamine hydrochloride to 10 Kg. of body weight. If histamine phosphate, also called ergamine acid phosphate, is used, the dosage should be increased to 0.17 mg. for each 10 Kg. of body weight. Such dosage in normal subjects produces a maximum secretion in from thirty to sixty minutes, and the secretion may extend over an hour and a half. Histamine salts may be procured from general chemical houses such as Central Scientific Company, 460 E. Ohio St., Chicago; Eimer and Amend, Third Avenue and Eighteenth Street, New York, the Eastman Kodak Company, Rochester, N. Y., or the Special Chemicals Company, Waukegan, Ill.

FLOCCULATION AND WASSERMANN TESTS—GRAM-NEGATIVE INTRACELLULAR DIPLOCOCCI

To the Editor:—What is your opinion as to the reliability of the flocculation test for syphilis as compared to the blood Wassermann test? Are there any diplococci (gram-negative and intracellular) other than gonococci; and if so, please name them. Please omit name and city.

M.D., Mississippi.

Answer.—Although there are reports in the literature of wide variations between results of Wassermann and flocculation tests, careful workers find agreement between the two classes of tests in approximately 90 to 96 per cent of cases.

Both the complement fixation and the flocculation tests are regarded as being of a physicochemical nature and not biologically specific. It is thought that both reactions are effected by the same conditions that control most colloid reactions. At present, serologists are unable to "render the factors exactly the same" in the conduct of complement fixation and flocculation tests, and for this reason serums and spinal fluids containing small amounts of syphilitic antibody may yield differing results.

The flocculation reaction is "greatly influenced by the quantitative relationship existing between the reacting substances present in the serologic system at the time the test is performed. Such relationship varies with each serum tested." Because of this, a given system may not result in a "complete and proper antigen precipitation in every case" (Levine, B. S.: *J. Lab. & Clin. Med.* **15**:985 [July] 1930).

"It would appear that the flocculation tests are more likely to yield falsely positive reactions in the hands of ordinary laboratory technicians than are the complement fixation tests, although in the hands of experts the incidence of falsely positive reactions has been remarkably low with both procedures . . . All flocculation and complement fixation tests are capable of yielding false reactions because of technical errors but the incidence of these is remarkably low in the hands of expert serologists and probably not as frequent as are the clinical errors in the diagnosis of syphilis . . . Under proper technical conditions they possess an extremely high practical specificity for syphilis in this country" (Kolmer, J. A.: *Am. J. Syph.* **15**:383 [July] 1931).

Because some serums will react at one time to a flocculation test and not to a Wassermann test, and vice versa, the two classes of tests supplement each other, and when carefully performed should show a high degree of relative agreement. It is thought that a weakly positive flocculation test is more difficult to read and to interpret than a weakly positive Wassermann reaction. A serum showing a strong positive flocculation test and a negative Wassermann reaction in a patient for diagnosis indicates the advisability of repeated tests and study of the patient.

The foregoing remarks refer more particularly to the routine test of Kahn, which is the most widely used flocculation test in this country; also to the routine Kline microscopic test and to the Hinton test. The remarks do not apply to the Kahn "presumptive test" or to the Kline "exclusion test." These two tests are too sensitive for routine use and may give false positive reactions. "There is a limit to which the delicacy of serologic procedures may be advanced without introducing the possibility of false positive reactions" (Kilduffe, R. A.: *Am. J. Clin. Path.* **1**:69 [Jan.] 1931).

The common gram-negative intracellular diplococci are the gonococcus and the meningococcus (Neisseria intracellularis or meningitidis).

According to Ford, Micrococcus catarrhalis is "occasionally intracellular in exudates" (Ford, W. W.: Textbook of Bacteriology, Philadelphia, W. B. Saunders Company, 1927, p. 380).

Ford also cites Diplococcus intracellularis-equi Johne "found by Johne in Borna's disease of horses (acute encephalitis)."

INFESTATION WITH STRONGYLOIDES INTESTINALIS

To the Editor:—I have a boy, aged 12 years, with a heavy infestation of Strongyloides stercoralis or intestinalis. I cannot find any definite reference to treatment. What would be a proper course to pursue? Please omit name.

M.D., West Virginia.

Answer.—In suggesting treatment, it is assumed that the infesting parasite is the one mentioned; i. e., Strongyloides intestinalis (stercoralis).

The following treatment should prove helpful: The patient should be given a soft, liquid, fat-free diet for three days, and each night 4 cc. (1 fluidrachm) of fluid extract of cascara sagrada in hot water. On the morning of the fourth day, the patient should remain in bed and have no breakfast. At 9 and 11 a. m. 1 Gm. (15 grains) of powdered thymol U. S. P. in 0.3 Gm. (5 grain) enteric capsules should be administered. Each hour, for five hours, the patient should take a cup of hot, weak, black, sweet coffee. At the end of that period, 0.8 Gm. (2 drachms) of magnesium sulphate in a glass of hot water should be taken, and the dose should be repeated in one hour.

The patient may then go on a light, low-fat diet for four or five days. Daily stool examination should be made for the presence of strongyloides or ova. During this week, 0.65 Gm. (10 grains) of precipitated sulphur with an equal quantity of lactose should be given in capsules three times daily.

Approximately one week after the first course of thymol, the initial procedure should be repeated (fat-free diet days, cascara, thymol, and so on).

In the average instance, such management should free the alimentary tract of its infestation. For a year, however, it is advisable to examine the stools freshly passed after the exhibition of a saline cathartic, at intervals of two months, for further evidence of the parasites. During this year, as a precautionary measure, a course of thymol should be exhibited several times.

Since the parasite usually enters the human being by way of the skin, a search should be made for patches of dermatitis on the body surface. Such areas should be well scrubbed with soft soap, U. S. P., and then kept covered with sulphur ointment, U. S. P., plus 1 per cent phenol (carbolic acid). This treatment for the dermal lesions should be kept up as long as necessary.

The region of the anus should be examined for the presence of urticarial wheals, particularly if areas of dermatitis are absent. Such wheals, according to Stitt, are due to penetration of larvae which have arisen in feces adhering to that area. Such wheals may account for reinfestation over long periods, unless they are recognized and treated. Thorough cleansing, after the fashion of caring for areas of dermatitis, and the careful application of sulphur ointment, should eliminate these foci of infestation.

Medicated colon lavages are of doubtful value, as strongyloides inhabits and causes lesions chiefly in the small intestine. Rather high eosinophilia is present when the adult female parasite is penetrating the crypts of Lieberkühn. In instances in which the question of symptoms being due to strongyloides arises, this eosinophilia has diagnostic importance.

Hookworm is frequently the offender at times when strongyloides is suspected (hookworm eggs greatly resemble those of strongyloides). Of differential value, diagnostically, is the observation that, in the stools of strongyloides infestation, eggs are rarely seen unless active purgation has been resorted to. When hookworm is the parasite present, eggs and worms commonly are present together in the stools.

TREATING GONORRHEA BY COLLOIDAL MERCURY SULPHIDE AND INTRAVENOUS HYDROCHLORIC ACID

To the Editor:—I noticed in the August issue of the *Urologic and Cutaneous Review* an article on the stimulation of leukocytosis in the treatment of gonorrhea, in which the author recommends three intravenous injections a week: one of 4 cc. of colloidal mercury sulphide-Hille and two of a 1:1,500 solution of hydrochloric acid intravenously, from 10 to 15 cc. being given at two-day intervals. Do you consider this a safe procedure or not? I had always considered any acid injection into the blood as carrying more or less risk. Would you think this treatment, without any local treatment, likely to produce a cure?

E. J. Stahl, M.D., Charleston, W. Va.

Answer.—Examination of the article quoted shows it to be one entitled "Stimulation of Leukocytosis in the Treatment of Gonorrhea." The plan of therapy was first suggested by work done by another physician in which mercurochrome-220 soluble was used intravenously as a stimulant for the white cells. This was in connection with gonorrheal infection. Proper records were not kept, however, and the observations were purely clinical. As a result of this two years of observation, the investigators then started the stimulation of phagocytes with intravenous injections of hydrochloric acid 1:1,500, and of colloidal mercury sulphide-Hille, or of milk intramuscularly. At first the hydrochloric acid was given by the intramuscular route, but later they tried it by the intravenous route, and since they felt that no harm was done, they have not hesitated to employ it by this route since then. They found that there was an increase in the leukocyte count running up to 3,500 or more within the first hour after the injection. The rationale of such a procedure is that of a foreign protein effect. Naturally, if one injects a solution of hydrochloric acid into the blood stream a certain number of red cells are going to be destroyed, with a resultant absorption of protein, an increased temperature and a certain amount of reaction like that seen in malaria. Of course, in malaria a larger number of red cells will be destroyed, and the reaction will be more severe. With this foreign protein effect there will be a mild leukocytosis, an increase of possibly 3,500, as the author states.

The query arises, Why give hydrochloric acid intravenously to get a leukocyte increase of 3,500, when the same increase can be attained by the use of various foreign proteins intramuscularly and with far less risk to the patient, and with no destruction of the red cells? For example, boiled milk intramuscularly, in doses of 5 cc., and gradually increasing, will certainly give an increased leukocyte count of probably even a larger amount. As to intravenous injection of the colloidal mercury sulphide-Hille, no rationale exists for its use in the treatment of gonorrhea, unless possibly for a mild foreign protein effect. Moreover, the Council on Pharmacy and Chemistry of the American Medical Association has recently gone on record as opposed to the use of this preparation by the intravenous route. Because of the large amounts of metallic mercury likely to be deposited in various parts of the system and not excreted, the use of this preparation intravenously is not considered a safe clinical procedure. Proof that it will cure a case of gonorrhea is certainly not available.

PREPARATION FOR SPECIALIZATION IN METABOLIC DISORDERS

To the Editor:—I desire to take up postgraduate work fitting me for specializing in metabolic diseases. I am writing to ask what books you would advise me to study (from anatomy up) previous to going out for my postgraduate work.

William Ross, M.D., La Mesa, Calif.

Answer.—Any good textbook of anatomy and physiology will serve as a beginning. Then Graham Lusk's "Science of Nutrition," as a classic background for the best in nutrition; Du Bois' "Metabolism in Health and Disease"; McLester's "Nutrition and Diet in Health and Disease," and Joslin's "Diabetes" may be read.

In addition to these, some of the many studies by McCollum, Mendel, Steenbock, Alfred Hess, McGarrison and other contributors to scientific literature would be valuable. Naunyn's original textbook on diabetes is still full of sound basic truth and will keep the student in the proper frame of mind toward the developmental aspects. Von Noorden and Isaacs have also an excellent German textbook on diabetes.

The thyroid literature is still too active to pick out the most important articles. At any rate, the few books mentioned will carry the reader into references that can occupy his time for quite a number of years.

ARTHRITIS OF CERVICAL SPINE

To the Editor:—A longshoreman, aged 59, who had never been sick before, fell down, May 15, and presented sprains and contusions of both ankles, the left more involved than the right. For two months he received baking treatments twice and thrice a week. Three times he had diathermy, each sitting lasting one hour. About this time he complained of stiff neck; the pain in the ankles increased, and he noticed fever. For a month he was in bed, being treated for acute articular rheumatism; after this he was at the hospital for two months. On his removal to his home, I was called to take care of him. The physical examination shows impossibility of movements and tenderness of the joints, the cervical vertebrae, both shoulders, and the knees, ankles and toes. Passive movements are also abolished, as any such attempt gives tremendous pain. I should appreciate an answer stating whether and how an injury to the ankles, such as described, may give rise to such a syndrome.

Salvatore Caridi, M.D., Woodcliff, N. J.

Answer.—This is evidently a case of arthritis of the cervical spine. Recommendations are rest in bed, with the head of the bed elevated, and head traction. Physical therapy, including radiant heat and gentle massage, should be of value. One can see no direct connection between the injury to the ankle and the arthritis of the cervical spine.

GUM RESECTION FOR PYORRHEA

To the Editor:—I wish to inquire whether or not excision of the gums in the so-called cure of pyorrhea is feasible and ethical. I have had quite a few patients who have had this operation done and most of them report varying results. I am of the opinion that it is impossible to sterilize the mouth, and I fail to see how cutting the gums away could effect a cure. Can you tell me anything about this method and whether or not you would advise a patient to have it done?

L. M. Harris, M.D., Columbus, Ohio.

Answer.—Gum resection for the purpose of eradicating pyorrhea pockets has been practiced since the latter part of the nineteenth century. This does not mean that every case of pocket formation along the root surfaces of teeth should be treated in this manner; however, in properly selected cases excellent results have been obtained. The criticism that it is impossible to sterilize the mouth and that such procedures are therefore not advisable is not well founded, as the same septic condition exists when any surgical intervention is attempted within the oral cavity. There is a short "correspondence" with a bibliographic reference of current literature on the subject in the November issue of the *Dental Cosmos*, page 1131.

COMING EXAMINATIONS

Alabama: Montgomery, Jan. 11. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

Arizona: Phoenix, Jan. 5-6. Sec., Dr. B. M. Berger, 12 North Central Ave., Phoenix.

California: Los Angeles, Feb. 1-4. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

Colorado: Denver, Jan. 5. Sec., Dr. Wm. Whitridge Williams, 422 State Office Bldg., Denver.

Connecticut: *Basic Science.* New Haven, Feb. 13. Prerequisite to license examination. Address, State Board of Healing Arts, 1895 Yale Station, New Haven.

District of Columbia: *Basic Science.* Washington, Dec. 29-30. *Regular.* Washington, Jan. 11. Sec., Dr. W. C. Fowler, District Bldg., Washington.

Hawaii: Honolulu, Jan. 11-14. Sec., Dr. James A. Morgan, Room 48, Young Bldg., Honolulu.

Illinois: Chicago, Jan. 12-14. Supt., Mr. Paul B. Johnson, Springfield.

Minnesota: *Basic Science.* Minneapolis, Jan. 5-6. Sec., Dr. J. C. McKinley, 126 Millard Hall, University of Minnesota, Minneapolis. *Regular.* Minneapolis, Jan. 19-21. Sec., Dr. E. J. Engberg, 524 Lowry Medical Arts Bldg., St. Paul.

Nebraska: *Basic Science.* Lincoln, Jan. 12-13. Act. Sec., Mr. P. H. Bartholomew, Lincoln.

Nevada: *Reciprocity.* Carson City, Feb. 1. Sec., Dr. Edward E. Hamer, Carson City.

New York: Albany, Buffalo, New York, Syracuse, Feb. 1-4. Chief, Mr. Herbert J. Hamilton, Room 315, State Education Bldg., Albany.

North Dakota: Grand Forks, Jan. 5-8. Sec., Dr. G. M. Williamson, Grand Forks.

Oregon: Portland, Jan. 5-7. Sec., Dr. C. J. McCusker, 1014 Medical Dental Bldg., Portland.

Pennsylvania: Philadelphia, Jan. 5-9. Sec., Mr. Charles D. Koch, Harrisburg.

Rhode Island: Providence, Jan. 7-8. Dir., Dr. Lester A. Round, 319 State Office Bldg., Providence.

South Dakota: The St. Charles Hotel, Pierre, Jan. 19-20. Dir., Dr. H. R. Kenaston, Bonesteel.

Vermont: Burlington, Feb. 9-11. Sec., Dr. W. Scott Nay, Underhill.

Washington: *Basic Science.* Seattle, Jan. 14-15. *Regular.* Seattle, Jan. 18-19. Dir., Mr. Charles Maybury, Olympia.

Wisconsin: Madison, Jan. 12-14. Sec., Dr. Robert E. Flynn, 315 State Bank Bldg., LaCrosse.

Wyoming: Cheyenne, Feb. 1. Sec., Dr. W. H. Hassed, Capitol Bldg., Cheyenne.

Pennsylvania July Examination

Mr. Charles D. Koch, secretary, Pennsylvania State Board of Medical Education and Licensure, reports the examination held at Philadelphia and Pittsburgh, July 7-11, 1931. Three hundred and seventy-nine candidates were examined, 373 of whom passed and 6 failed. The following colleges were represented:

College PASSED	Year Grad.	Number Passed
Yale University School of Medicine	(1929), (1930)	2
Georgetown University School of Medicine	(1930, 15), (1931)	16
George Washington University Medical School	(1930, 3)	3
Howard University School of Medicine	(1930, 5)	5
University of Georgia Medical Department	(1928)	1

Book Notices

Selected Writings of John Hughlings Jackson. Volume I: On Epilepsy and Epileptiform Convulsions. Edited for the Guarantors of "Brain," by James Taylor, M.D., F.R.C.P., with the advice and assistance of Gordon Holmes, M.D., F.R.C.P., and F. M. R. Walshe, M.D., F.R.C.P. Cloth. Price, 25/-. Pp. 500. London: Hodder & Stoughton, Ltd., 1931.

Probably the number of neurologists who think and of those who care to know of the evolution of neurologic knowledge will be fairly indicated by the extent of the sale of this volume and of the one to follow; for no thinking neurologist can afford to be without this work and no one interested in the history of his chosen specialty will want to miss it. The papers composing the present volume concern epilepsy and epileptiform convulsions. The book contains such a mass of information that detailed review is out of the question, but no physician can read it without learning a multitude of things, besides enjoying a scientific banquet of neurologic knowledge. Any one of several chapters (on study of convulsions, on the scientific and empiric investigation of epilepsy, on convulsive seizures, on temporary paralysis after seizures) will richly repay the purchaser. In truth, one cannot be fully informed on epilepsy without study of Dr. Jackson's principal papers. For instance, the three (Harveian) lectures on the diagnosis of epilepsy are more, much more, than directions on how to detect epilepsies and to distinguish them from other conditions. They embrace a fascinating and illuminating discussion of the nature of the symptoms, a graphic description of different types, a philosophical consideration of the physiology and pathology of fits, and illustrative examples, with sage remarks based on the wide experience of an acute observer. Dr. Jackson, we fear, is known to most physicians only for the one type of epilepsy named for him, but the wide range of his meticulous observations, the clarity of his reasoning and the broad scope of his conclusions may well serve as a model and an inspiration alike to practitioner and to savant. With infinite patience and tact he constantly strove at the impossible task of teaching others to observe and to think as he did. His exposition of the logical approach and further procedure in the study of any case is not to be improved on; it is valuable equally to clinician and to research worker.

Although this volume nominally deals with epilepsy and cognate states, it abounds in unexpected nuggets of knowledge and wisdom belonging to other lodes. Jackson's remarks on insanity are decidedly illuminating. Nothing could be more satisfying and helpful than what he writes of consciousness, the will, the relation of mind to matter (brain), the relation of volition to movement, and the like. Hundreds, maybe thousands, of papers and probably whole books have been written on aphasia by authors in total ignorance of what Hughlings Jackson had said on the subject. Yet this master's dicta and surmises are priceless. A few random quotations may be added: "No one is fitted to begin the materialistic study of diseases of the brain unless he has a good knowledge of psychology." "To say that ideas or sensations produce movements is to use neither psychological nor materialistic language, but a mixture of both." "Unless a man can put the particular phenomena he himself sees under more general laws, or unless he tries to do this, he can scarcely be said to know or to be studying a thing in a very valuable sense." "Numbness of the hand before an epileptic fit, for example, coloured vision, . . . are states of consciousness, . . . as much as . . . the notion of justice is." "Without a considerable clinical knowledge of cases no one is fitted to begin the scientific comparative study of nervous diseases." "To many [observers] unfamiliarity is the same thing as unreality." This lucid thinker protested against "explanations which verbally explain everything and yet in reality explain nothing" and "a whole family of psychologico-materialistic confusions." To say that the volume reads like a romance is strictly true but not in the sense that it is "light" reading to be quickly skimmed with a pleasant titillation of one's imagination. It is meaty from cover to cover.

Practical Physiological Chemistry: A Book Designed for Use in Courses in Practical Physiological Chemistry in Schools of Medicine and of Science. By Philip B. Hawk, M.S., Ph.D., President of the Food Research Laboratories, Inc., New York City, and Olaf Bergeim, M.S., Ph.D., Associate Professor of Physiological Chemistry in the University of Illinois, College of Medicine, Chicago. Tenth (25th anniversary) edition. Cloth. Price, $6.50. Pp. 929, with 288 illustrations. Philadelphia: P. Blakiston's Son & Company, Inc., 1931.

This edition of the well known book on physiologic chemistry, which gained such recognition at the time when Philip B. Hawk was professor of physiologic chemistry at the University of Illinois, is in keeping with its predecessors in that it contains considerable material not included in the preceding edition. Noteworthy is the fact that the issuance of this book in 1931 marks the twenty-fifth anniversary since the appearance of the first volume. The subject of metabolism has been particularly enlarged, so that instead of one chapter it has been divided into chapters on respiratory metabolism and neutrality regulation; energy metabolism; protein, carbohydrate and fat metabolism, and inorganic metabolism. The recent account of the isolation of the precursor to vitamin A and the isolation in crystalline form of vitamin D make the present chapter on the vitamins somewhat behind the discoveries. The authors state that the isolation in crystalline form of vitamin D is still to be achieved, and just a few months after the issuance of the book that achievement was made. This serves to illustrate the difficulties confronting the author of a textbook on any of the basic sciences having to do with biology. The volume is well illustrated.

Der Einfluss der Ernährung auf die Konstitution des Organismus: Ergebnisse experimentell-biologischer. Forschungen. Von Prof. Dr. A. Katase, Professor an der medizinischen Akadamie zu Osaka. Paper. Price, 10 marks. Pp. 162, with 80 illustrations. Berlin: Urban & Schwarzenberg, 1931.

Katase stresses the point of view that environment and not heredity determines constitution. The chief factor in the environment which develops constitution is diet. An acid-forming diet makes for the tall slender type, while an alkali-forming diet develops the broad muscular individual. Katase obtains the experimental evidence for his conclusions by feeding rabbits either an acidic or a basic diet. Those animals fed a diet potentially acid are thin and long. Roentgen studies reveal long medullary cavities of the bones. The viscera, for example, the heart and uterus, are small. On the other hand, those rabbits fed potentially alkaline diets are broader, more muscular and have larger viscera. Though one would wish that the experiments had not been done on rabbits, since their kidneys are not capable of forming ammonia for the neutralization of acids, it is most interesting that these two types of individuals, as Katase points out, are subject to different diseases. The tall thin person is more prone to infections, especially those of childhood, while the broader type is apt to acquire the diseases of later life; e. g., arteriosclerosis, nephritis and emphysema. Perhaps the chief importance of Katase's careful work is that it adds experimental data to a subject clouded by vague hypotheses.

Lactobacillus Acidophilus: An Annotated Bibliography to 1931. By W. D. Frost, Ph.D., Dr.P.H., Professor Agricultural Bacteriology, University of Wisconsin, and Hazel Hankinson, B.A. Paper. Price, $1. Pp. 160. Milton, Wisconsin: Davis-Greene Corporation, 1931.

An annotated bibliography is presented of 5 books and 175 articles dealing with Bacillus acidophilus. Of the 175 articles, 142 were originally published in the United States, 79 in Germany, 7 in France, 4 in England, and 3 in other countries. Although a period of thirty years is covered, by far the majority of articles (76 per cent) have appeared during the last ten years. The articles are divided into several groups according to subject matter. The history of Bacillus acidophilus begins with 1900, when Moro discovered the organism. The characteristics of the organisms are discussed in twenty-five articles, but a perusal of them leads one to think that much more work must be done on this phase of the subject. The bacteriologic flora of the intestine has received considerable study; it is agreed that although the intestinal flora may be altered markedly by diet, diet alone cannot be depended on, except in rare cases, to establish an acidophilic flora. The implantation of Bacillus acidophilus in the intestine is best accomplished by massive doses of the organism administered in milk, supplemented with certain carbohydrates. The therapeutic value of acidophilus administration needs more study. Most of the articles deal with chronic constipation, this condition being much benefited, according to the published reports. There are a considerable number of articles discussing the relationship of Bacillus acidophilus with Bacillus bulgaricus and with the organism found associated with dental caries. For persons manufacturing acidophilus products, articles dealing with their preparation are grouped together. An index of articles is published by subject, by author and by chronological order.

Handbuch der pathogenen Mikroorganismen. Herausgegeben von W. Kolle, R. Kraus und P. Uhlenhuth. Lieferung 50. (Schluss des Werkes). Gesamtinhaltsübersicht aller Bände des Werkes. Gesamtsachverzeichnis. Third edition. Paper. Price, 30 marks. Pp. 342. Jena: Gustav Fischer, 1931.

The fiftieth issue of the Handbuch contains the table of contents and the index, marking the close of the great work. This indispensable aid to the reader seems to be up to the best tradition of the publishing house that has long set so high a standard for scientific work. German scholarship and industry have rendered a great service to scientific medicine in conceiving and carrying through so successfully this monumental treatise.

A Text-Book of Experimental Cytology. By J. Gray, M.A., F.R.S., Lecturer in Experimental Zoology, University of Cambridge. Cloth. Price, $7.50. Pp. 516, with 205 illustrations. New York: Macmillan Company, 1931.

A great mass of material is here marshaled by an active contributor to our knowledge of cell physiology. He critically and judicially examines the evidence for the participation of physical processes in the interactions of cells and their environments. The chemical aspects of the problems are not discussed and their importance is minimized. To what extent, he asks, can we explain the phenomona of cell division and growth, of fertilization, phagocytosis and ciliary movement in terms of surface tension, permeability, electric charge, hydrogen ion concentration and colloidal state? Incidentally, many of the significant results of the tissue culture and microdissection methods are reviewed. All this is preceded by surveys of cell physiology, colloidal systems and protoplasmic structure. Under the circumstances, mathematics must needs "perk a learned snout far beyond the cellarage of a footnote," but not often, and the general conclusions are usually stated so as to be clear to most biologists. The discussions of cell permeability and of phagocytosis have much of value to clinical investigators. There is a good presentation of the thesis that the cell movements, from pseudopod formation to muscle contraction, are fundamentally the same. The illustrations are good, the index is detailed, and the typography is above reproach.

Medicolegal

Power of Workmen's Compensation Commissioner to Punish for Contempt

(In re Hayes (N. C.), 156 S. E. 791)

On March 3, 1930, Dr. R. B. Hayes was present as a witness before the chairman of the North Carolina industrial commission. He had professionally attended the claimant, who was seeking compensation. Dr. Hayes had been sworn and had testified on both direct and cross examination. The chairman of the commission then asked Dr. Hayes whether he had an opinion as to whether or not a blow received by the claimant on October 19 would have produced a paralytic stroke on January 12. Dr. Hayes admitted that he had an opinion, but he refused to express it unless he received compensation as an expert. Section 3893 of the Consolidated Statutes provides that experts, when compelled to attend and testify as witnesses, shall be allowed such compensation and mileage as the court in its discretion may allow. The chairman of the commission, however, maintained that it was not up to him to qualify Dr. Hayes as an expert and committed him to jail for contempt of what the chairman described as "the Court." Dr. Hayes sought to obtain his release through a writ of habeas corpus, but failed. Thereupon he obtained a writ of certiorari for a review of the case by the Supreme Court of North Carolina.

Power is expressly conferred by the statute creating the North Carolina industrial commission, said the Supreme Court, for that commission or any member of it to subpena witnesses to attend and testify at a hearing before the full commission or before any member, and the statute provides that "the superior court shall, on application of the commission or any member or deputy thereof, enforce by proper proceedings the attendance and testimony of witnesses and the production and examination of books, papers and records." This provision that the legislature had made for enforcement by the superior court of the attendance and testimony of witnesses and the production and examination of books, papers and records, however, the Supreme Court thought was not adequate for a situation such as that presented in the present case. If a witness in attendance at a hearing, after having been duly sworn, can with impunity refuse to answer a question propounded to him which is pertinent to the matters in dispute between the parties, then, the Supreme Court thought, the industrial commission would be without adequate power to perform its duties. Since the legislature in providing the commission with the aid of the superior court in enforcing the attendance and testimony of witnesses did not in express terms—nor, in the opinion of the Supreme Court, by implication—deny to the commission or any member thereof the power to compel a witness in attendance at a hearing, after having been duly sworn, to testify, the court, without deciding whether the North Carolina industrial commission was or was not a court, and without citing any statutory authority or judicial precedent in support of its opinion, concluded that the commission or any of its members has the power to adjudge a witness in contempt who has deliberately and persistently refused to answer a question propounded to him and to punish such witness by fine or imprisonment. The judgment of the industrial commissioner was therefore affirmed.

The question raised by Dr. Hayes at the hearing before the chairman of the industrial commission, said the Supreme Court, when he refused to answer the question addressed to him because it was addressed to him as an expert and he had not been paid as an expert nor assured that he would be so paid, was not presented to the Supreme Court for decision and had not been decided by that court. It has been held in a few courts that a witness who has been summoned as an expert in a judicial investigation cannot be adjudged in contempt for refusing to give such testimony unless he has been compensated for his professional opinion. The better opinion, however, said the Supreme Court of North Carolina, is that an expert summoned to testify, who refuses to answer questions "without compensation other than his witness fees," is in contempt, and when an expert voluntarily submits himself to an examination as such, he can in no case refuse to answer one particular question after having without objection answered others.

Evidence: Admissibility of Physician's Office Records.—The appellee, Dennis Bisimanis, based his suit on double hernias, which he claimed were caused by his having been negligently struck by the defendants, with an automobile, Oct. 30, 1929. The case was tried, Jan. 30, 1930, and judgment given in favor of Bisimanis. Thereafter the defendants learned that some time before the date of the alleged accident a physician had found that Bisimanis was then suffering from double hernias. They then moved for a new trial, on the ground of newly discovered evidence. In connection with that motion, it was stipulated between counsel for Bisimanis and counsel for the defendants that a certain physician, if he were present and testifying on the motion, would testify that the records in his office showed that he examined one Dennis Bisimanis in his office, March 25, 1929, and found that he was suffering from double hernia, and that he advised an operation, but that the physician had no recollection of the matter independent of his office records. A rehearing was denied, and the defendants appealed to the Supreme Court of Alabama. On behalf of Bisimanis it was argued that neither the hospital [sic] records nor their contents were evidence of the facts. But, said the Supreme Court, these records, under the well settled rules of the court, were admissible on proof that the witness knew the facts when the records were made, knows that the records show the true facts, and now has no independent recollection. The cause was remanded for a new trial.—*Ohme v. Bisimanis (Ala.), 132 So. 161.*

Lymphatic Leukemia Attributed to Trauma.—The cause of lymphatic leukemia is not known to medical science. It cannot be inferred, however, from the facts that the plaintiff was well and able to work up to the time of an injury and after the injury was found to be suffering from lymphatic leukemia, that the injury caused the disease. If the disease was caused or aggravated by the injury, the plaintiff must establish that fact by a fair preponderance of evidence.—*Boyer v. Department of Labor and Industries (Wash.), 295 P. 737.*

Workmen's Compensation Acts: Compensability of Carbon Monoxide Poisoning.—The death of a workman in a mine from the inhalation of carbon monoxide in the course of his employment was, in the opinion of the court of appeals of Ohio, Carroll County, due to an "accidental injury" within the meaning of the Ohio compensation act, and not to an occupational disease.—*Industrial Commission of Ohio v. Tolson (Ohio), 174 N. E. 622.*

Privileged Communications: Waiver by Offering Testimony of Physician.—Where a party to an action puts his physician on the stand to prove that the party was incompetent to make a certain contract, he thereby waives his statutory privilege of maintaining the secrecy of communications between him and his physician. The adverse party may thereafter cross-examine the physician.—*Travelers' Building and Loan Ass'n. v. Hawkins (Ark.), 34 S. W. (2d) 474.*

Compensation of Physicians: Liability of Member of Family Who Summons Physician.—It is a general proposition supported by many authorities that he who orders a physician to come to his home to treat a member of his family becomes responsible for payment for the physician's services unless he makes it known to the physician that he disavows responsibility.—*Benton v. Stadler (Wis.), 234 N. W. 739.*

Society Proceedings

COMING MEETINGS

Annual Congress on Medical Education, Medical Licensure and Hospitals, Chicago, February 15-16. Dr. William D. Cutter, Secretary, Council on Medical Education and Hospitals, 535 North Dearborn St., Chicago.

Mid-South Post-Graduate Medical Association, Memphis, Tenn., February 9-12. Dr. A. F. Cooper, Bank of Commerce Building, Memphis, Secretary.

Society of American Bacteriologists, Baltimore, December 28-31. Dr. James M. Sherman, Cornell University, Ithaca, N. Y., Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Ophthalmology, St. Louis

14: 1101-1202 (Nov.) 1931

*Concerning Cyclodialysis in Simple Glaucoma. H. S. Gradle, Chicago. —p. 1101.
Bacterial Flora in Egyptian Trachoma. P. Thygeson, Denver.—p. 1104.
Cyanosis Retinae. P. C. Kronfeld, Chicago.—p. 1108.
Bilateral Hole at Macula. G. C. Kreutz, Detroit.—p. 1116.
Variations in Normal Blind Spot with Especial Reference to Formation of Diagnostic Scale: II. Color Blind Spot. H. A. Wentworth, Philadelphia.—p. 1118.
Elements of Safety in Cataract Extraction. C. S. O'Brien, Iowa City. —p. 1132.
Hyperphoria, Its Etiology, Diagnosis and Treatment. J. H. Dunnington, New York.—p. 1140.
Simplified Method of Muscle Resection for Squint. S. A. Agatston, New York.—p. 1144.
Christian's Syndrome: Case. R. S. Jason and S. V. Abraham, Chicago. —p. 1146.

Cyclodialysis in Simple Glaucoma.—Gradle believes that cyclodialysis offers practically an 80 per cent chance of success, provided the indications for the operation are adhered to. The indications for cyclodialysis in simple glaucoma are: (1) pure simple glaucoma without inflammatory reaction; (2) that type of case in which continued use of miotics just fails to maintain the integrity of the visual fields, the visual acuity and the balance of intra-ocular tension, and (3) the malignant simple glaucoma in which the peripheral defect of the visual field reaches to within ten degrees of the point of fixation. Cataract formation occurs in slightly more than 10 per cent of the cases after cyclodialysis. When proper indications exist, cyclodialysis is to be preferred to iridectomy or fistulizing operations, because of less damage to the integrity of the eye as a visual organ, less danger of immediate postoperative complications, no danger of late infection, and possibilities of repetition if unsuccessful.

American Journal of Physical Therapy, Chicago

8: 205-232 (Nov.) 1931

Galvanism: Theoretical and Practical. J. E. G. Waddington, Detroit. —p. 211.

Isolated Giant Growth of Branch of Pulmonary Artery Associated with Congenital Bronchiectasis: Case. S. R. Rosenthal, Chicago.—p. 387.
*Generalized Actinomycosis (Pyemic Form): Case. P. F. Shapiro, Chicago.—p. 397.
*Bartonella Anemia in Nonsplenectomized Rats. L. Rosenthal and B. L. Zohman, Brooklyn.—p. 405.
Normal Renal Glomerulus of Man: Histologic Consideration. D. L. Wilbur, Rochester, Minn.—p. 413.
Effect of Injection of Trypan Blue on Rate of Sedimentation of Erythrocytes in Inflammation. G. H. Klinck, Jr., Philadelphia.—p. 429.

Rickets and Dentin Calcification.—According to Becks and Ryder, a rachitic diet (McCollum's 3143) produces marked pathologic changes in the dentin if the diet is maintained during the development of the teeth. These changes increase in extent and severity as the period of the diet is prolonged. The changes induced are analogous to those produced in the long bones under the same dietary conditions. In the early stages the changes consist of a diminution in the amount of calcium salts deposited, even after such a short period as seven days; a change in the type of calcification, from a homogeneous to an irregular, globular type, and the continued formation of dentinoid matrix, which appears to widen as a result of the slowing down of the calcification. Atrophy of the odontoblasts appears after about fourteen days, increasing in severity as the feeding experiment progresses. This is found first in the most recently formed cells, spreading slowly to the older odontoblasts. Since the diet is deficient only in vitamin D, it is believed that this primary atrophy of odontoblasts develops when all the cellular vitamin D is utilized. Because of the similarity in function of odontoblasts and osteoblasts, it would seem that the changes in bones in rickets are probably due to a primary involvement of the osteoblasts. Certain marked changes result from the odontoblastic atrophy: complete arrest of calcification in contrast with continued deposition of lime salts by adjacent vital odontoblasts; in cases in which single odontoblasts degenerate, no cementing substance is formed, and capillaries become included by the continued formation of matrix by the adjacent vital cells. On the basis of the data presented, it is believed that the odontoblasts are chiefly responsible for the formation of dentin. They are required to produce the cementing substance which holds von Korff's fibers in place. Their presence is necessary to form Tomes' processes and so give nutrition and calcifying material to the dentin, and furthermore in order that calcium salts may be deposited and the matrix calcified.

Actinomycosis.—Shapiro reports a case of generalized, florid, pyemic actinomycosis, which demonstrates the predilection of actinomycetes for hematogenous spread. In such cases the lymphatic system is spared. There is a marked tendency toward the development of local actinomycotic thrombophlebitis, and when generalization does occur, it does so practically only by way of the blood stream.

Bartonella Anemia in Rats.—Rosenthal and Zohman describe experiments in which they found that blockade of the reticulo-endothelial system, combined with a superimposed bartonella infection, produces the blood picture of anemia and a severe bartonella infection. In trypanosome-infected animals, blockade without superimposed infection or superimposed infection without blockade produces the same results. The cellular changes in the spleen of the blockaded, infected rat consist, essentially, of hyperplasia of the pulp with proliferation of the follicles. In the liver and bone marrow, foci of necrosis are present, irregularly scattered and of different size. In rats that previously have been splenectomized, have developed a bartonella infection and anemia, and have recovered, blockade with india ink or injection of trypanosome-infected blood causes a recurrence of the disease.

Complications of Peptic Ulcer. J. C. Hill, Newton.—p. 615.
Study of Incidence and Symptoms of Ectopic Pregnancy. M. C. Hennessy, Council Bluffs.—p. 623.

Psychopathic Personality.—According to Woods, persistently futile or annoying behavior is in many cases understandable. After all cases due to insanity, intellectual defectiveness and ordinary selfishness or weakness are removed, there is, however, a remainder of cases in which one cannot fathom the motives. These persons are called psychopaths and their constitutional makeup is called psychopathic personality. Common to all these cases of misbehavior are the following characteristics: persistence, fixity in the constitution of the person, disadvantageousness, incorrigibility, short-sightedness, basally defective affect, and a tendency to slip into psychosis or psychoneurosis. Psychopaths are abnormal and usually require institutional control. If no psychotic or psychoneurotic process is present, they should be disciplined for law breaking. If wise discipline has proved ineffectual after two or three applications, the offending psychopath should be permanently restrained in a proper state institution.

Puerperal Eclampsia and Conservative Treatment. D. L. Jones, Fulton.—p. 610.
Health Units, Group Practice and Community Hospitals as Remedy for Scarcity of Physicians in Rural Districts. R. C. Burrow, Cunningham.—p. 612.

Torsion of Normal Ovary and Tube with Rupture of Ovary.—Northcutt and Baron report a case of torsion of the normal ovary and tube with rupture of the ovary. They believe that this is the fourteenth case on record in which the ovary was involved and that it is the first case on record in which rupture followed the torsion. In the differential diagnosis of abdominal pain in young girls, torsion of the ovary must be considered, particularly when associated with pain on straining at stool. Anatomic anomalies must be considered a strong factor in the predisposing causes to torsion of the normal ovary and fallopian tube.

Roentgen Diagnosis in Intravenous Pyelography.—According to Peters, intravenous pyelography offers a simple, painless method of examining the kidney pelvis, ureters and bladder, roentgenographically producing urograms of diagnostic quality. While this method is reasonably innocuous, its indiscriminate use is not to be encouraged. With more experience in its use and skill in the interpretation of the observations, the diagnostic criteria will be as definite as those of cystoscopic pyelography. Intravenous pyelography does not replace the older method. Its use in demonstrating function in surgical conditions of the kidney is of great value, both alone and with ureteral catheterization. The uses of this method alone and in combination with retrograde catheterization will increase with more experience. Iopax serves a dual purpose. The time of appearance of the opaque medium on the film, together with physical and chemical tests of the urine, gives a fair estimate of kidney function. This method broadens the field of pyelography to the following, heretofore denied this important diagnostic aid: (*a*) infants and children, (*b*) debilitated adults, (*c*) urethral stricture cases, (*d*) cases with deformities, and (*e*) malignant cases and others unsuited for retrograde catheterization. It is the method of choice in the absence of a competent urologist.

Tuberculous Meningitis.—Hearn emphasizes the fact that severe headache in a person with tuberculosis which is not relieved by ordinary methods, and especially if accompanied by high temperature and elevation of the pulse, should be regarded as suggestive of tuberculous meningitis. No improvement can be hoped for, and death usually occurs within four to six weeks from tuberculous meningitis, but spinal puncture done every forty-eight hours will help make the patient more comfortable.

Northwest Medicine, Seattle

30: 437-482 (Oct.) 1931

•Chronic Pyuria in Children. M. F. Campbell, New York.—p. 437.
New Method of Employing Skeletal Traction. R. Anderson, Seattle.—p. 444.
Craniocerebral Trauma Implicating Superior Longitudinal Sinus: Four Case Reports. D. G. Dickerson, Seattle.—p. 449.
Diagnosis and Management of Craniocerebral Injuries. W. A. Bunten, Cheyenne, Wyo.—p. 453.
Course of Gonorrhea as Recorded by Photomicrographs of Discharge. W. R. Jones, Seattle.—p. 460.
Black Tongue: Case Reports. T. G. Mitchell, Seattle.—p. 464.
Free Choice of Physicians. A. H. Peacock, Seattle.—p. 467.

Chronic Pyuria in Children.—Campbell points out that, when chronic pyuria exists in a child, the diagnosis of chronic pyelitis is usually made and the child is inadequately treated for months or years. Because the renal lesion is primarily a suppurative interstitial nephritis and the pelvic changes are of lesser importance, he believes the pathologically correct designation pyelonephritis should supplant the clinically convenient though inadequate term pyelitis. These patients should be given the benefit of an intensive course of medical therapy, but if, after one month, they remain pyuric, a complete urologic examination should be carried out. From a large clinical experience in this field it is found that infants and children may suffer with almost every one of the various types of diseases of the urinary tract which in the past one has been accustomed to consider as adult lesions. The treatment of these diseases in juveniles differs in no wise from that in adults. It cannot too urgently be stressed that these young patients are entitled to the same advantages of modern urologic methods that adults demand, especially since in juveniles the morbidity risk entailed by examination is less than half that in adults. Only by this method can the correct diagnosis be made and only by radical surgical treatment will many of these children be permitted to enjoy adult life.

Public Health Reports, Washington, D. C.

46: 2663-2707 (Nov. 6) 1931

•Pellagra-Preventive Value of Canned Spinach, Canned Turnip Greens, Mature Onions, and Canned Green Beans. G. A. Wheeler.—p. 2663.
Technic for Adjustment of p_H of Tissue Cultures Planted in Carrel Flasks. W. R. Earle.—p. 2668.

Pellagra-Preventive.—Wheeler tested canned spinach, canned turnip greens, mature onions and canned green beans for their relative pellagra-preventive potency. He found that canned spinach supplies the pellagra-preventive vitamin but cannot be regarded as especially rich in it. It is, however, considered an important contributory source of this factor. Canned turnip greens supply the pellagra-preventive vitamin and, at least in liberal quantity, adequately supplement an otherwise pellagra-producing diet. This substance meets many of the requirements of a practical and effective dietary supplement in the pellagrous sections. The mature onion is a very poor source of the pellagra-preventive vitamin. Canned green beans are, relatively, a poor source of the pellagra-preventive vitamin.

Nonspecific Protein Therapy in Gynecology. H. W. Yates and D. Davidow, Detroit.—p. 529.

Laryngotracheobronchitis.—Schenck calls attention to the fact that foreign bodies, especially those of vegetal origin, may cause laryngotracheobronchitis. Acute laryngotracheobronchitis was of nondiphtheritic origin in about 13.5 per cent of 810 suspected cases. A mortality of practically 24 per cent is shown in a large number of reported cases. Opinion is divided between the use of intubation and of tracheotomy, with a majority favoring the latter method of relieving stenosis. The author believes that suction or bronchoscopic removal of secretion or of dried crusts causing laryngeal stenosis will save many lives.

Congenital Hemolytic Jaundice.—Warfield believes that the differential diagnosis of congenital hemolytic jaundice is not difficult if one keeps the disease in mind. From pernicious anemia with jaundice, the diagnosis should not be difficult. Increased fragility of the red cells is never present in pernicious anemia, and the spleen is not apt to be enlarged. Blood smears may be something alike in the two diseases, but no one with any experience should confuse the two blood smear pictures. From so-called Banti's disease, cirrhosis of the liver with splenomegaly and anemia of a chlorotic type, the diagnosis may be a little confusing. In such cases the skin is not infrequently slightly lemon tinged, and acute attacks of pain and fever may occur. Here again the increased fragility of the red cells is diagnostic. The family history will also be helpful in diagnosis. In the South and in the tropics, chronic malaria may enter the differential diagnosis. If no parasites can be found, again the increased fragility of the cells will establish the diagnosis. In all other diseases simulating congenital hemolytic jaundice, not one has this peculiarity of the red cells. The test is not difficult to perform and should be done whenever there is a suspicion of the disease in question.

Pathology of Papilledema.—Wolff and Davies describe experiments on animals in which they demonstrated that nondiffusible dyes injected into the cranial subarachnoid space at pressures compatible with life do not enter the optic nerve. The claims of previous investigators to have produced papilledema by the injection of fluids into the cranial subarachnoid space at pressures compatible with life are not upheld by the authors' study. Anatomic observations were made on the normal structure of the optic nerve head in the dog and in man. Structural reasons are advanced for the special site of commencement of papilledema in man and for the extent of distribution of the edematous fluid associated with papilledema.

Sinusitis and Its Roentgenologic Demonstration.—Hodgson emphasizes the fact that when roentgenograms of the accessory nasal sinuses are taken the positions used must be absolutely standard for all patients; that is, in all cases the positions must be exactly the same. It is only by such a technic that the normal can accurately be comprehended and the abnormal detected with the greatest possible exactitude. Roentgenograms must be taken in the erect posture in order to determine the presence or absence of fluid. Unless this is done, many cases of infection of the anterior group of sinuses will be overlooked in the roentgen examination. Six roentgenograms must be taken to include all the accessory nasal sinuses, and the roentgenograms must be technically perfect.

Vaccination Against Diphtheria.—Kolle believes that in combating epidemic diphtheria and in reducing further the morbidity, mortality and lethality of this disease, active immunization with suitable antigens (vaccines) is not only hopeful but recommendable. He recommends for immunization the use of antigens, which are tested for sterility and innocuousness; that is, for nontoxicity with the lowest irritating power. The diphtheria toxins, freed from toxicity by the addition of solution of formaldehyde, so-called formol toxoids or anatoxin are the most recommendable for active immunization of children. For testing of these vaccines and others, it is necessary to determine a standard vaccine to be used for comparison, by testing each batch. Exact definite regulations are needed for the methods of testing. In order to obtain immunity of sufficient strength and duration, one must make three injections of the vaccine, increasing the doses. Intramuscular injections of the formol toxoids must be made. Investigation must be made to determine whether the methods of testing the immunizing power of the vaccines in large series of animals by testing them within a certain time after immunization with definite quantities of toxin can be replaced by other direct or indirect methods (flocculation, determination of the binding power, and so on). The immunization can be carried out during an epidemic. Animal experiments show that a negative phase after the injection of immunizing vaccine does not exist. Immediately after injection, one can find a resistance against infection with living bacilli or its toxins.

Intractable Incontinence of Urine.—Gibson reports a case of intractable incontinence ensuing on traumatic stricture of the urethra and complicated by grave renal sepsis. Mechanical relief of the incontinence was effected by transplantation of the ureters into the pelvic colon. The pathologic condition of pyonephrosis in the right kidney, however, precluded any hope of a successful cure. A marked feature was the progressive anorexia of the most incorrigible type. Emaciation thus became extreme. Doubt is cast on the value of nephrostomy as a surgical procedure, the resulting urinary fistula tending to prove intractable. The suggested cure of such a fistula by nephrectomy was out of the question in the author's case. The procedure of transplanting the ureters into the intestine is of great value in such cases as the one described, more especially if carried out before renal sepsis has supervened. It is a sound surgical procedure not fraught with any serious risk, provided due attention is paid to details of technic.

*Volhard's Tests of Renal Function. Pasteur Vallery-Radot and A. Lafitte. —p. 1557.

Volhard's Tests of Renal Function. — Pasteur Vallery-Radot and Lafitte stress the value of specific gravity in the study of urinary function. Volhard's tests are (1) the dilution test and (2) the concentration test. The dilution test is performed as follows: The subject in a fasting condition, having urinated, drinks 1,500 cc. of water or very weak tea between 7:30 and 8:30 a. m. He remains in bed and urinates every half hour from 8 to 12. It is important to consider, on the one hand, the quantity of urine eliminated and the manner of elimination and, on the other hand, the specific gravity of the specimens of urine. A subject with normal kidney function will eliminate in the four hours a quantity of urine equal to and sometimes larger than the quantity of water ingested; during the first two hours, more than half of the total is voided; the different fractions of urine are not equa quantity; and finally the specific gravity should be low (1.000 to 1.003) but not higher than 1.003, and the total u evacuated should be at least 1,300 cc. The concentration is performed as follows: The subject two days before the gets an ordinary diet and drinks from 1,500 to 2,000 cc liquid. The day of the test he remains in bed and ing during a period of twenty-four hours, bread, meat, eggs, pa rice or potatoes, normally salted. Green vegetables and f are excluded because of the water which they contain. drinks altogether from 400 to 500 cc. of water in small tionated quantities. He should urinate every two to four ho Normally the total volume of urine varies the day of the from 300 to 750 cc. The specific gravity of the urine is im tant—a portion should have a specific gravity of at least (a smaller figure denotes that the kidneys concentrate poo The two tests demonstrate by dilution the function of glomeruli, and by concentration the function of the tub The tests of Volhard are compared with other tests in cur usage, such as blood urea, Ambard's constant, and the phe sulphonphthalein test. The authors conclude that there is *parallelism between Volhard's tests and other tests.* In c test the renal functions examined are distinctly different. number of described instances the other tests would not de nate the difficulty that was clearly demonstrated by Volha tests. The tests cannot be interchanged.

Suprarenals in Regulation of Arterial Tension.—B sotti describes experiments which led him to conclude t unilateral or bilateral abdominal sympathetic denervation as ciated with section of the large or small splanchnic nerve d not cause any change in the arterial tension. Extirpation one suprarenal generally does not modify the arterial tensi Extirpation of both suprarenals in an animal is followed by progressive fall in the arterial tension and death in from fo to sixty hours. Dogs deprived of one suprarenal and the med lary substance of the other present a hypotension of from to 4 cm. of mercury, the tension remounting progressiv until the initial level is attained (from twenty to thirty da after the operation). When demedullized animals (tension normal level) were bled to 1.5 per cent of their body weig there was a more marked and more lasting hypotension th when normal animals were bled. Ablation of the medulla substance of the suprarenals caused an asthenia and a hyp tension of the vasomotor system with diminution of the norn functional capacity. At the beginning of the abdominal sy pathetic denervation and suprarenal demedullization the arter tension fell for some time but later regained its initial lev

Allergic Diseases. A. Cionini.—p. 493.

Diagnostic Value and Pathogenesis of a New Dors Pain Point.—Campanacci recalls the subjective and the objec tive pain symptoms that are encountered in appendicitis, reviev ing particularly, on the one hand, the abnormal localizatio of subjective pain, and, on the other hand, the painful poin (direct and indirect) that are objectively observable. He th describes a new (dorsal) painful spot, to which he first calle attention in 1927, occurring in cases of appendicitis. He tel how to locate it, how frequently it is manifested, its clinic diagnostic value and its probable pathogenesis.
